Equation [67] assumes that there are no surface losses, in other words, that the electrode is perfectly insulated. This assumption is an approximation but it offsets to a great extent the error introduced by neglecting the Joule effect in the electrode. That this is so is proved by the fact that the relation between the rate of fusion v and current density i, derived from the foregoing assumptions, is in good agreement with the experiment. This relation is obtained as follows:

It has been shown in Part 1 that in the absence of surface losses the rate of heat q'' absorbed in the electrode per unit area is

$$q'' = (T_1 - T_0) c\rho v \quad [68]$$

$c\rho$ is the specific volume heat content (c specific heat, ρ density), and T_1, T_0, and v, as previously, the temperature of fusion, the initial temperature, and the rate of fusion, respectively. On the other hand, q'' is a fraction of the heat generated by the arc, which is proportional to the product VI, where V is the voltage drop across the arc, and I is the current intensity. Experiment shows that for a given type of electrode the voltage drop V is fairly constant within a large range of current densities, and that for various types of coated-steel electrodes it varies between 25 and 35 volts. Thus for a given type of electrode of a diameter d, it is possible to write

$$q'' \frac{\pi d^2}{4} = fI \quad [69]$$

where f is a constant (13).

Substituting in Equation [68], there follows

$$\frac{fI}{\pi d^2/4} = (T_1 - T_0) c\rho v$$

hence

$$v = f_0 i \quad [70]$$

where

$$f_0 = \frac{f}{(T_1 - T_0)c\rho}$$

Relation, Equation [70] has been checked experimentally and has been found to hold within a reasonable degree of accuracy for moderate current densities and for the first 3 to 4 in. of the electrode. The values of f_0 reported in the literature for a mild-steel electrode lie between 1.24×10^{-3} and 1.56×10^{-3} cu in. per amp per min.

Substituting Equation [70] in [67] there follows

$$T = T_0 + (T_1 - T_0)e^{-2\lambda f_0 i\xi}$$

or putting

$$i = I \Big/ \frac{\pi d^2}{4}$$

$$T = T_0 + (T_1 - T_0)e^{-f'I\xi} \quad \ldots\ldots\ldots [71]$$

where

$$f' = \frac{2\lambda f_0}{\pi d^2/4} = \frac{8\lambda f_0}{\pi d^2} \quad \ldots\ldots\ldots\ldots\ldots [72]$$

In Fig. 3 the ratios of $(T - T_0)/(T_1 - T_0)$ have been plotted against the distance ξ from the location of the arc in inches, for four different values of current density, namely, 145, 165, 185, and 240 amp. These values may be considered as being within workable range of current intensities for a $^5/_{32}$-in. mild-steel electrode. The following values were used to calculate the factor f' appearing in Equation [71]

$2\lambda = 1.00$ sq in. per min

$f_0 = 1.25 \times 10^{-3}$ cu in. per amp per min

$d = {}^5/_{32}$ in.

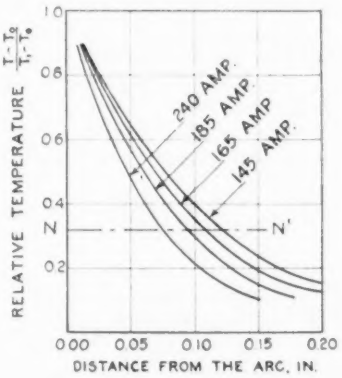

FIG. 3 TEMPERATURE DISTRIBUTION IN MILD-STEEL ELECTRODE FOR VARIOUS CURRENT INTENSITIES

It appears from Fig. 3 that the higher the current intensity the shorter is the range over which the electrode is affected by the heat of the arc. This condition is well illustrated in Fig. 4, which shows macroetched sections made through the axis of a $^5/_{32}$-in. electrode submitted to the current intensities mentioned. Because of the recrystallization process the part of the electrode which has been heated beyond some 950 F responds more readily to the etching (10 per cent solution of nitric acid) than the rest of the electrode. It is seen that in accordance with diagrams, Fig. 3, the extent of the recrystallized zone is greater for the low current intensity than it is for high current intensity, see also

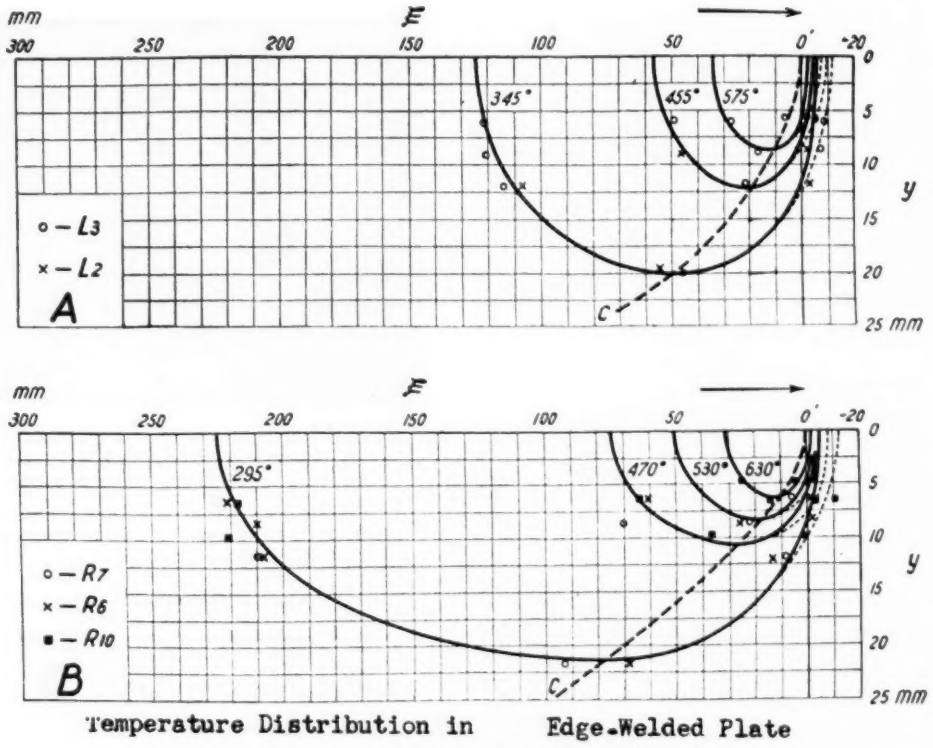
line NN', Fig. 3, corresponding to the temperature of recrystallization of mild steel $(T_1 - T_0/T_1 - T_0 \approx 0.32)$.

ARC-WELDING OF THIN PLATES



Temperature Distribution in an Edge-Welded Plate. The validity of Equation [31], Part 1, in the case of arc welding was tested experimentally by Schmerber and the author (12). They deposited a weld layer at a constant rate along one of the edges of a flat bar, 5.5 in. wide, and measured the variation of temperature in the bar produced by this operation. Assuming no losses of heat through the surface, the temperature can be taken as being uniform through the thickness. Hence the heat flow is of a two-dimensional nature, and Equation [31], Part 1, is applicable. For the purpose of computation, a constant value of heat conductivity k was adopted = 0.1 cal per deg C per cm per sec, but the diffusivity coefficient $1/2\lambda$ was made to vary according to a linear law with the temperature. Under these circumstances, the agreement between the measurement and computation was quite satisfactory, except at the immediate neighborhood of the arc, Fig. 5. There, the computed isotherms were closer to the origin than the measured values. This discrepancy could be explained by the fact that the theory considered the source of heat as a line, whereas in practice the source of heat had a finite size.

Rate of Cooling in Thin Butt-Welded Plates. On the basis of the foregoing experiment it can be expected that Equation [31] will be applicable also to the case of thin butt-welded plates. Hess and his co-workers (14) determined experimentally the rates of cooling produced very near to the weld in plates of various thicknesses. If the temperature is assumed constant through the thickness, these rates of cooling can also be derived from Equation [31] by differentiating the latter with respect to time. In so doing, attention is called to the fact that in the present application the rates of cooling are measured at some distance from the location of the heat source. Hence, according to the theory of Bessel functions (10), Equation [31] can be reduced to a more simple expression to read

$$T - T_0 = \frac{q}{2\pi kg}\sqrt{\frac{\pi}{2\lambda vr}}\, e^{-\lambda v\xi - \lambda vr}$$

$$= \frac{q}{2\pi kg}\,\frac{e^{-\lambda v(\xi + r)}}{\sqrt{vr}}\,\sqrt{\frac{\pi}{2\lambda}} \quad \ldots\ldots\ldots [73]$$

where T is the temperature measured at a distance $r = \sqrt{\xi^2 + y^2}$ from the source, T_0 the initial temperature, q the rate of heat input, v the speed of the source, and k, $c\rho$, and $1/2\lambda = k/c\rho$ as

Temperature Distribution in Edge-Welded Plate

FIG. 5 TEMPERATURE DISTRIBUTION IN EDGE-WELDED PLATE

(Continuous lines, calculated; broken lines, experimental. *A*, Current, 93 amp; welding speed, 0.21 cm per sec or 4.95 ipm. *B*, Current, 141 amp; welding speed, 0.43 cm per sec or 10.1 ipm. L2, L3, R7, R6, R10 are different specimens. Courtesy *The Welding Journal*.)

previously, the heat conductivity, volume specific heat, and heat diffusivity, respectively.

Along the weld, $y = 0$, hence $r = /\xi/$; also $\xi = -vt$, hence Equation [73] can be further simplified as follows

$$T - T_0 = \frac{1}{2\sqrt{\pi kc\rho}} \times \frac{q}{gv} \times \frac{1}{\sqrt{t}} \quad \ldots\ldots [74]$$

Expression q/gv represents, as it is easy to see, the amount of heat per unit section of plate, measured in the direction of welding. In practice, the welding conditions are defined by another value more readily determined, namely, the total amount of energy J/gv per unit section of plate supplied by the arc, expressed in joules per sq in. This value is related to the former by a coefficient which defines the heat efficiency of the arc, and which Hess and co-workers represented by the symbol (I.F.) input factor. Thus

$$T - T_0 = \frac{(\text{I.F.})}{2\sqrt{kc\rho\pi}} \times \frac{J}{gv} \times \frac{1}{\sqrt{t}} \quad \ldots\ldots [75]$$

or

$$(T - T_0)\sqrt{t} = C \text{ (independent of time)} \quad \ldots\ldots [76]$$

By differentiating with respect to time there follows

$$\frac{dT}{dt}\sqrt{t} + \frac{1}{2}\frac{T - T_0}{\sqrt{t}} = 0$$

or

$$\frac{dT}{dt} = -\frac{1}{2}\frac{T - T_0}{t} \quad \ldots\ldots [77]$$

Equation [77], due to Hess and co-workers (14), states that the rate of cooling at a given temperature T is proportional not only to this temperature but also to the converse of time t that it has taken for the point considered to cool down to the temperature T after the welding arc has passed through this point. In this respect the rate of cooling in welding is quite different from the rate of cooling in quenching, for which no dependence on time is assumed (15). As will appear later, the factor 1/2 at the right-hand side of Equation [77] is characteristic for the two-dimensional problem of welding.

If time t is eliminated from Equations [77] and [75], the following expression is obtained

$$\frac{dT}{dt} = -\frac{2\pi kc\rho}{(\text{I.F.})^2} \times \left(\frac{gv}{J}\right)^2 \times (T - T_0)^3 \quad \ldots\ldots [78]$$

or

$$\left(\frac{dT}{dt}\right)^{1/3} \times \frac{J}{vg} = \frac{\sqrt[3]{2\pi kc\rho}}{(\text{I.F.})} \times (T - T_0)^{2/3} \quad \ldots\ldots [79]$$

Since the right-hand side of Equation [79] is a constant for a given type of steel, electrode, and temperature T, the product on the left-hand side also must be constant, no matter what are the individual values of rates of cooling, energy inputs, and thickness. This condition has been tested for the case of 1/4-in. and 1/2-in. butt-welded plates using experimental results of Hess and co-workers (14), obtained very near to the weld.[7] When the products figuring on the left-hand side of Equation [79] are plotted as a function of rates of cooling at 1300 F, the diagram, Fig. 6, is obtained. From this diagram it appears that the 1/4-in. butt-welded plate behaves like a thin plate for all rates of cooling at 1300 F, while the 1/2-in. plate behaves like a thin plate only for rates of

[7] It can be shown that the rate of cooling very near to the weld is not appreciably different from that in the weld itself.

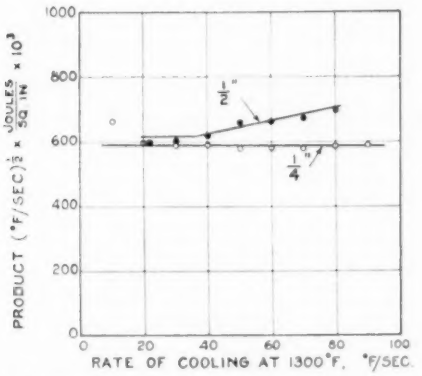


FIG. 6 TWO-DIMENSIONAL HEAT FLOW IN ¼- AND ½-IN. BUTT-WELDED PLATES AS EVIDENCED BY CONSTANT VALUE OF PRODUCT INDICATED

cooling at 1300 F which are smaller than 50 deg F per sec. The reason for this discrepancy will be discussed later.

ARC WELDING OF THICK PLATES

Rate of Cooling in Butt-Welded Plates. Following the ideas developed in the section on the arc welding of thin plates, it may be anticipated that since Equation [31] has approximated fairly well the conditions of heat flow in butt-welded plates, Equation [43] may approximate likewise the conditions of heat flow in thick butt-welded plates. If the observation is limited to the surface of the weld, the distance R, figuring in Equation [43], is simply the distance $/\xi/$ covered by the arc in a given period of time t; thus

$$T - T_0 = \frac{q}{2\pi k} \times \frac{1}{\xi} \quad \ldots\ldots [80]$$

Equation [80] does not contain explicitly the speed v, and it does not depend upon the diffusivity of the material. In fact the same expression is obtained, if the point source instead of being in motion remains stationary, except that in this case ξ represents not only the distance behind the source, but the distance from the source measured in any direction.[8] On the other hand, if ξ is expressed in terms of the distance covered by the arc in time t, then $\xi = vt$, and Equation [80] becomes

$$T - T_0 = \frac{1}{2\pi k} \times \frac{q}{v} \times \frac{1}{t} \quad \ldots\ldots [81]$$

The quantity (q/v) represents the heat input per unit length and is to be compared with a similar quantity (q/vg) used in the study of thin plates. As in the latter case, we shall write

$$q/v = (\text{I.F.})J/v \quad \ldots\ldots [82]$$

where J/v represents the total energy input of the arc per unit length and (I.F.) the heat efficiency of the arc. With reference to Equation [82], Equation [81] may be rewritten as follows

$$(T - T_0) \times t = C \text{ (independent of time)} \quad \ldots\ldots [83]$$

Hence by differentiating

$$\frac{dT}{dt} = -\frac{T - T_0}{t} \quad \ldots\ldots [84]$$

This expression, also due to Hess and co-workers (14), differs from Equation [77], derived previously for the rate of cooling in a thin plate, only by the absence of the factor 1/2. Thus if conditions of welding are such that the same temperature T is reached at the same time t in both the thin and thick plates, the rate of cooling still will be twice as great in the thick plate as in the thin one.

If time t is eliminated from Equations [84] and [81], then with reference to Equation [82] the following formula is obtained

$$\frac{dT}{dt} = -\frac{2\pi k}{(\text{I.F.})} \times \frac{v}{J} \times (T - T_0)^2 \quad \ldots\ldots [85]$$

or

$$\frac{dT}{dt} \times \frac{J}{v} = -\frac{2\pi k}{(\text{I.F.})} \times (T - T_0)^2 \quad \ldots\ldots [86]$$

The right-hand side of Equation [86] is a constant for a given temperature and a given material, hence the product on the left-hand side also must be constant for any particular value of rate of cooling, energy input, and speed.

Although, strictly speaking, this condition holds only for the points of weld deposit for which $R = \xi$, points of the base metal very close to the weld may be expected to satisfy the condition mentioned with a reasonable degree of accuracy. With this in mind, experimental results of Hess and co-workers (14) on 1 and 1½-in. steel plates have been used to compute the products figuring on the left-hand side of Equation [86] for various rates of cooling at 1300 F. When plotted as a function of these rates, they gave a fairly constant value, Fig. 7. The values for the 1½-in. plate are in general more consistent than those for the 1-in. plate. Thus the 1½-in. plate and to some extent also the 1-in. plate behave under the particular condition of cooling like plates of infinite thickness.

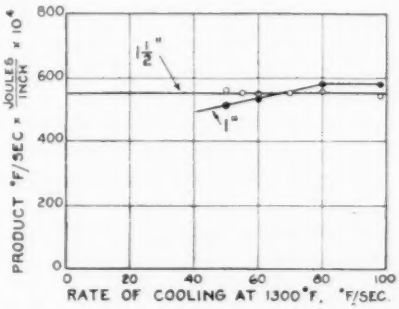

FIG. 7 THREE-DIMENSIONAL HEAT FLOW IN 1- AND 1½-IN. BUTT-WELDED PLATES AS EVIDENCED BY CONSTANT VALUE OF PRODUCT INDICATED

Determination of Heat Diffusivity From Rates of Cooling in Thin and Thick Butt-Welded Plates. If rates of cooling have been determined for a particular temperature T and known conditions of welding in a thin and thick butt-welded plate, then assuming the same heat efficiency (I.F.) in both cases, there follows when Equation [75] is divided by Equation [85]

$$\frac{\left[\left(\frac{dT}{dt}\right)^{1/2}\left(\frac{J}{vg}\right)\right]}{\left[\frac{dT}{dt} \times \frac{J}{v}\right]} = \sqrt{\frac{c\rho}{2k}} \times \frac{1}{\sqrt{\pi}} (T - T_0)^{-1/2} \quad \ldots [87]$$

but

$$\frac{c\rho}{2k} = \lambda$$

hence the diffusivity

$$\frac{1}{2\lambda} = \frac{1}{2\pi(T - T_0)} \times \frac{\left[\frac{dT}{dt} \times \frac{J}{v}\right]^2 \text{ thick plate}}{\left[\left(\frac{dT}{dt}\right)^{1/2} \times \frac{J}{vg}\right]^2 \text{ thin plate}} \quad \ldots [88]$$

[8] Reference (9) p. 151.

Substituting in Equation [88] the values taken from Figs. 6 and 7, for the $^1/_4$-in. and $1^1/_2$-in. plates, respectively, the value of the diffusivity becomes

$$\frac{1}{2\lambda} = \frac{1}{2\pi(1300 - 68)} \times \frac{(550 \times 10^4)^2}{(590 \times 10^3)^2} = 0.0112 \frac{\text{in.}^2}{\text{sec}}$$

$$= 0.072 \frac{\text{cm}^2}{\text{sec}}$$

as against the value of 0.0685, computed for pure iron from the data of the International Tables for 1300 F (16).

Considering the uncertainty attached to the determination of the heat conductivity k, and the probable error of measurements, this agreement appears quite satisfactory. However, it must be borne in mind that the assumption on which Equation [88] is based precludes any variation of the diffusivity with temperature, hence the value of 0.072 sq cm per sec must be regarded as an average rather than as a particular value of the diffusivity.

Temperature Distribution in Thick (and Thin) Arc-Welded Plates. On the basis of the foregoing results it can be assumed that the application of Equation [43] will yield a satisfactory picture of the temperature distribution during welding in thick butt-welded plates. More specifically, the conception will apply to a situation created by a top weld layer when the plates have been allowed to cool down to the room temperature. This situation is represented in Fig. 8 for various conditions of welding by means of a family of isotherms drawn around the instantaneous position of the electrode (11). Because of the quasi-stationary state of heat flow, the same figure may be used to depict the variation of temperature at a given section of plate and at various instances of welding.

For the purpose of computation, the following values were substituted in Equation [43], using C.G.S. units

q = 0.239 (I.F.) × V × I where 0.239 is the thermal equivalent of watts
(I.F.) = heat efficiency of arc assumed = 0.65 (12)
V = voltage drop in arc assumed = 25 volts (12)
I = current intensity in amp, variable
k = heat conductivity—0.1 cal per cm per deg C per sec, for steel and 0.485 cal per cm per deg C per sec for aluminum
λ = one half of the converse value of diffusivity, assumed = 5 sec per sq cm for steel and 1.2 sec per sq cm for aluminum

The main characteristics of the temperature distribution obtained under these conditions, Fig. 8, are as follows:

1 The rise of temperature in front of the heat source is much steeper than the fall of temperature behind the heat source.

2 Because of the fact that the heat does not propagate instantly in metals, the temperature does not pass through the maximum at the same time at various points of the same cross section. There is a lag at points which are farther away from the weld, as shown by curve n-n connecting the points of maximum temperature. This lag is a function of the speed of welding and diffusivity of metal (compare Fig. 8, A, B, and D).

3 Considering an instantaneous position of the electrode, curve n-n separates points in the solid with rising temperature from points in the solid with falling temperature.

As for the influence of the welding conditions, it is seen that:

1 An increase in the speed of welding, Fig. 8, A and B, produces a greater lag in the temperature distribution at a given cross section, hence the heat is more concentrated around the heat source. However, the temperature distribution along the line of welding, behind the electrode, remains unchanged, in accordance with Equation [80].

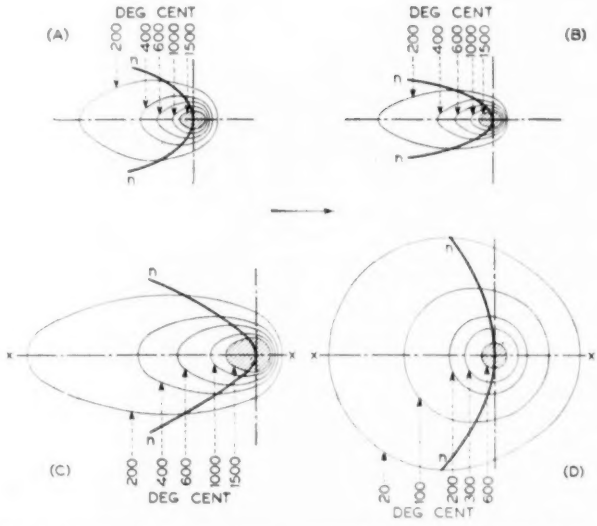

FIG. 8 TEMPERATURE DISTRIBUTION IN THICK BUTT-WELDED PLATE
(For details see the text. Courtesy of *The Welding Journal*.)

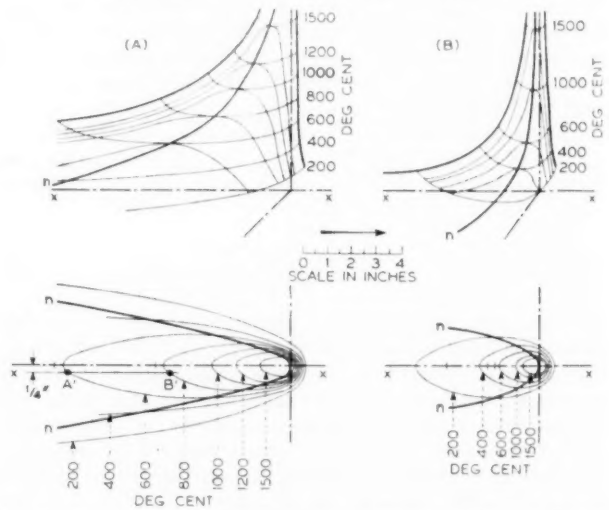

FIG. 9 TEMPERATURE DISTRIBUTION IN THIN AND THICK BUTT-WELDED PLATE
(*Left*, thin plate, 0.2 in. thick; *right*, thick plate. Same material, i. e., mild steel, and same welding technique in both cases, i.e., 200 amp, 8.3 ipm. Top view isometric projection; bottom view topographic projection. Courtesy of *The Welding Journal*.)

2 An increase in the current intensity, Fig. 8, A and C, extends the range of heat in the solid, but does not affect the shape of isotherms.

3 An increase in the heat conductivity and diffusivity of metal, Fig. 8, C and D, affects both the shape and the size of isotherms. The increase of the range of heating in front of the electrode is especially noteworthy.

4 An increase in the initial temperature, i.e., the preheating, causes a corresponding increase in the numerical value of each isotherm, but does not change its shape or size. However, the preheating has a marked effect upon the rate of cooling, as shown by Equation [85]. This effect is discussed in more detail in the experimental work on weldability (14) and (17).

Basically the same conclusions apply to thin welded plates, as can be easily demonstrated by means of Equation [73]. However, there is a fundamental difference in the conditions of welding of a thin and thick plate, due to the different nature of heat

flow. This difference is well apparent in the shape and size of isotherms drawn in Fig. 9.

Application to Actual Welding Practice

Determination of Cooling Time. In so far as welding practice is concerned, neither of the solutions already discussed is quite satisfactory. Because of the finite thickness of plates, the conditions of welding seldom correspond to that of a very thin or very thick plate. At a short distance from the arc there is a considerable temperature gradient through the thickness, but as the arc moves away from the section considered, the temperature becomes more uniform across the thickness. Thus the heat flow changes from a three-dimensional state to a two-dimensional one, as the distance from the arc increases. This condition has been discussed in Part 1, and an appropriate solution for this case has been obtained in the form of Equation [63].

In actual welding practice it is important to determine the time required for the weld to cool down to a given temperature, rather than to obtain a complete pattern of the temperature distribution around the electrode. Under these circumstances Equation [63] can be simplified by writing for a given spot of the weld bead, t seconds after it has been deposited on a plate of thickness, g

$$\xi = -vt;\ y = 0;\ z = 0$$

$$R_0 = |vt|;\ R_n = \sqrt{(vt)^2 + (2ng)^2},\ n = 1, 2, 3 \ldots . [89]$$

Substituting in Equation [63], there follows

$$T - T_0 = \frac{1}{2\pi k} \times \frac{q}{v} \times \frac{\mu}{t} \ldots\ldots\ldots\ldots [90]$$

where

$$\mu = 1 + 2 \sum \frac{e^{-\lambda v^2 t(s_n - 1)}}{s_n} \ldots\ldots\ldots\ldots [91]$$

and

$$s_n = R_n/vt$$

As previously, the rate of heat delivered to the plate will be replaced by the rate of energy input of thewelding arc, J multiplied by the heat efficiency of the arc (I.F.), thus

$$T - T_0 = \frac{(\text{I.F.})}{2\pi k} \times \frac{J}{v} \times \frac{\mu}{t} \ldots\ldots\ldots\ldots [92]$$

Equation [92] can be made to correspond "formally" to Equation [81] derived for a very thick plate, by introducing a "fictitious" time of cooling $t^* = t/\mu$, which for convenience we shall call the "reduced" time of cooling. With this in mind Equation [92] can be rewritten as follows

$$T - T_0 = \frac{(\text{I.F.})}{2\pi k} \times \frac{J}{v} \times \frac{1}{t^*} \ldots\ldots\ldots\ldots [93]$$

As seen from Equation [91], the reduced time of cooling depends upon the thickness of the plate g, on the speed of welding v, and the diffusivity of metal $1/2\lambda$. Actually, however, the thickness is the major factor, and for the usual range of welding speeds, from 6 to 12 ipm, the influence of speed can be neglected.

Fig. 10 shows the relation between the true and reduced time of cooling for various thicknesses of steel, assuming a diffusivity of 1 sq in. per min and a welding speed of 7 ipm. It is seen that as the time of cooling increases, the value of the reduced time of cooling, t^* differs more and more from that of the true time of cooling t, and so more so as the thickness is smaller. Since Equation [93] formally represents the conditions of a very thick plate and of a three-dimensional state of heat flow, the discrepancy between t and t^* is a measure of the departure from a three-dimensional heat flow. On the basis of Fig. 10 it may be predicted that in the vast majority of cases the $^1/_4$-in. plate will behave like a very thin plate, and the $1^1/_2$-in. plate like a very thick plate, and this prediction is in accordance with the findings of this and the preceding section. Also, it may be safely stated that plates over $1^1/_2$ in. thick will always behave like a very thick plate. Thus for plates thicker than $1^1/_2$ in. the reduced and the true cooling times are the same.

How well Equation [93] fits the actual conditions of welding is best determined by comparing the time of cooling computed from this formula using the chart, Fig. 10, with the time of cooling

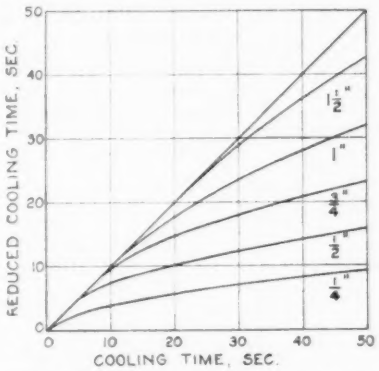

Fig. 10 Relation Between Cooling Time and Reduced Cooling Time for Plates of Various Thickness

measured in the experimental work of Hess and co-workers (14) on steel plates. In doing so, it must be remembered that the actual measurements of temperature were made not in the weld bead itself, but at a small distance from the bead. However, it can be shown that the error due to this factor is small after the first 5 to 10 sec of cooling. Another important factor is the proper choice of the heat efficiency (I.F.), and the heat conductivity k. From previous work (12), the I.F. was assumed to be 0.65. As for the heat conductivity k, a few trials showed that the value of $k = 0.080$ cal per deg C per sec fits best the experimental results at 1300 F. This value is commensurate with that determined previously, Equation [88].

Using the values given and expressing the temperature T in deg F, the energy input J/v in joules per in., and the reduced time t^* in seconds, Equation [93] reads for the case of butt-welded steel plates as follows

$$T - T_0 = 0.22 \left(\frac{J}{v}\right) \frac{1}{t^*}$$

hence the reduced time of cooling

$$t^* = \frac{0.22}{T - T_0} \frac{J}{v} \ldots\ldots\ldots\ldots [94]$$

Figs. 11 to 15, inclusive, show the agreement between computed and measured times of cooling for various thicknesses using three or four different energy inputs. The agreement in the important range of temperatures from 1300 to 575 F, is in general better than 5 per cent if no preheat is employed. The agreement is not as good with preheated plates, probably because the preheating operation was not maintained during welding (14). Notwithstanding this discrepancy, the general validity of Equation [93] in the range of temperatures from 1300 to 575 F may be considered as sufficiently established for practical purposes.

Determination of Rates of Cooling. By differentiating Equation [92] with respect to time there follows that (18)

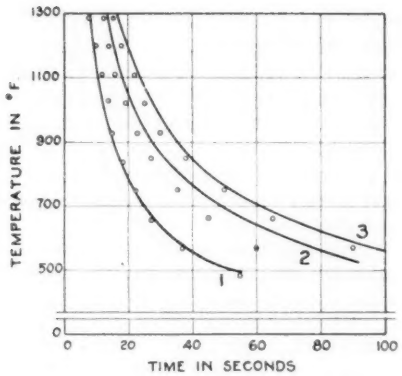

FIG. 11 WELD-COOLING CURVES IN 1/4-IN. PLATE AT ROOM TEMPERATURE

(Continuous lines computed; isolated circles measured by Hess and coworkers. 1, 17,000 joules per in.; 2, 22,800 joules per in.; 3, 28,000 joules per in.)

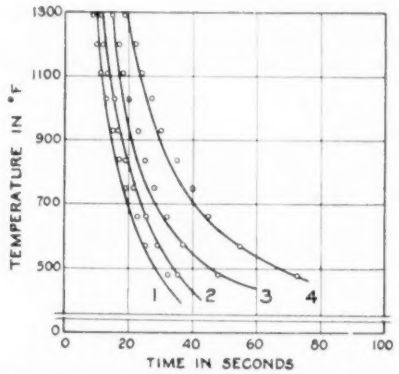

FIG. 15 WELD-COOLING CURVES IN 1 1/2-IN. PLATES AT ROOM TEMPERATURE

(Continuous lines computed; isolated circles measured by Hess and coworkers. 1, 53,000 joules per in.; 2, 63,500 joules per in.; 3, 76,400 joules per in.; 4, 100,500 joules per in.)

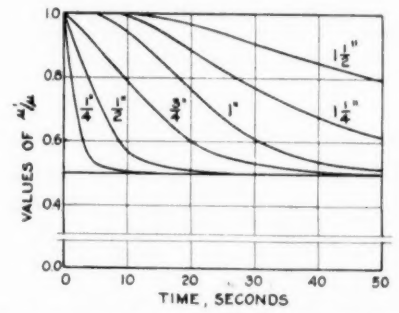

FIG. 16 RELATION BETWEEN WELD-COOLING TIME t AND COEFFICIENT $\left(\frac{\mu'}{\mu}\right)$ FOR VARIOUS THICKNESSES OF STEEL

hence by comparing Equation [96] with Equation [92]

$$\frac{dT}{dt} = -\frac{T - T_0}{t}\frac{\mu'}{\mu} \quad \ldots\ldots\ldots\ldots\ldots [97]$$

Equation [97] is of the same type as Equations [77] and [84] for the thin and thick plates, respectively; the only difference is that the coefficient (μ'/μ) instead of being a constant is a function of time and thickness, and to a much lesser degree of speed of welding and diffusivity. Assuming as previously, the value of 1 sq in. per min for the diffusivity and 7 ipm for the speed of welding, Fig. 16 shows the dependence of (μ'/μ) on time for various

thicknesses of plate. As expected, the values of (μ'/μ) vary between $^1/_2$ and 1, the line $^1/_2$ denoting conditions identical to that of a very thin plate and the value 1, conditions identical to that of a very thick plate. In accordance with previous results it is seen that the $^1/_4$-in. plate behaves like a thin plate less than 5 sec after the cooling process has started, whereas the $1^1/_2$-in. plate remains practically under the conditions of a very thick plate up to 30 sec of cooling.

Equations [93] and [97] along with charts, Figs. 10 and 16, may be used conveniently for a speedy determination of rates of cooling.

Suppose, for example, it is desired to determine the rates of cooling in a $^3/_4$-in. plate when using an energy input of 50,000 joules per in. The three following temperatures of preheat will be examined: 72 deg, 200 deg, and 400 deg F.

From Equation [93] the corresponding reduced times of cooling are 11.8, 13.7, and 18.4 sec.

Referring to the chart, Fig. 10, we find for a $^3/_4$-in. plate the true cooling times, namely, 13.5, 18.0, and 30.5 sec, respectively, and from the chart, Fig. 16, the corresponding values of (μ'/μ) = 0.72, 0.64, and 0.54, respectively.

Substituting in Equation [97], the following rates of cooling are obtained: 49.5 deg F per sec, 27.2 deg F per sec, and 10.5 deg F per sec, as compared to the values determined by Hess and coworkers, namely, 51 deg F per sec, 32 deg F per sec, and 15 deg F per sec. As expected, the computed rates of cooling are lower than those actually measured for higher temperatures of preheat.

3 MISCELLANEOUS APPLICATIONS OF THEORY OF MOVING SOURCES

Introduction

Because of lack of experimental data, the applications described in this part are of a more or less tentative character. The purpose of this discussion is not so much to arrive at numerical results as it is to find a scientific approach to the solution of the problems presented. In view of the success which such an approach has had in the problems of welding, it is believed that the considerations which follow will be of more than academic interest.

Rate of Extrusion in Continuous Casting. Continuous casting is a metallurgical process in which liquid metal is fed into a die and extruded in the form of a solid rod at a constant rate by means of a pair of rollers placed behind the die (19). To make the extrusion operation possible the rod must leave the die at a temperature at which the metal can be hot-worked and which consequently represents a given fraction of the temperature of fusion. In other words, the die must be capable of removing the heat from the cast metal to bring about the required drop of temperature. If radial temperature gradients in the rod are neglected, this drop of temperature may be regarded as being produced by a linear flow of heat with surface losses. On the other hand, by the process of extrusion each section of the rod is moved gradually from the inlet of the die where it is at the temperature of fusion T_1 to the outlet of the die, where it has been cooled down to the temperature of extrusion T_2. Thus the heat flow is of a quasi-stationary nature and Equation [23] is applicable. If the die is kept at a constant temperature T_0 and if the length of the die from the inlet to the outlet is L, then Equation [23] may be rewritten as follows

$$T_2 - T_0 = (T_1 - T_0)e^{-(\sqrt{\lambda^2 v^2 + PH/A} - \lambda v)L} \quad [98]$$

The remaining symbols in Equation [98] have the following meaning

λ = one half of the converse value of diffusivity
v = rate of extrusion
P = perimeter of rod
A = cross section of rod
H = dissipation ratio, see Equation [20]

For a circular rod of diameter D, the fraction $P/A = 4/D$. Putting further

$$\ln \frac{T_2 - T_0}{T_1 - T_0} = -m \quad [99]$$

Equation [98] becomes

$$m = \left[\sqrt{(\lambda v)^2 + \frac{4H}{D}} - \lambda v\right] L \quad [100]$$

or

$$m^2 = -2m\lambda vL + \frac{4HL^2}{D}$$

or

$$2\lambda vD = \frac{4HD}{m} \times \frac{L}{D} - m \Big/ \frac{L}{D} \quad [101]$$

Assuming a constant value of m, Equation [101] gives the relation between the rate of extrusion v and the mechanical and thermal characteristics of the extrusion. The former is represented by the ratio L/D which is a function of the friction between the die and the cast.

Since the load-carrying capacity of the rod at the outlet of the die has a limiting value, the higher the friction coefficient, the smaller the ratio L/D. On the other hand, the thermal characteristics of the extrusion process are determined (*a*) by the coefficient 2λ, which is the ratio of the volume heat capacity of the rod to its heat conductivity k, i.e., $\frac{c\rho}{k}$ (c = specific heat and ρ = density); and (*b*) by the coefficient H, which is the ratio of the heat dissipation h, and the heat conductivity of the rod, k. Thus both 2λ and H contain k in the denominator. This fact will be brought out later in the discussion.

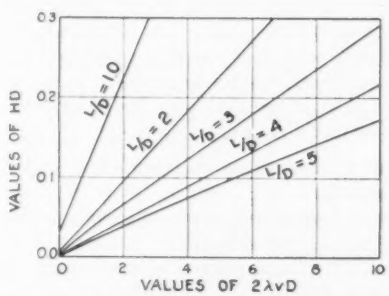

Fig. 17 Relation Between Rate of Extrusion and Heat-Dissipation Ratio in Continuous Casting

Fig. 17 shows the relation between the rate of extrusion and the surface transfer coefficient of the interface between the die and the rod for various values of L/D, computed according to Equation [101]. For the purpose of computation, the fraction $T_2 - T_0/T_1 - T_0$ has been taken as 0.7; thus ln 0.7 = —0.36. Likewise, dimensionless numbers rather than specific values of speed and dissipation ratio have been plotted in order to make the discussion more general. Because of the fact that for values of $L/D > 2$ the second term on the right-hand side of Equation [101] becomes very small as compared to the first one, the speed of extrusion increases almost proportionally to the coefficient H and the relative length of the die L/D. It also increases with the ratio $H/2\lambda$, which as pointed out previously, is nothing else but the ratio of the heat dissipation h to the volume heat capacity

of the metal. The fact that the heat conductivity of the cast metal does not appear in these relations is noteworthy. It shows, for example, that other conditions being equal, the rate of extrusion of copper wire will not be substantially greater than that of iron wire, in spite of the much higher heat conductivity, as the volume heat capacity is not very much different for these metals.

To obtain an approximate idea of the order of magnitude of the rate of extrusion which can be expected, assume the following values for an iron wire 1 cm diam ($\sim$ $^3/_8$-in.) when cast in a metallic die

h = 0.012 cal per sq cm per deg C per sec (20)
k = 0.08 cal per cm per deg C per sec (16)
$c\rho$ = 1.2 cal per cu cm (16)[9]

hence

$$HD = 0.15 \text{ and } 2\lambda D = 15 \text{ sec per cm}$$

Assuming further L/D = 2, 3, and 4, respectively, the following values of $2\lambda vD$ are obtained from Fig. 17: 3.15, 4.8, and 6.6, hence

v = 0.2 cm per sec, 0.33 cm per sec, and 0.44 cm per sec

Actually, these values may be substantially increased by improving both the heat dissipation h and the lubrication condition between the mold and cast, i.e., the ratio L/D, when using graphite instead of metal for the dies (19). At present, none of these coefficients is very accurately known to permit more than a qualitative statement. However, a method of obtaining a value of some of these coefficients is proposed in the following section.

Method of Determining Value of Diffusivity and Heat-Dissipation Ratio. Equations [23] and [24] provide a convenient method of obtaining, in a single experiment, the coefficients λ and H, the former being one half of the converse value of diffusivity, the latter the dissipation ratio. To this end the metal to be tested is formed into a thin-walled cylinder and surrounded by the medium whose value of H with respect to the metal in question is to be determined. A source of heat in the form of a coil is then moved inside the tube at a rate which will practically produce a uniform temperature distribution in the thickness of the tube, and of sufficient intensity to bring the temperature of the tube to the desired maximum value. The temperature of the surrounding medium is kept at a constant temperature T_0.

By means of thermocouples spot-welded to the tube, the temperature at a given cross section of the latter is taken for three positions of the heat source as follows:

1 Position x_1, for which the temperature has reached the maximum value T_1.

2 Position x_2, preceding the position x_1 and for which the temperature had a given value $T_2 < T_1$.

3 Position x_2' following the position x_1, and for which the temperature has dropped back to the value T_2.

Calling g the thickness of the tube, the ratio of the perimeter P to the cross section A, entering Equations [23] and [24] is simply $1/g$ thus

$$\frac{T_2 - T_0}{T_1 - T_0} = e^{-\left[\sqrt{(\lambda v)^2 + H/g} - \lambda v\right](x_1 - x_2)} \quad [102]$$

and

$$\frac{T_2 - T_0}{T_1 - T_0} = e^{-\left[\sqrt{(\lambda v)^2 + H/g} + \lambda v\right](x_2' - x_1)} \quad [103]$$

These two equations can be rewritten in a more simple form by putting

$$\ln \frac{T_2 - T_0}{T_1 - T_0} = -m \quad [104]$$

[9] Strictly speaking, coefficient 1.2 must also include the latent heat of fusion.

$$\frac{x_1 - x_2}{g} = u; \qquad \frac{x_2' - x_1}{g} = u' \quad [105]$$

hence

$$\frac{m}{u} = \sqrt{(\lambda v g)^2 + Hg} - \lambda v g \quad [106]$$

and

$$\frac{m}{u'} = \sqrt{(\lambda v g)^2 + Hg} + \lambda v g \quad [107]$$

Solving for λvg and Hg there follows

$$\lambda v g = \frac{m}{2}\left(\frac{1}{u'} - \frac{1}{u}\right) \quad [108]$$

and

$$Hg = \frac{m^2}{uu'} \quad [109]$$

hence finally the average diffusivity between the temperatures T_1 and T_2

$$\frac{1}{2\lambda} = \frac{4v}{m}\frac{(x_2' - x_1)(x_1 - x_2)}{(x_2 + x_2' - 2x_1)} \quad [110]$$

and the average dissipation ratio between $(T_1 - T_0)$ and $(T_2 - T_0)$

$$H = \frac{m^2 \times g^2}{(x_2' - x_1)(x_1 - x_2)} \quad [111]$$

Characteristically, the expression for diffusivity does not depend on the thickness of the tube and the expression of H does not depend on speed.

Control of Factors Governing Flame-Hardening and Continuous-Quenching of Steel Products. The purpose of flame-hardening is to produce a hardened case in steels of proper carbon and alloy content by raising the temperature of the case above the upper transformation point of steel Ac_3, and by quenching it as rapidly as possible in water. When dealing with parts of some length, such as gear rims or rails, the rise of temperature is accomplished by means of an oxyacetylene torch moving at a constant speed v, and the quenching, by a water sprinkler which moves closely behind the torch.

In what follows it will be assumed that the part has a rectangular section and that the flame of the oxyacetylene torch covers uniformly the surface over its whole width g, but that it extends over only a small portion l of its length. Thus the heat flow may be considered as being produced by a narrow plane source of heat moving at a constant speed, v. This case has been examined in Part 1, and Equations [51] and [60] have been derived to describe the temperature distribution around the heat source. Of these, Equation [51] represents an almost uniform rise of temperature which will result in the heated part throughout its thickness, at some distance behind the source, if there are no losses to the surrounding. This rise of temperature is then merely the consequence of the storing up of the heat, and if the latter is delivered at a rate of q thermal units per unit time, the rise of the temperature T_2 behind the source over the initial temperature T_0 is in accordance with Equation [51]

$$T_2 - T_0 = \frac{q}{c\rho agv} \quad [112]$$

As previously $c\rho$ (c=specific heat, ρ=density) represents the volume specific heat, and v the speed at which the source moves. As for the symbols a and g, their previous meanings must be inverted in order to keep up with the present description of things.

They are accordingly; a = the thickness, and g = the width of the heated part.

As has been shown in Fig. 2, for the case of a very narrow plane source, T_2 also represents the temperature at some depth below the location of the heat source. This temperature is quickly approached by the bulk of the metal as the heat source moves away from the section considered. For convenience, temperature T_2 will be called the "bulk" temperature. With this in mind, Equation [60] represents the relative rise of the maximum surface temperature T_1, as compared to the rise of the bulk temperature of the piece. Fig. 18 shows the same relation graphically. Here for convenience the converse of the relative rise of temperature, namely $(T_2 - T_0)/(T_1 - T_0)$, has been plotted as a function of a dimensionless number $\lambda v a$, whose significance will be explained shortly, and for various lengths l of the source referred to the thickness a of the piece l/a. Assuming that in flame-hardening the surface temperature is required to reach a constant value T_1 and that T_0 is the practically constant room temperature, Fig. 18 shows that the higher the number $\lambda v a$ the smaller will be the rise of the bulk temperature T_2. The same result is obtained by decreasing the relative length of the source l/a.

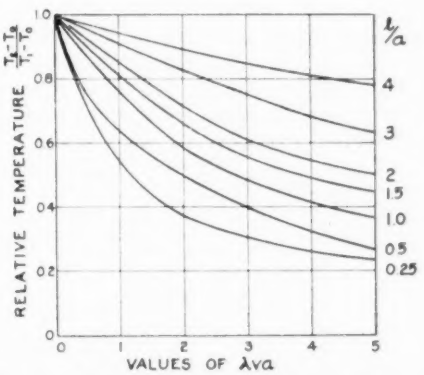

FIG. 18 RELATION BETWEEN RISE OF SURFACE TEMPERATURE T_1, AND THE RISE OF TEMPERATURE OF BULK OF MATERIAL T_2, FOR VARIOUS CONDITIONS OF FLAME-HARDENING

In order to interpret the number $\lambda v a$, attention is called to Equation [112]. If k is the heat conductivity of the material, it will be recalled that by definition

$$\frac{c\rho}{k} = 2\lambda \quad \ldots\ldots\ldots\ldots\ldots\ldots [113]$$

hence Equation [112] can be rewritten as follows

$$\lambda v a = \frac{q}{g} \times \frac{1}{2k(T_2 - T_0)} \quad \ldots\ldots\ldots\ldots [114]$$

In this relation q/g is the rate of heat per unit width and it may be considered as a characteristic of the heat source employed. When comparing Equation [114] with the chart, Fig. 18, it is found that $\lambda v a$ is a parameter which allows expression of the maximum surface temperature T_1, or the bulk temperature T_2, whichever is made variable, as a function of the heat characteristic (q/g) of the torch, and also another characteristic of the torch represented by the relative length l/a. Neither of these characteristics can be measured directly, but indirectly both can be determined by using Equation [114] and chart, Fig. 18, in reverse.

To this end, a trial experiment can be set up using a sample of the material to be treated in the form of a rectangular bar and measuring the temperature at a certain point of the surface and below the surface, while the latter is being heated, by passing over it the torch whose characteristics are to be determined. The following measurements are made:

1 Initial temperature, T_0.
2 Maximum temperature T_1 at the surface.
3 Temperature T_2, for which the surface temperature is almost the same as the depth temperature.
4 Speed of motion, v of the torch.
5 Width g, and thickness a of the bar.

Assuming an average constant value for λ and k, the value of q is thus determined from Equation [112] and the value of l from the chart, Fig. 18. For example, if $T_1 - T_0$ has been measured to be 800 C (1440 F) and $T_2 - T_0 = 400$ C (720 F), and if, furthermore, the speed at which the torch moved was 0.85 cm per sec, (0.336 ips), and the section of the bar 5 cm wide and 1 cm thick (about $2 \times {}^3/_8$ sq in.), then assuming, according to previous discussion, $k = 0.08$ cal per cm per deg C per sec, and $\lambda = 6$ sec per sq cm for steel, the value of q is found from Equation [114] as

$$q = 6 \times 0.85 \times 1 \times 5 \times 2 \times 0.08 \times 400 = 1640 \text{ cal per sec}$$

and l/a from the chart, Fig. 18, with $(T_2 - T_0)/(T_1 - T_0) = 0.5$ and $\lambda v a = 5.1$, as 2; hence $l = 2$ cm (= 0.79 in.).

If each torch thus has been rated for a given value of q and l, it then becomes possible to determine for what thickness of steel it is best fitted. As a usual practice, it may be attempted to keep the maximum surface temperature slightly above Ac_3 and the bulk temperature slightly below Ac_1, thus the ratio $(T_2 - T_0)/(T_1 - T_0)$ will be around 0.66, and the value of $\lambda v a$, according to Equation [114] around 0.01 (q/g), if q/g is expressed in cal per cm per sec. Assume, for example, a torch is used for which $q/g = 400$ cal per cm per sec, and $l = 2$ cm. It is required to find the thickness a for which it is fitted and the speed of motion v.

From Equation [114] $\lambda v a = 0.01 \times 400 = 4.00$ and from the chart, Fig. 18, the intersection of $(T_2 - T_0)/(T_1 - T_0) = 0.66$, and $\lambda v a = 4$, gives $l/a = 3$. Thus $a = {}^2/_3$ cm = 0.26 in. and since $\lambda v a = 4$, the speed $v = 1$ cm per sec, or about 23 ipm. If the bulk of the material is to be kept much below Ac_1, for example around 600 F, then $(T_2 - T_1)/(T_1 - T_0)$ is around 0.33 and $\lambda v a = 0.005$ (q/g). Hence with the same type of torch as before, $\lambda v a = 2$, and $l/a = 0.2$; $a = 2/0.2 = 10$ cm (4 in.). The speed, however, is reduced as much as the thickness has been increased, becoming only 1.5 ipm.

Continuous Quenching. If the heat, instead of being delivered to the piece, is being withdrawn at a rate of q thermal units per unit time, under conditions similar to that of flame-hardening, then Equation [114] and the chart, Fig. 18, can be used to control the final temperature T_2 to which the surface of a piece previously heated to a temperature T_0 will be automatically reheated after having been quenched down to the temperature T_1. This problem can be solved in a manner similar to that outlined for the flame-hardening. To make the conditions more specific, suppose it is desired to improve the hardness of the top surface of a rail by means of water-quenching, followed by tempering at 500 C (950 F). Using the theory of a moving-plane source, this treatment can be attempted in one continuous and single operation as follows: After the rail has left the rolling mill at some 980 C (1800 F), it is quenched by means of a water sprinkler moving at a constant speed v. The problem is then reduced to the determination of the characteristics of the water sprinkler in such a way that the surface of the rail after being quenched to the temperature of 20 C (86 F) is reheated to a bulk temperature of 500 C (950 F). To this end, suppose that the head of the rail is 2 in. wide and $1^1/_2$ in. thick, or approximately 5×4 sq cm, and that the heat content of the web can be neglected. Then by assuming that the water spray covers a surface of 5×5 sq cm, the value

of l/a is $5/4 = 1.25$. On the other hand, $(T_2 - T_0)/(T_1 - T_0) = \frac{500 - 980}{20 - 980} = 0.5$; hence from the chart, Fig. 18, $\lambda va = 3.2$. If this value is substituted in Equation [114], then by putting as previously $k = 0.08$ cal per cm per deg C per sec, and $\lambda = 6$ sec per sq cm, the value of q becomes

$$q = -3.2 \times 5 \times 0.16 \times 480 = -1240 \text{ cal per sec}$$

Since $\lambda va = 3.2$, the speed of motion is

$$v = 3.2/6 \times 4 = 0.132 \text{ cm per sec} = 3.15 \text{ ipm}$$

A similar computation will show that if it is desired to obtain a tempered martensite at 100 C (= 212 F) at the surface, the heat must be removed from the surface at a rate of 2280 cal per sec with the same speed of motion.

Before closing, emphasis again is put on the tentative character of the foregoing computation. There is obviously need for some preliminary experimentation before the theory expounded can be used as a practical tool much in the same way as this has been done for welding.

Appendix 1

Use of Instantaneous Sources for Solution of Heat Flow Due to Moving Sources

The solution of heat flow in an infinite solid due to a source moving in a given direction may be obtained by adding the contributions of an infinite number of small instantaneous sources placed one behind the other at infinitely small intervals of time, along the direction of motion. If the direction of motion is taken as the x-axis, then the contribution of an infinitesimal instantaneous point source dQ placed at a distance x' from the origin at a time t', may be represented as follows in so far as the increase of temperature dT of a point (x, y, z) at any moment $t \geq t'$ is concerned[10]

$$dT = \frac{\sqrt{2\lambda}\, dQ}{8\pi^{3/2}k} \times \frac{1}{(t-t')^{3/2}} \times e^{-\frac{\lambda}{2(t-t')}[(x-x')^2+y^2+z^2]}$$

where dQ is the quantity of heat of the point source, k is the heat conductivity, and 2λ is the converse of heat diffusivity. However, if the law of motion is given, x' is a known function of t'; and the same is true for the amount of heat delivered by the moving source; thus

$$Q = \phi(t') \text{ or } dQ = \phi'(t')dt'$$

and

$$x' = f(t')$$

hence

$$T - T_0 = \frac{\sqrt{2\lambda}}{8\pi^{3/2}k} \int_0^t \frac{\phi(t')}{(t-t')^{3/2}} e^{-\frac{\lambda}{2(t-t')}\left\{[x-f(t')]^2+y^2+z^2\right\}} dt' \qquad \ldots\ldots [A]$$

This is the most general equation of heat flow in an infinite solid due to a moving-point source. Similar expressions can be derived for moving line and plane sources.

As a particular case, put

$$Q = qt'$$

and

$$x' = vt'$$

where q and v are constants.
Then Equation (A) becomes

$$T - T_0 = \frac{\sqrt{2\lambda}}{8\pi^{3/2}} \frac{q}{k} \int_0^t \frac{dt'}{(t-t')^{3/2}} e^{-\frac{\lambda}{2(t-t')}[(x-vt')^2+y^2+z^2]} \qquad \ldots\ldots [B]$$

Put

$$t - t' = \tau^2;\ x - vt = \xi;\ \xi^2 + y^2 + z^2 = R^2$$

There follows

$$T - T_0 = -\frac{\sqrt{2\lambda}}{8\pi^{3/2}} \frac{q}{k} \int_0^t \frac{2\tau d\tau}{\tau^3} e^{-\frac{\lambda}{2\tau^2}[R^2+2v\xi\tau^2+v^2\tau^4]}$$

$$= \frac{\sqrt{2\lambda}}{4\pi^{3/2}} \frac{q}{k} e^{-\lambda v\xi} \int_0^t \frac{d\tau}{\tau^2} e^{-\frac{\lambda R^2}{2\tau^2}-\frac{\lambda\tau^2}{2}}$$

[10] Reference (9), p. 150.

or letting $t \rightarrow \infty$

$$T - T_0 = \frac{\sqrt{2\lambda}}{4\pi^{3/2}} \frac{q}{k} e^{-\lambda v \xi} \int_0^\infty \frac{d\tau}{\tau^2} e^{-\frac{\lambda R^2}{2\tau^2} - \frac{\lambda \tau^2}{2}} \quad \ldots\ldots [C]$$

The infinite integral appearing in Equation [C] can be solved by means of the Bessel function $K_{1/2}(x)$. To this end put a new variable α, such that

$$\tau = \alpha R \sqrt{2\lambda} \quad \ldots\ldots [D]$$

The substitution of Equation [D] in Equation [C] gives

$$T - T_0 = \frac{q\sqrt{2\lambda}}{4\pi^{3/2} k} e^{-\lambda v \xi} \times \frac{1}{R\sqrt{2\lambda}} \int_0^\infty e^{-(\lambda v R)^2 \alpha^2 - 1/4\alpha^2} \alpha^{-2} d\alpha$$

But according to the theory of Bessel functions (10)

$$\int_0^\infty e^{-(\lambda v R)^2 \alpha^2 - 1/4\alpha^2} \alpha^{-2} d\alpha = \sqrt{2\lambda R}\ K_{1/2}(\lambda v R)$$

and furthermore

$$K_{1/2}(\lambda v R) = \frac{\sqrt{\pi}}{\sqrt{2\lambda v R}} e^{-\lambda v R},$$

hence finally

$$T - T_0 = \frac{q}{4\pi k} e^{-\lambda v \xi} \frac{e^{-\lambda v R}}{R}$$

This expression has been derived previously in Part 1 in a more simple way for a three-dimensional case.

Using similar procedures for the line and plane instantaneous sources, Expressions [31] and [18] can be derived for the two-dimensional and linear heat flow, respectively.

Appendix 2

Expansion of Solution [45] in a Fourier Series

As shown by Carslaw,[11] if $f(y)$ is an even function of y which can be expanded, as also $f(y \pm 2na)$, in a Fourier series of cosines of multiples $\pi y/a$, then

$$\sum_{-\infty}^{\infty} f(y \pm 2na) = \frac{1}{a} \int_0^\infty f(y) dy + \frac{2}{a} \sum_1^\infty \cos \frac{\pi n y}{a} \int_0^\infty f(y') \cos \frac{\pi n y'}{a} dy$$

Let $f(y) = K_0(\lambda v \sqrt{\xi^2 + y^2})$, then

$$\sum_{-\infty}^{\infty} K_0\left(\lambda v \sqrt{\xi^2 + (y \pm 2na)^2}\right) = \frac{1}{a} \int_0^\infty K_0\left(\lambda v \sqrt{\xi^2 + y^2}\right) dy + \frac{2}{a} \sum_1^\infty \cos \frac{\pi n y}{a} \times \int_0^\infty K_0\left(\lambda v \sqrt{\xi^2 + y'^2}\right) \cos \frac{\pi n y'}{a} dy'$$

But, by virtue of the integral representation of Bessel function (10)

$$\int_0^\infty K_0\left(\lambda v \sqrt{\xi^2 + y^2}\right) dy = \frac{1}{\lambda v} \int_0^\infty e^{-(\lambda v \xi)^2 t^2 - 1/4t^2} t^{-1} dt \times \int_0^\infty e^{-(\lambda v y)^2 t^2} d(\lambda v y) = \frac{1}{\lambda v} \frac{\sqrt{\pi}}{2} \int_0^\infty e^{-(\lambda v \xi)^2 t^2 - 1/4t^2} t^{-2} dt = \frac{\pi}{2\lambda v} e^{-\lambda v |\xi|}$$

[11] Reference (9), p. 159.

Likewise

$$\int_0^\infty K_0\left(\lambda v \sqrt{\xi^2 + y'^2}\right) \cos \frac{\pi n y'}{a} dy' = \frac{1}{\lambda v} \int_0^\infty e^{-(\lambda v \xi)^2 t^2 - 1/4t^2} t^{-1} dt \times \int_0^\infty e^{-(\lambda v y')^2 t^2} \cos\left(\frac{\pi n}{\lambda v a} \lambda v y'\right) d(\lambda v y')$$

$$= \frac{\sqrt{\pi}}{2\lambda v} \int_0^\infty e^{-(\lambda v \xi)^2 - \mu_n^2/4t^2} t^{-2} dt = \frac{\pi}{2\lambda v \mu_n} e^{-\lambda v \mu_n |\xi|}$$

where $$\mu_n = \sqrt{1 + \left(\frac{\pi n}{\lambda v a}\right)^2}$$

hence recalling that

$$2\lambda = \frac{c\rho}{k}$$

we obtain expression, Equation [48] or [49], according to whether ξ is positive or negative.

Discussion

R. H. Cameron.[12] This paper is of considerable interest to the writer as a mathematician, because it shows that data of important practical significance can be calculated by the use of higher mathematics and higher mathematical techniques. While undoubtedly many of the author's conclusions have been or will be checked directly by experiment, his methods make it possible quickly to calculate data and plot curves which could be obtained directly only by a very large number of time-consuming and costly experiments. His theory of quasi-stationary states simplifies many practical problems to the point where calculation is possible and provides a method of attack on other problems which have not yet been put on a mathematical basis.

The author's technique changes a problem involving moving heat sources into one involving only fixed sources or singularities, and thus extends the classical methods of treating fixed sources to the more difficult problems of moving sources. These methods apply to such apparently diverse problems as arc welding, the rate of extrusion of a continuous casting, continuous quenching, and the heating effects of the passage of a bullet in a gun barrel.

Finally, his methods can be used in connection with experimental work to suggest the design of experiments, the direction they should take, and the interpretation of the results. His method for determining the values of diffusivity and heat-dissipation ratio is an example in point.

M. W. Rubesin[13] and R. C. Martinelli.[14] The author has presented an extremly interesting and useful contribution to the field of heat conduction. It is interesting to note that, due to the quasi-stationary state existing about the moving source, the method of relaxation can be readily applied to the problem.

A heat balance is made on a lattice of sides δ and depth $\delta/2$ situated directly below the moving source and moving with the source at a velocity v. Consideration is taken of the heat generated by the source, the heat conducted into the lattice by conduction, and the heat carried into the lattice by the movement of material through the lattice. Heat balances are made on other lattices surrounding the one about the source and a set of relaxation patterns established. Calculations show that the results of this numerical method check reasonably with the analytical results of the author.

[12] Professor of Mathematics, University of Minnesota, Minneapolis, Minn.

[13] University of California, Berkeley, Calif.

[14] Assistant Professor of Mechanical Engineering, University of California. Mem. A.S.M.E.

Heat losses from the surface can also be accounted for by the method of relaxation.

Author's Closure

Professor Cameron's comments coming from a mathematician are very much appreciated. The technical man neither ignores nor belittles the value of the mathematics, but the thing he is primarily interested in is the final numerical value of the solution and not the way in which the latter has been obtained. Unfortunately, many a mathematician does not appreciate this point of view as fully as Professor Cameron does. They are inclined to consider the ultimate step of the analysis which consists of putting the solution in a form suitable for numerical computation as some sort of "puka" mathematics to be left to the computing machines. While the latter certainly are tremendous time savers, they hardly afford as complete a view of the problem as a mathematical analysis does, especially when it comes to the consideration of singularities. Some of the problems of heat flow require the use of the highest mathematical techniques, and it is only through the co-operation of mathematicians who are skilled in those techniques that a substantial progress in the theory of heat flow can be made.

The emphasis on the mathematical analysis does not preclude the use of numerical methods for particular applications. From this point of view the remarks made by Mr. Rubesin and Professor Martinelli are most welcome. The author is not enough familiar with the relaxation method to see the advantages that it offers in the treatment of a general problem of heat flow, like the one developed in the present paper, but he is aware of the possibilities which it affords in solving particular problems with specific boundary conditions. For example, he would be very much interested to see the discussers treat the following two problems which are of importance in arc welding:

1 Heat flow due to a moving plane source of a circular shape, and

2 Heat flow in a plate heated by a moving point source on one face and cooled by liquid medium on the other face.

The solution of the first problem may give a better insight into the phenomena of temperature distribution in the molten pool, and the second is of especial interest in ship-repair welding.

In closing the author wishes to thank all discussers for their kind interest in his paper.

Cutting Action of Reamers

By T. F. GITHENS,[1] CLEVELAND, OHIO

The cutting action of reamers resembles in many ways the cutting action of boring tools or twist drills. There is a common misconception that a reamer somehow gets into a hole and then scrapes the hole to size by means of its longitudinal cutting teeth. What really happens is that a reamer, a small amount larger than the hole to be finished, must cut its way into the hole by its entering teeth; and then produce a smoothly finished hole, round, straight, in proper alignment, and as near to the standard reamer size as possible. Reamers are provided with three kinds of clearance, point, peripheral, and longitudinal. Reamers can be made with combinations of positive, negative, and zero radial and axial rakes. The angle of the point and the feed per revolution affect the true rake angle of the cutting edge. Reamers must be kept sharp. The standard reamer made accurately to size and carefully used to produce a standard hole has been the most important factor in interchangeable manufacture. All classes of fit can be made by proper allowance on the shaft and the maintenance of the dependable standard hole produced by the standard reamers. These and other facts concerning reamers are explained in this paper.

Machine and Hand Reamers

A MACHINE reamer is a tool used for enlarging a hole, previously formed, and for freely cutting this hole as round, smooth, straight, in proper alignment, and as close to the standard or exact size as possible (1).[2]

A reamer is accomplishing its purpose when it cuts freely a round, smooth, straight hole its own size.

The principal parts of a machine reamer are shown in Fig. 1. These definitions and those for hand reamers are explained in the American Standard for Reamers (2).

The principal parts of a hand reamer are shown in Fig. 2.

Reamer Clearances

A reamer without clearance cannot cut because its cutting edges cannot get under the surface of the metal to lift or sever the chip from the metal. If forced into a hole it merely rubs or burnishes the surface of the hole and either heats the tool sufficiently to draw the temper, or tears the hole, or does both. A reamer having proper clearance cuts freely and smoothly (1).

There are three kinds of clearance on reamers, as follows:

1 Clearance on the entering ends of the teeth. This clearance is illustrated in Fig. 3 and is sometimes called "point" clearance.

2 Clearance along the lands or peripheral part of the reamer. This is sometimes called "radial relief" or clearance. This is illustrated in Fig. 5.

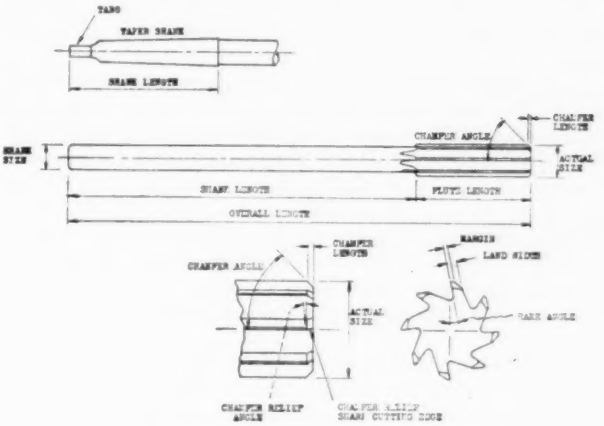

FIG. 1 MACHINE REAMER

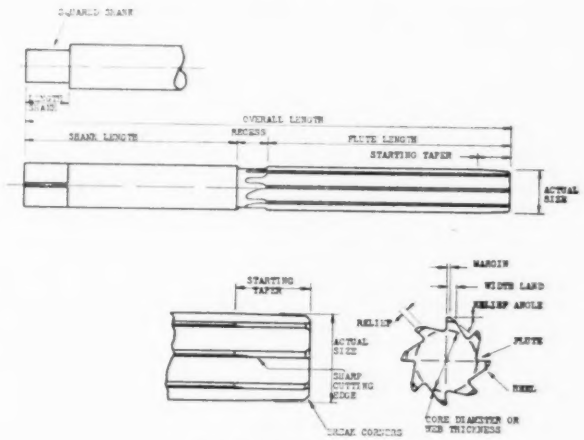

FIG. 2 HAND REAMER

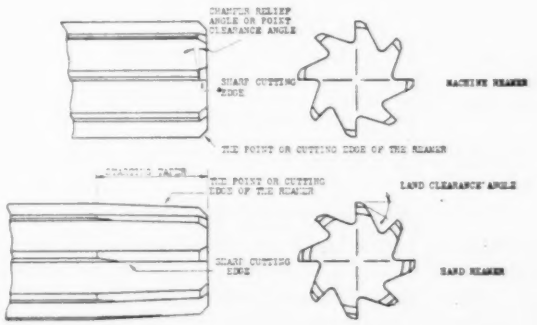

FIG. 3 CUTTING ENDS OR POINTS, SHOWING CUTTING EDGES AND CLEARANCES

3 "Longitudinal relief" or "back taper," which is a very slight taper of about 0.0001 in., which makes the reamer smaller toward the shank in order to prevent the back end from enlarging the hole or dragging and thereby roughing up the finish of the hole, Fig. 7.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Point Clearance

The entering cutting edges on chucking reamers are usually beveled at an angle of from 40 to 50 deg for the purpose of keeping the extreme cutting corner as obtuse as possible, which helps to keep it sharp for a longer time. This cone shape also aids the reamer in centering itself in the work. These cone-shaped edges must be ground to a sharp edge with clearance for end-cutting, Fig. 3.

Hand reamers have a much longer taper, about 0.015 in. per in., and they are used for finishing purposes only. These reamers are but slightly smaller at the entering end, as it is necessary to remove only a small amount of metal in the finishing process. This long taper allows a scraping cut to be taken in such a manner that very accurate and smooth holes are produced. The taper edges must be ground to a sharp edge with clearance. A bevel of about 45 deg is also put at the long end of the tapering point to aid the hand reamer in entering the hole, but there should be so little stock left in the hole that this bevel should do no cutting, Fig. 3.

Fluted chucking reamers which are sometimes required for very accurate and smooth holes often have a slight second bevel in addition to that already mentioned, which acts like the taper on a hand reamer, thus making a smoother hole than would otherwise be the case. This is shown in Fig. 4; the length of this second taper need be only $^1/_{16}$ in. and must be ground to a sharp edge with proper clearance (1).

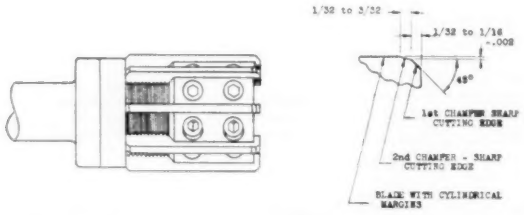

Fig. 4 Second Bevel on Point or Cutting Edges of Adjustable-Blade Reamers

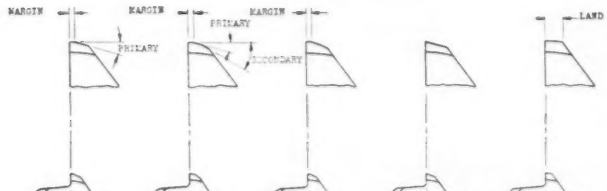

Fig. 5 Types of Side Clearance or Radial Relief

Side Clearance or Relief

Side clearance is illustrated in Fig. 5 and is formed by grinding away a portion of the land, usually leaving a slight cylindrical margin. The action of a reamer without side clearance is best understood by comparing a single tooth of the reamer with a boring tool having no clearance behind the cutting edge, as shown in Fig. 6, in which H is the hole to be bored, D the cutting edge, A is the side of the tool or peripheral land, with small sector B exactly concentric with the hole. Clearance is shown on the end of the boring tool at C.

It will be seen that great pressure would have to be exerted in the direction indicated by arrow X to hold the tool against the work, because the tool can cut the metal only at edge D, which enters the metal in the direction of the length of the hole, and

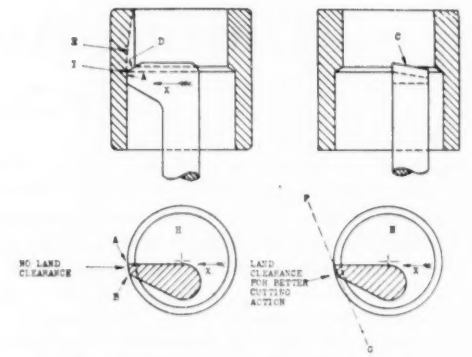

Fig. 6 Cutting Action of Boring Tool
(Land clearance improves performance.)

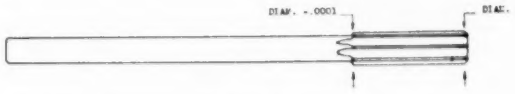

Fig. 7 Longitudinal Clearance or Back Taper

therefore there is no cutting action accomplished by the part shown at B. This part only rubs and as there is some spring to the tool it does not cleanly sever the chip produced by cutting edge D. Therefore part B is forced outward at each succeeding revolution as the tool is advanced, which results in producing a tapering hole as shown on dotted line E. This could be overcome only by exerting enough pressure in the direction of arrow X to hold sector B absolutely to its line of travel and by having the surface so hard and smooth that it could not tear the wall of the hole (1).

Another factor that also tends to produce a tapered hole and that requires additional pressure in the direction of the arrow is the dulling or rounding over of the extreme corner of the tool at 1. This dulling action is very severe at this point. The easiest and surest way to overcome these difficulties is to relieve the surface B along a line represented by FG. This reduces the required pressure in the direction shown by arrow X, and also lessens the trouble due to the dulling of the extreme cutting corner, and makes it possible to bore a hole the sides of which are practically parallel. The hole will also be smoother, as the side of the tool will scrape out the roughness left by the dulled corner as it follows after it. It must therefore be evident that a reamer without radial or side clearance is working under great difficulties and the chances for accurate work are small. It is also evident that as the surfaces of the reamer, which correspond to B, advance into the metal they should be lubricated and this can be done by lubricating the cutting edges as well.

Side relief is necessary for accurate reaming, yet a slight margin or cylindrical portion of the land must be left on the reamer to aid it to maintain correct size of the hole and allow the reamer to be sharpened many times without losing its original size. If the margin can be prevented from abrading or wearing away, the reamer can be sharpened back indefinitely. Of course some abrading and wear cannot be prevented, and commercial reamers are usually made a few ten-thousandths oversize so as to allow longer tool life and still produce accurate holes.

Rake Angles

The "rake angle" of a tool is the angle between the top cutting surface of a tool and a plane which is perpendicular to the surface of the work and to the direction of motion of the tool with respect to the work.

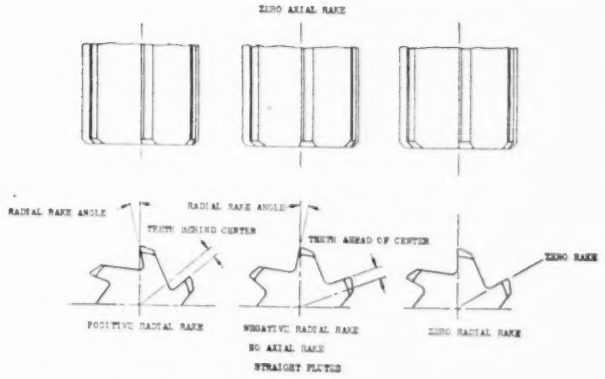

FIG. 8 TYPES OF RADIAL AND AXIAL RAKE

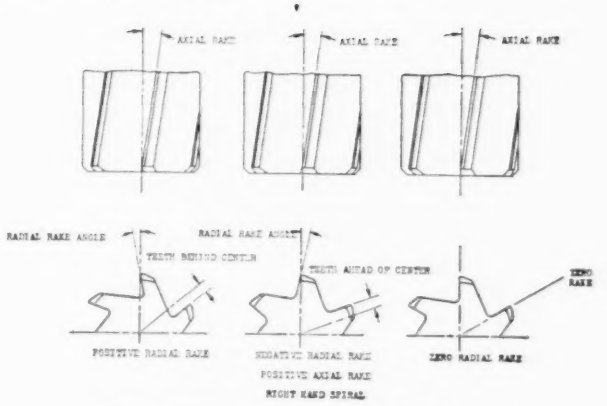

FIG. 9 TYPES OF RADIAL AND AXIAL RAKE

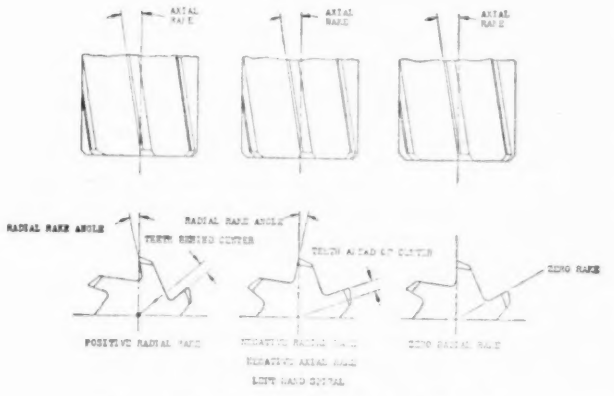

FIG. 10 TYPES OF RADIAL AND AXIAL RAKE

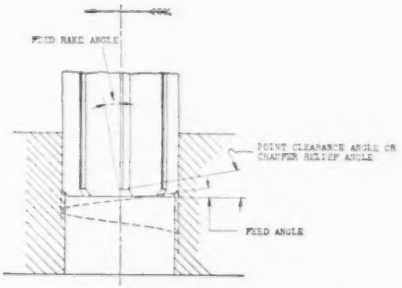

FIG. 11 RAKE ANGLE DUE TO FEED

(The angle that the reamer makes with the work as it feeds into the hole. Point clearance angle or chamfer relief angle should be greater than the feed angle shown. The action of the feed increases the rake angle of the reamer by the amount shown by the "feed-rake angle.")

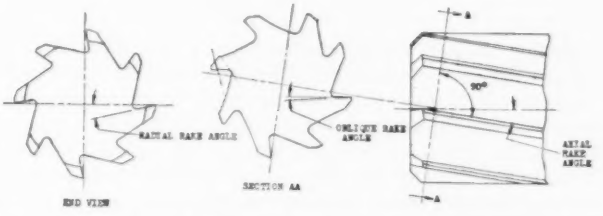

FIG. 12 RAKE ANGLE NORMAL TO HELIX ANGLE OR OBLIQUE RAKE ANGLE

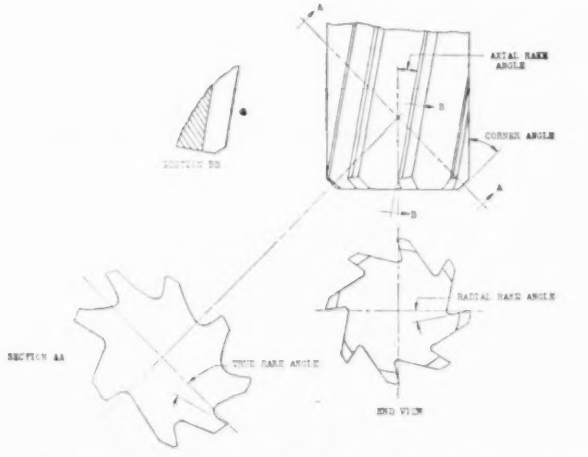

FIG. 13 TRUE RAKE ANGLE, NORMAL TO CUTTING EDGE OF CHAMFER, RESULTING FROM A GIVEN COMBINATION OF RADIAL-RAKE ANGLE, AXIAL-RAKE ANGLE, AND CORNER ANGLE OR POINT CHAMFER

The "axial-rake" angle is the same as the "helix angle." The "radial-rake" angle is the angle between the face of the flute and a radial line drawn to edge of the margin.

The best rake angle for each material, speed, feed, and machine-operating condition is a matter of trial and experiment.

Figs. 8, 9, and 10 show some possible combinations of axial and radial rakes with which reamers can be made.

Fig. 11 shows that the manner in which the reamer approaches

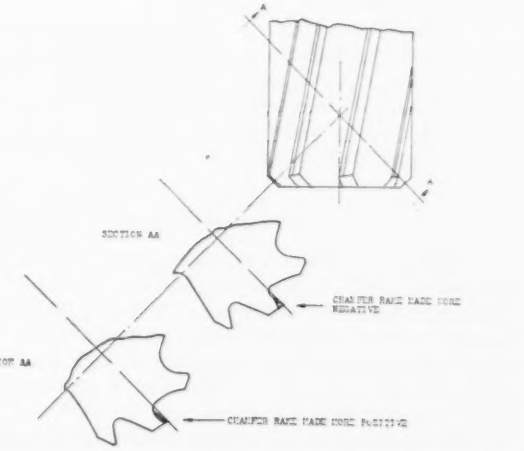

FIG. 14 POSITIVE OR NEGATIVE RAKE MAY BE VARIED ON CUTTING EDGES OF CHAMFER

the work affects the rake angle. The larger the feed per revolution the larger is the rake angle due to the feed.

Fig. 12 shows how the axial- and radial-rake angles combine to affect the oblique rake angle shown (3).

Fig. 13 shows a section at right angles to the point cutting edge at the actual and cutting edge of the reamer. This true rake angle depends upon the combined values of the radial rake, the axial rake, and the point angle or bevel.

Fig. 14 shows how in special cases with great care in grinding, the cutting rake of the point cutting edges may be varied for different materials and cutting conditions.

Form of Flutes

The style of flute is of the greatest importance, as its shape and area determine the relative strength of the tooth and the ability to carry away the chips. Large chip space and strength are desirable in all reamers but they are of greater importance in reamers designed for taper-reaming and for use in machines. The cutting face of a reamer tooth should have a fillet, see Fig. 15,

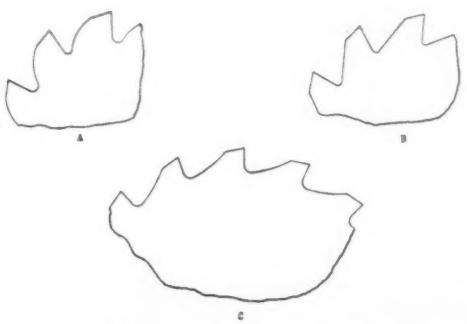

Fig. 15 Different Forms of Flutes Used for Various Types of Reamers

beginning about midway between the top and bottom of the tooth where great strength is desired, as in machine reamers, and nearer the bottom where the strength is of less importance, as in hand reamers. This fillet does not reduce the chip area materially because the chips tend to curl in most metals and this curl conforms to the shape of the fillet. Theoretically, the shape of the back of the tooth should be a convex parabola from the cutting edge to the base or junction of the fillet to obtain maximum strength. For manufacturing reasons a straight line or a concave curve which is tangent to the fillet and which lies outside the parabola is standard practice.

At *A* in Fig. 15 is shown a tooth with convex parabolic flank which is rarely used except on heavy chucking reamers where the cuts are heavy; at *B* is shown the straight flank; while at *C* is shown the concave-curve flank largely used by most manufacturers. Shape *C* provides a large chip area, and where uneven spacing is practiced the lands are most easily kept at uniform width (1).

Prevention of Chatter

Another desirable feature in a reamer, and especially a taper or hand reamer, is that it be able to cut a round smooth hole without chattering. There is an erroneous opinion prevalent that an even number of flutes chatter more than an odd number. This is a fallacy and our experience shows that an odd number of flutes will chatter as readily as an even number, especially when the reamer has more than four flutes.

Chatter may sometimes be eliminated by reducing the amount of clearance. To make reamers suitable for reaming most kinds of material met with in ordinary practice a considerable amount of clearance must be given, and this would produce chatter by biting in unless it is offset by some other features.

Chatter may sometimes be reduced by making the setup as rigid and strong as possible and by using pilots and guide bushings.

Chatter may also be reduced by cutting down the speed of the reamer. Speeds must not be so high as to permit chatter (5). Too low a feed may in some cases cause chatter due to glazing of the hole. Too much positive rake angle or too much negative rake angle may also cause chatter.

Reamers as commercially made usually have the cutting teeth unequally spaced. Fig. 16 shows a reamer with even spacing and a reamer with one type of uneven spacing. The reason for providing this uneven spacing is to reduce the possibility of chatter.

Fig. 17 shows a chucking reamer about to enter a hole. If the axis of rotation *A-A* of the reamer is exactly in line with the axis of the hole *B-B*, and all cutting conditions correct, such as speed not too high, feed not too low, amount of stock sufficient for a chip, rake not too hooked or too negative, the work and reamer rigidly held and guided if possible, there should be no chatter and a round, smooth, accurately sized hole should be produced.

However, if the axis of the reamer is out of line with the axis of the hole, or if a hard spot in the steel is cut, or if the reamer teeth are not sharpened accurately so that they are all at the same angle and length; one tooth of the reamer may cut a little deeper than the others, and in addition to the motion of rotation about its axis, the reamer will also acquire a secondary form of rotation as shown in Fig. 18.

This shows the situation greatly exaggerated. Tooth 1 has cut deeply into the metal and for an instant the reamer will rotate about the instantaneous center 1, until tooth 2 bites into the metal. Tooth 2 now becomes the instantaneous center of rota-

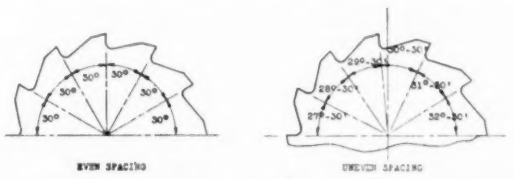

Fig. 16 Unequal Spacing of Flutes to Avoid Chatter

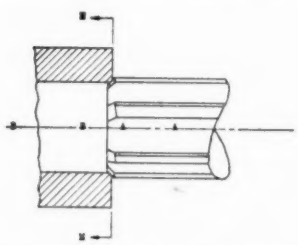

Fig. 17 Unequal Spacing of Flutes to Avoid Chatter

Fig. 18 (*left*) Unequal Spacing of Flutes to Avoid Chatter
(Section *M-M* of Fig. 17 greatly exaggerated. Reamer while rotating about its axis rotates also about center 1, a small amount, until tooth 2 cuts.)

Fig. 19 (*right*) Unequal Spacing of Flutes to Avoid Chatter
(Section *M-M* of Fig. 17 greatly exaggerated. Reamer while rotating about its axis rotates also about center 2, a small amount, until tooth 3 cuts.)

tion (see Fig. 19) and the reamer rotates until tooth 3 bites in, and so on all around the reamer. This continues while the reamer is rotating about its axis. A very bad condition such as described would result in chatter. If the teeth are unevenly spaced so that the distances between 1 and 2, 2 and 3, etc., are not the same, the jump or biting-in of the teeth will be unevenly distributed, and the cut gradually may become smooth and chatterless.

Cutting Action

The cutting action of a reamer has been shown in Fig. 6 to be similar in many respects to that of a boring tool. In Fig. 20 is shown a boring tool about to enlarge or finish-cut a rough hole. It must cut it sway into the hole by its sharp, cleared, end cutting edge *D*. Similarly the reamer must cut its way into the small rough hole by its sharp, cleared, end cutting beveled teeth or point.

The cutting action of a reamer is in some respects similar to that of a drill. Fig. 21 shows a drill about to cut through and enlarge a rough hole. The drill is larger than the rough hole and in order to enter, the drill must cut its way in. Similarly, in the same figure the reamer must be larger than the rough hole and must cut its way into the hole by its end cutting or beveled teeth. The cutting action of the longitudinal margins or lands is explained in connection with Fig. 6.

Fig. 22 shows the similarity of the cutting action of a drill and a hand reamer. The cutting action of a reamer is in some respects similar to that of an end mill as shown in Fig. 23, assuming that the direction of feed for both tools is helically axial.

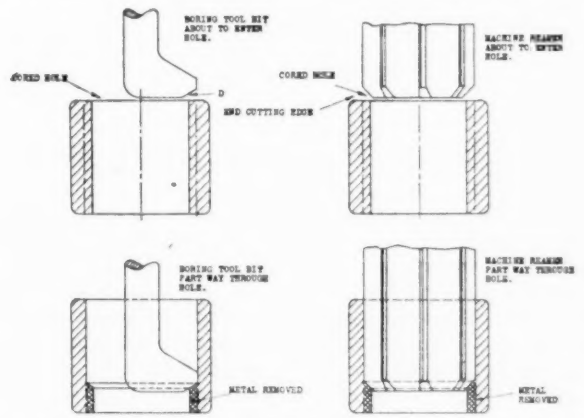

Fig. 20 Similarity of Cutting Action of a Boring-Tool Bit and a Reamer

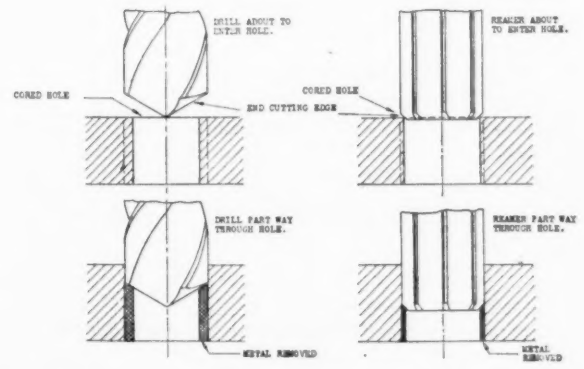

Fig. 21 Similarity of Cutting Action of a Twist Drill and a Machine Reamer

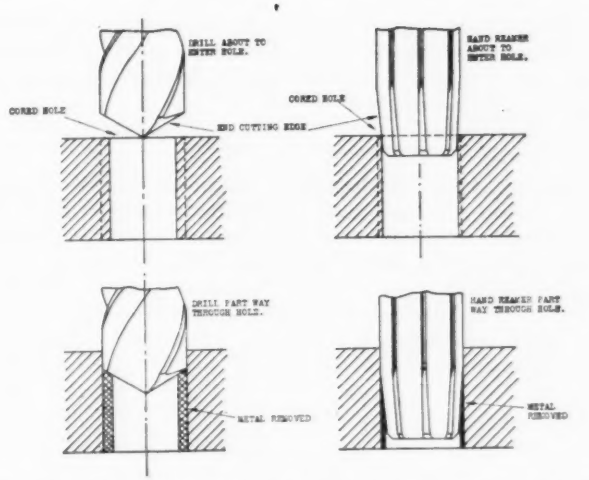

Fig. 22 Similarity of Cutting Action of a Twist Drill and a Hand Reamer

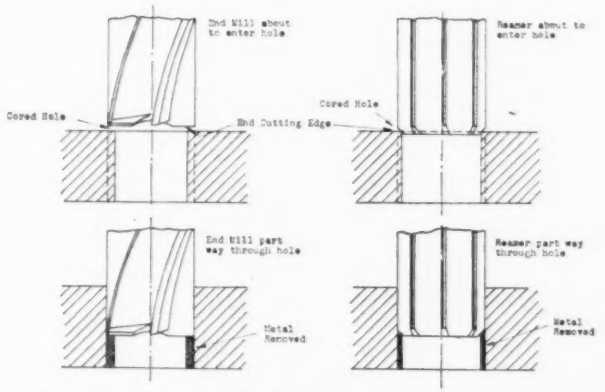

Fig. 23 Similarity of Cutting Action of an End Mill and a Machine Reamer

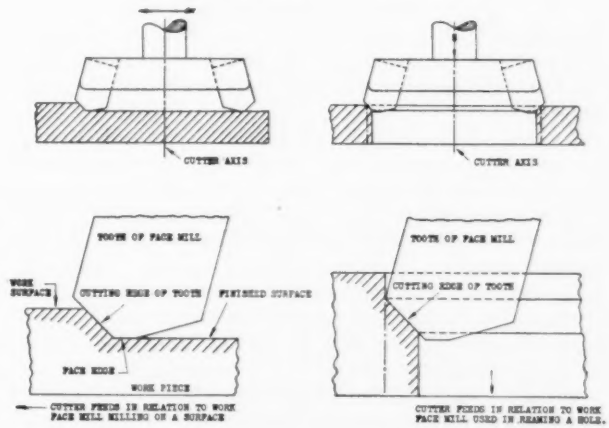

Fig. 24 Similarity of Cutting Action of a Face Mill and a Machine Reamer

The bodies of both tools fit in the holes they cut. Of course, in an end mill the direction of feed is usually perpendicular to the axis of the tool, not along the axis. Also an end mill will not usually produce as accurate a hole as a reamer because its longitudinal teeth are backed off sharp with no margins or lands.

Fig. 24 shows how a face mill, usually used for cutting along the surface of a piece of work, might be used to enlarge a hole.

This shows that the cutting action of face-milling teeth is essentially similar to that of reamer end cutting teeth. The lands or margins on a reamer serve the same purpose of smoothing the cut that the faces do on a face mill.

Reamer Sharpening

After a reamer has been used for a number of holes it will show signs of wear. These signs should be carefully watched and studied and at the proper time the reamer should be resharpened. In general, higher speeds will cause the reamer to dull faster, but higher speeds also give higher production. The finish required also determines the speed possible.

It will be noticed that the reamer will become dull along its once sharp edges *A-B*, Figs. 25 and 27, with the greatest wear at

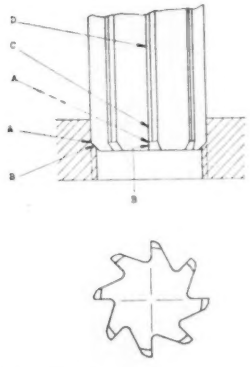

Fig. 25 Wear of Reamer Cutting Edges

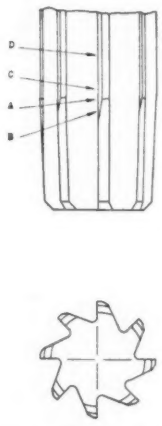

Fig. 27 Wear of Hand-Reamer Cutting Edges

the corners *A*. After a number of holes have been reamed the corner *A* will become completely rounded off. If the reamer is continued in use after this corner has become worn, the sharp edge along the margin *A-C* will also become worn and abraded starting at *A* and working back along the margin or land *A-C*. If the reamer is kept in use in this dull condition it will be completely ruined, the margins all the way back to *D* will become abraded, and the reamer cannot ream a smooth hole to the correct size.

The first result of using a dull reamer will probably be undersize holes, the reamer will be actually forced through the hole without cutting its true size. This of course, causes unnecessary wear on the reamer lands. If at the first sign of holes coming smaller in size the reamer is sharpened, holes up to size will be again produced.

To sharpen the reamer it is necessary to grind only the point or cutting edges back as shown at *A-D*, Figs. 26 and 28, with the proper clearance. The edges are ground back until the corner and marginal dullness between *A* and *C* is removed.

The importance of frequent reamer point sharpening for accurate and smooth holes cannot be overemphasized, especially as it is as simple an operation as drill point sharpening, and a very similar one. Frequent sharpening prolongs the life of the accurately sized reamer margins and lands, and guards against their abrading or wearing undersize and producing undersize holes.

Just how often a reamer should be sharpened or what tool life a reamer should have in minutes of use per grind or number of inches of holes reamed per grind must be determined by trial for each particular application.

In general, the higher the cutting speed the shorter will be the

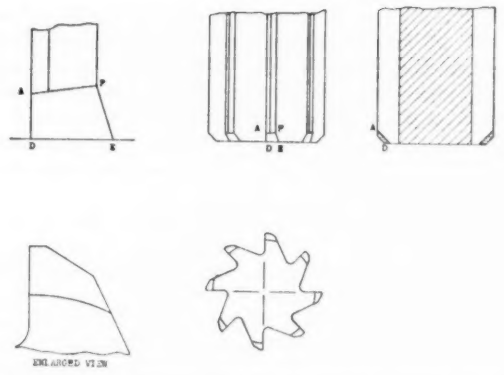

Fig. 26 Sharpening of Reamer-Point Cutting Edge

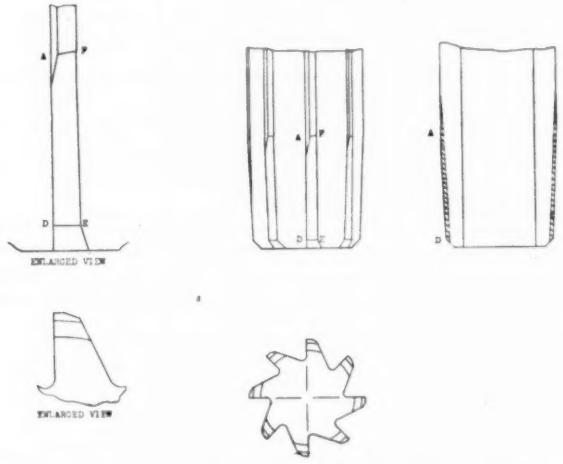

Fig. 28 Sharpening of Hand-Reamer Point Cutting Edge

tool life, but of course the high cutting speed has the advantage of high production, if the finish and accuracy of the holes produced are satisfactory.

On single-operation machines where it is a simple matter to take out a tool and resharpen it, low tool life and high production are desirable. On a multispindle automatic it might be uneconomical to change tools more than once a shift, and here slower speeds and longer tool life on a particular operation may be better.

In any case, the use of a dull tool is very poor economy. It is destructive of the reamer and productive of poor and unaccepta-

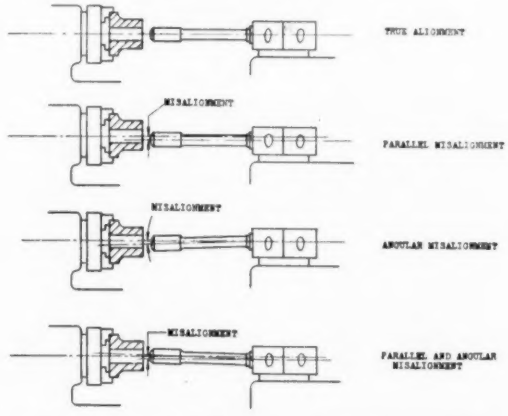

Fig. 29 Floating Toolholders and Alignment

ble work. Some methods for sharpening reamers are shown in Fig. 28.

Floating Toolholders

It should always be borne in mind that a reamer produces its best work when taking light cuts. If the holes are being finish-reamed in a machine, good work has been done by holding the reamer in a chuck, collet, or holder that will float smoothly without jumping. Some good work is done with holders that allow the reamer to float perpendicular to its axis as well as at an angle (1). This floating action is necessary because it is almost impossible to hold the reamer so that it is exactly concentric with the hole, and at the same time have the line of travel of the axis of the reamer coincide or line up with the axis of the hole. A reamer must align itself with the hole it is cutting for extreme precision. The lands or margins of the reamer must be a snug fit in the hole that the reamer is finishing. The axis of the rotating reamer must coincide within a very small amount with the axis of the tool.

This floating alignment and rigidity of cut are both difficult to attain but are necessary for good work.

Speeds, Feeds, and Lubricants

No definite rules can be given to cover the speeds and feeds that should be used in reaming. Several factors govern the correct feed and speed. The material to be reamed and the material of the reamer are perhaps the most important governing factors. The finish desired in the hole and whether hand feed or machine feed is used, govern the selection of the proper feed. The type of lubricant used, or whether the reamer is piloted or guided in any way, also influence the decision.

In general, reamers should be run at about one half to two thirds the speed of the corresponding drill. It is always best to start the reamer somewhat slower than this, and gradually increase the speed until the best condition is found. If the reamer is run at too slow a speed the production will suffer, while if run too fast, the wear on the reamer will dull it too soon. Somewhere between these two extremes is the proper speed which gives a high productivity with a long reamer life.

Feeds should be from 2 to 3 times the feed of the corresponding drill. The higher feed causes increased production and reduced tool wear. If too fine a feed is used, the reamer will be subjected to unnecessary wear. Too coarse a feed will produce feed marks in the hole. The desired finish must be balanced against the production per hour.

Feeds are governed by the size of the reamer and the material reamed. A general rule is first to try a feed of 0.002 to 0.004 in. per revolution for reamers smaller than $^1/_8$ in.; 0.004 to 0.008 for reamers $^1/_8$ to $^1/_4$ in.; 0.008 to 0.014 for reamers $^1/_4$ to $^1/_2$ in.; 0.014 to 0.030 for reamers $^1/_2$ to 1 in.; and 0.030 to 0.050 for reamers larger than 1 in. Alloy and hard steels should generally be reamed with the lighter feeds, while cast iron, brass, and aluminum are sometimes reamed with the heavier feeds. Suggested speeds for reamers are given in Table 1.

TABLE 1 SUGGESTED SPEEDS FOR HIGH-SPEED REAMERS

Material reamed	Speed, fpm
Aluminum and its alloys	130–200
Bakelite	70–100
Brass and bronze, ordinary	130–200
Bronze, high-tensile	50–70
Cast iron, soft	70–100
Cast iron, hard	50–70
Cast iron, chilled	20–30
Malleable iron	50–60
Magnesium and its alloys	170–300
Monel metal	20–30
Steel, machinery (0.2 to 0.3C)	50–70
Steel, annealed (0.4 to 0.5C)	40–50
Steel, tool (1.2C)	30–40
Steel, forgings	30–40
Steel, alloy	30–50
Steel, stainless, free-machining	40–50
Steel, stainless, hard	20–30

Lubricants

Lubricants have many functions, several of which are as follows:

1 To cool both the cutting edges of the tool and the work being machined. This can best be done by directing as large a volume of the coolant as possible on the cutting edges. On thin-walled work it often helps to allow a large volume of flow onto and around the piece.

2 To lubricate the chips; this aids in chip clearance.

3 To improve the finish of the work. The selection and proper application of the lubricant will materially influence the machined finish.

It is suggested that lubrication problems be referred to a reputable manufacturer of cutting oils. The following list of lubricants should be used as suggestions only:

1 Aluminum and its alloys: Soluble oil, kerosene, and lard-oil compounds, light nonviscous neutral oil, kerosene, and soluble-oil mixtures.

2 Brass: Dry, soluble oil, kerosene, and lard-oil compounds, light nonviscous neutral oil.

3 Copper: Soluble oil, winter-strained lard oil, oleic-acid compounds.

4 Cast iron: Dry or with a jet of compressed air for a cooling medium.

5 Malleable iron: Soluble oil, nonviscous neutral oil.

6 Monel metal: Soluble oil, sulphurized mineral oil.

7 Steel, ordinary: Soluble oil, sulphurized oil, high E.P. value mineral oil.

8 Steel, very hard and refractory: Soluble oil, sulphurized oil, turpentine.

9 Steel, stainless: Soluble oil, sulphurized mineral oil.

10 Wrought iron: Soluble oil, sulphurized oil, high animal-oil-content mineral-oil compound.

Regular Reamers and Basic Standard-Hole System of Tolerances

Varying degrees of accuracy result from the use of different tools employed in the drilling, boring, and reaming of holes. The cost of obtaining the accuracy required by some kinds of work would be prohibitive for others. Therefore the proper tools for producing holes in any class of work are those best adapted to produce the required accuracy from the standpoint of an over-all economy. By an over-all economy is meant the greatest number of suitably finished holes that can be produced for each dollar paid out for tools, labor, and machine expense.

Drilled holes are neither round, straight, nor of uniform diameter when compared with the accurate holes required by most industries, although they may be sufficiently accurate to meet the requirements of holes for rough bolts, rivets, and similar classes of work. When a close fit is required holes are usually finished by reaming. When holes of extreme accuracy are required it is necessary to use two reamers in order to obtain the desired results. For all such work as holes for pins, rods, or finished bolts, one reaming operation is sufficient, and even in many grades of machines the holes for journals are finished with a single machine-reaming operation. Before selecting a type of reamer for any class of work, it is advisable to study the cutting action of different reamers in order to select the one best adapted to each class.

In some shops the practice is to produce round, smooth, straight holes, as close to the standard or exact size as possible. All the tolerance or allowable error is above the basic or exact size. In other words, the hole must be slightly oversize, not

undersize. This enables holes to be produced in large numbers, which are sure to make the proper fits. Many shops insist that all holes in parts belonging to good work must be hand-reamed, and in such a manner that the work is subjected to no distortion due to holding or clamping. This is sometimes done by holding the hand reamer in a vise and passing the work over the reamer with a screwlike motion, the reamer scraping only a few thousandths out of the hole. Other shops insist that the holes be finished on the chucking machine, and in this case the chucking reamers must be accurate and the work not distorted by the chuck if good results are to be expected.

The standard reamer and the standard basic plug-and-ring gage have been the foundation of interchangeable manufacturing.

A standard basic 1-in. hole may be defined as one which will just receive a 1-in. plug gage which measures exactly 1 in. diam as measured on a measuring machine. The hole which receives this plug gage will also receive an accurately finished shaft of the same size (4).

In practical manufacturing the "go" gage is not usually exactly 1 in. diam but has a plus wear allowance and a plus manufacturing tolerance, which means that the basic hole in practical manufacturing is slightly large.

Commercial reamers are made slightly oversize because the hole made by the reamer must be large enough to receive the "go" working gage. Reamers as made commercially have also a slight plus wear allowance and a slight plus manufacturing tolerance (2). This assures that all holes carefully reamed as near to the exact size of the reamer as possible will all accept standard commercial "go" plug gages and will all receive finished shafts made to the correct sizes, with proper allowances between hole and shaft depending upon the class of fit wanted.

Many parts made by interchangeable mass-production methods depend upon the precision and uniformity of the reamer sizes to maintain hole sizes which will be basic, with a very small tolerance oversize. The holes are sure to be large enough and yet not too large to produce undesirable results.

American Standard for Allowances, Tolerances, and Gages for Metal Fits

Since 1926 the foregoing standard has been in use as a guide for the correct dimensions of holes made for interchangeable manufacturing.

This standard is based upon the same principles as the successful American Standard for Screw Threads ASA B1.1-1935. These are the same dimensions as published in Handbook H-28 Screw Thread Standards for Federal Services.

In both of these standards the minimum hole is taken as the basic or standard size. This means that the interference point or place where metal-to-metal fit occurs between hole and shaft will be at this basic dimension no matter what class of fit is specified. This is illustrated in Figs. 30 and 31.

The advantage of the standard-hole system is that it enables standard basic plug gages to be carried in stock and establishes definite minimum hole sizes, below which the holes cannot go, and maintains universal interchangeability.

If it is necessary to change tolerances or allowances on a given fit, this can be done in the basic-hole system without changing the "zero," "base," or "interference line," as the minimum hole is left constant, and the maximum hole, or minimum or maximum shaft sizes are changed. The standard plug gage always rejects any hole below basic size which might destroy interchangeability.

It is easier to produce plug gages, blocks, and measuring rods to high grades of precision, for use in measuring hole members than it is to produce gages for measuring shaft members. Hole members are best measured with fixed-size gages and also are best produced with fixed-size or solid reamers, or broaches. Shaft

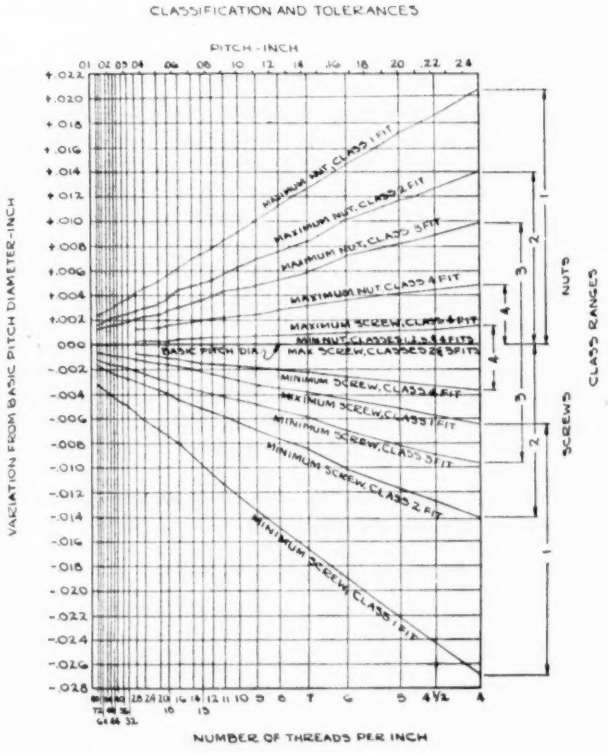

Fig. 30 Relation of Maximum and Minimum Pitch Diameters of Classes 1, 2, 3, and 4 Fits to Basic Pitch Diameters

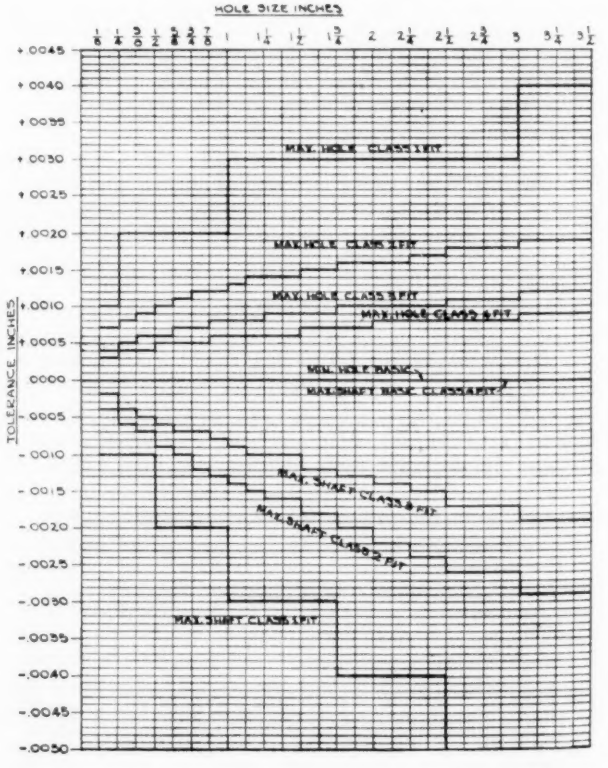

Fig. 31 Basic Minimum Hole for All Classes of Fits
(American Standards Association.)

members are more easily measured with adjustable gages and also more easily produced with adjustable tools such as lathe tools or grinding wheels. Changes in allowances or tolerances for various fits can thus be more readily made on the shaft member than on the hole member.

Fig. 32 shows how a standard commercial reamer would produce holes of any class of fit desired, if the reamer were carefully used so as to cut close to its exact size. Also, if properly sharpened and cared for, a long life of the reamer may be obtained before its lands are worn so undersize that the reamer will produce holes below the minimum size.

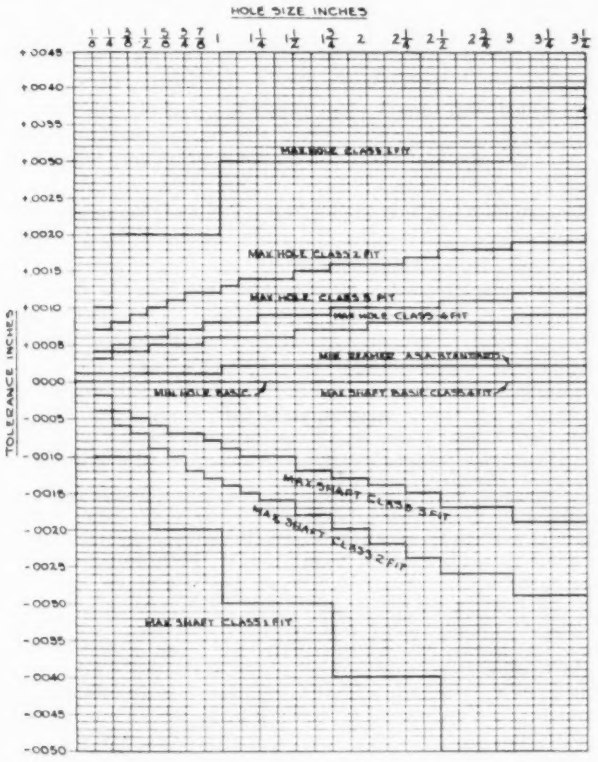

FIG. 32 STANDARD REAMER TO PRODUCE STANDARD HOLES OF ALL CLASSES OF FITS

Another advantage of the basic-hole system of fits is that it allows one standard-size reamer with definite tolerances to be carried in stock throughout industry for the convenience of the customer and user. These reamers will produce universal interchangeable work for any of the classes of fit.

The fact that the reamer is accurately sharpened to size is no guarantee that the hole made will be as accurate as the reamer. The accuracy of the hole depends upon many factors, such as hand- or machine-reaming, machinery and fixture in good condition or badly worn, the kind of material reamed, the kind of lubricant, and the skill and carefulness of the mechanic.

It was to take care of this great variety of working conditions that different tolerances were put on the various classes of standard holes in the report of Allowances and Tolerances of the American Standards Association, ASA B4a-1925.

It was realized by the committee which wrote this report that the one standard-size reamer will produce holes of varying tolerances depending upon the conditions of its use. Extreme accuracy and precision are usually expensive, and it is uneconomical to make a hole perfect when one not so good will serve the purpose just as well. Therefore the various classes of holes and fits were provided as a measure of economy. It was intended all along, however, that but one standard size of reamer would be necessary; careful use of this reamer would produce a Class 3 or 4 hole; rough, rapid, or worn machine use would produce a Class 1 hole.

It has sometimes been thought that large tolerances were put on rough holes to allow for wear on the reamer, whereas the large tolerances are really there to indicate that costly tooling and hand-finishing are not necessary when an inexpensive rapid job is sufficient for the purpose.

Long wear life of the reamer will be obtained by keeping the point sharp and the lands in good condition rather than by using an oversize reamer which will produce holes that are too large.

It has sometimes been suggested that the American Standard for Tolerances, Allowances, and Gages for Metal Fits should contain a basic-shaft standard as well as the present basic-hole standard. It is believed that it would be better not to do this because it would imply the standardizing and carrying in stock of a different minimum or basic plug gage for each class of fit for each nominal size of hole, Fig. 33. Also it would imply the use of a different-size reamer for each class of fit. These solid tools are difficult to produce and expensive to maintain. It is more eco-

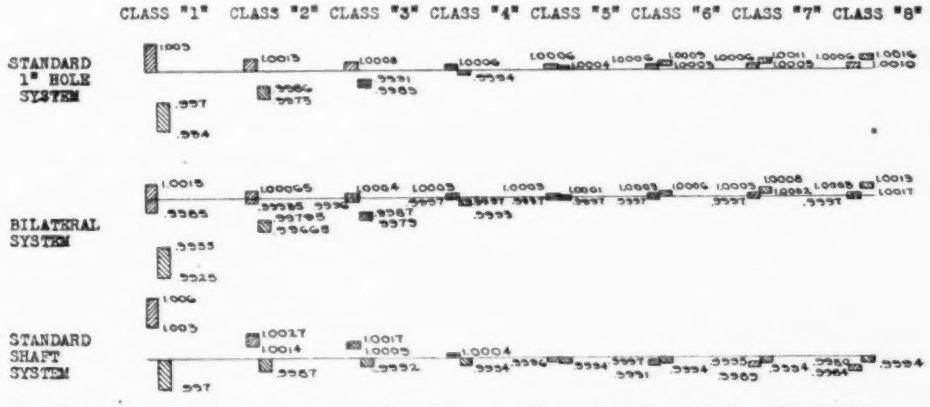

FIG. 33 STANDARD-HOLE SYSTEM USES ONE STANDARD BASIC-SIZE PLUG GAGE TO CHECK MINIMUM HOLE SIZE FOR ALL CLASSES OF FITS

(Sketch made to show that standard-hole system uses the one standard basic-size plug gage to check minimum hole size for all classes of fits. This means that interchangeability is positively maintained for any allowance between hole and shaft and any tolerance on shaft. The "zero line," "interference line," or "metal-to-metal fit contact line" is always at the basic dimension, always at the standard minimum hole. Standard stock reamers, if carefully used and maintained sharp, will produce these standard holes for a long period of reamer-wear life.)

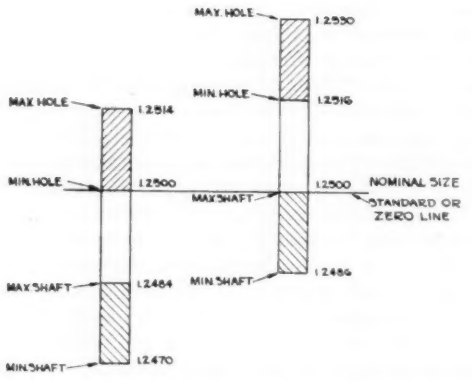

FIG. 34 HOLE SIZES FOR STANDARD-HOLE AND STANDARD-SHAFT SYSTEMS

nomical to obtain various classes of fit by maintaining standard holes and varying the shaft dimensions.

If for some particular reason it is found better to use the maximum size of the shaft as standard, as shown in Fig. 34, the size of hole becomes special and special drills and reamers must be obtained. Special tools are always more costly than the regular and also require longer waits for deliveries. As there is less use for a special tool, it lies in the toolroom for a longer time unused, and the overhead of manufacturing is increased.

For example, in Fig. 31 a standard shaft system of fit calls for 1.2500 as the maximum shaft size and 1.2516 as the minimum hole size. This can be considered the same as a basic-hole system of fits using a "special size" 1.2516 as the basic hole. This (as all standard shaft fits do) requires special-size reamers. From the tables of allowances and tolerances the maximum and minimum shafts and holes are easily found for special as well as standard sizes. In other words, the holes of the "standard-shaft" system, are nothing but "special" holes of the standard-hole system. The standard shaft system is really a special, nonstandard use of the standard-hole system.

In this connection E. C. Peck (1) states: "I see no need whatever for a basic shaft standard. The only example I have ever heard given is the one where two free fits are required on the ends of the shaft and a force or tight fit wanted in the center, and this has been done economically and satisfactorily for years by the 'basic-hole system.' All during World War I, I saw the drawings for millions of interchangeable parts, and I never saw any that were not made to the 'basic-hole' system."

Thus the publishing of special tables for the standard shaft system is unnecessary, as all the values for tolerances and allowances may be taken from the Standard Hole System of tables, merely by basing all the fits on the minimum-size hole.

CONCLUSIONS

A reamer is a cutting tool and like other cutting tools it must be provided with correct clearances, rakes, and other features of good tool design. Its cutting edges must be sharpened frequently to prolong the useful life of the tool and to produce accurately smoothly finished holes.

The standard reamer made with standard manufacturers' tolerance is one of the most important tools used by the interchangeable production manufacturers.

The standard reamer is an important feature of the standard-hole system of allowances and tolerances for metal fits and provides the most economical method of securing precision fits and universal interchangeability.

Utilization of Producer Gas in Industrial Furnaces

By D. B. HENDRYX,[1] PITTSBURGH, PA.

Producer gas is the cheapest artificial fuel per Btu that can be made from solid fuel. This paper discusses the economics, the equipment, and methods of generating producer gas for industrial uses.

MOST gas-producer projects look good on paper. The basic idea of a low-cost gaseous fuel, made from coal at a central point and distributed in pipes to the furnaces, is excellent and attractive.

Producer gas for industrial uses only is discussed in this paper, as contrasted to gas manufactured for public-service distribution. It is made from coal or coke, and the solid fuel is completely transformed into gas in the process. Producer gas is the cheapest artificial fuel per Btu that can be made from solid fuel.

Comparative Cost of Fuels

The economics of the fuel situation must be considered first. The cost of fuels can be compared on a Btu basis, but this must be the total cost of heat delivered to the furnace, including fuel and ash handling, power, steam, depreciation, etc. In most industrial districts, coal is the cheapest fuel, but for various reasons it frequently cannot be used in furnaces in its crude form, either on grates or as pulverized fuel. Such considerations as furnace temperature and atmosphere, reversing and regeneration, control, delayed combustion, radiant flame, localized heating, freedom from ash, handling of coal and ashes, and many others may rule out the use of coal.

Under such conditions, if natural gas or fuel oil is available at a reasonable price, or if a by-product fuel such as coke-oven or blast-furnace gas can be used, one would hesitate before building an expensive gas-producer plant, with its attendant dirt, heat, and operating difficulties. If the fuel requirements do not amount to more than 1500 lb of coal per hr, a gas producer would seldom be justified; but if coal is cheap compared to other fuels, and if a gaseous fuel is needed, the use of producer gas will be worth investigation.

Table 1 may be used for a quick comparison between the costs of several fuels. It shows the price that can be paid for fuel oil or natural gas as compared to cost of coal delivered to the gas-producer plant, taking into account the cost of making the producer gas, including depreciation, and the cost of heating and atomizing the oil. The cost of gasifying 1 ton of coal or coke was estimated at $1.75; but this figure might be higher or lower, depending upon the size of the plant, wage rates, number of men required for operation, and similar factors (see Table 2). This table does not agree at all with the comparisons made in the advertising matter of many manufacturers, for the reason that they use a much lower charge for producer operation.

The choice of fuels cannot always be made strictly on a cost basis. The supply of natural gas or oil may be restricted or cut off suddenly in the coldest winter weather, while coal will probably always be available, in spite of numerous recent threats against the life of one of our greatest industries. The relative prices of fuels do not remain constant. Since 1939, the price of natural gas has stayed the same in most districts, while coal has advanced 30 to 45 per cent, and fuel oil 50 to 100 per cent. Any of these conditions may make the construction of a gas-producer plant imperative.

As can be seen from the cost of gasifying coal shown in Table 2, the item of depreciation is a very appreciable part of the cost. But once the money for a producer plant has been spent, due to emergency conditions or for other reasons, the matter of depreciation can be neglected, and natural gas or oil would have to be about 10 per cent cheaper than indicated in Table 1, in order to compete with producer gas.

TABLE 1 COMPARISON OF FUEL COSTS

Hot raw producer gas			Fuel oil	Natural gas
Price of coal per ton delv'd. 27,000,000 Btu	Cost of producer gas per ton coal 19,200,000 Btu	Cost of producer gas per 1,000,000 Btu	Equivalent price per gal, or 145,000 Btu	Equivalent price per 1000 cu ft or 1,000,000 Btu
$2.00	$3.75	$0.195	$0.0253	$0.195
2.50	4.25	0.221	0.0291	0.221
3.00	4.75	0.247	0.0328	0.247
3.50	5.25	0.273	0.0366	0.273
4.00	5.75	0.299	0.0404	0.299
4.50	6.25	0.325	0.0442	0.325
5.00	6.75	0.351	0.0480	0.351
5.50	7.25	0.377	0.0517	0.377
6.00	7.75	0.403	0.0555	0.403
6.50	8.25	0.430	0.0594	0.430
7.00	8.75	0.456	0.0632	0.456

Cost of gasifying coal per net ton is assumed to be $1.75 (see Table 2).

Cost of producer gas per million Btu is based on:	Per lb coal
60 cu ft of gas at 60 F per lb coal, and 140 Btu per cu ft	8400 Btu
Sensible heat with gas delivered to furnace at 700 F, 60 cu ft of gas at 11 Btu per cu ft	660 Btu
Tar, 60 cu ft of gas at 0.0006 lb tar per cu ft and 15,000 Btu per lb tar	540 Btu
Total	9600

Heat in producer gas at 700 F per ton coal, 2000 × 9600 or 19,200,000 Btu.

Price of fuel oil allows for charge of $0.003 per gal for steam, power, and depreciation but no charge for depreciation. If depreciation charge on gas-producer plant is neglected, deduct $0.0046 per gal from price of oil shown.

Price of natural gas covers fuel cost only. If depreciation charge on gas-producer plant is neglected, deduct $0.032 per 1000 cu ft from price of gas shown.

Selection of Producer-Gas Fuel

If the foregoing considerations seem to warrant the construction of a producer plant, the next step is to decide what fuel will be used to make the gas. There are two distinct types of producer gas—that made from bituminous coal, and that made from anthracite or coke. Since bituminous coal in most parts of the country is cheaper than anthracite or coke, it follows that gas manufactured from it will be the cheapest gas that can be made. Cost alone, however, may not be the deciding factor.

If the heat requirements of the furnaces are large, if the gas can be burned in the furnaces through a few ports instead of a

TABLE 2 GAS-PRODUCER OPERATING COSTS

Fuel:	Small plant, 1 8-ft producer Per week	Per ton	Larger plant, 2 10-ft producers Per week	Per ton
Tons of coal gasified	120	...	400	...
Tons of coal used to generate steam for blowing producers	8	...	25	...
Operating cost:				
Labor				
Gas producer and boiler operator 1 man 168 hr at $.80	$134.40	...	$134.40	...
Dust removal from dust legs				
Small plant 16 hr at $.65	10.40	...	...	...
Larger plant 32 hr at $.65	...	...	20.80	...
Coal and ash handling at $.10 per ton coal	12.00	...	40.00	...
Burning out flues, once every 6 weeks, averaging 1 man per week 8 hrs at $.65	5.20	...	5.20	...
Repair labor				
Small plant, 1 man 4 hr at $.90	3.60	...	...	...
Larger plant, 1 man 8 hr at $.90	...	...	7.20	...
Total labor	$165.60	$1.28	$207.60	$0.52
Power				
Small plant 1100 kwhr at $.012	13.20	0.11	...	...
Larger plant 2400 kwhr at $.012	...	...	28.80	.07
Repair materials, including coal machinery, producers, auxiliaries, boilers, painting, etc., estimated average during life of plant	30.00	0.25	60.00	0.15
Boiler feedwater and producer cooling water, based on recirculation of cooling water, 190 gal per ton coal at $.10 per M gal	2.28	0.02	7.60	0.02
Oil, grease, waste, supplies	3.00	0.03	6.00	0.02
Coal for steam, at $3.50 per ton	28.00	0.23	87.50	0.22
Total cost of gasifying coal, no depreciation charge		$1.92		$1.00
Depreciation, on basis of 10 per cent per year on investment of the following:				
Small plant, and gas mains $60,000	115.00	0.96	...	...
Larger plant, and gas mains 100,000	...	...	192.00	.48
Total, including depreciation		$2.88		$1.48

large number of individual burners, and if the producers can be located near the furnaces, the selection would favor hot raw gas made from bituminous coal. If less fuel is needed, or if gas must be distributed to a number of furnaces or individual burners located at some distance from the producer plant, the greater expense of using anthracite or coke might be warranted. Wherever practical, both kinds of gases are used in their hot raw state.

It seems to be a current belief that a "gas coal," with a volatile content above 35 per cent, is the best fuel for bituminous producers. It does make a rich gas, and it is usually a free-burning coal which does not cake badly in the producer. On the other hand, the gas may contain more vaporized tar which will be objectionable unless the gas can be kept hot until it reaches the furnaces. The ideal producer fuel would be a 2 or 3-in. lump coal, with fines below $^3/_4$ in. screened out, having an ash-fusion point above 2500 F, and free-burning characteristics which prevent the top of the fuel bed from becoming a sticky mass and caking. In actual practice, mine-run or slack coals are often used at some reduction in capacity, although more dust is carried over into the mains when using fine coal. A gummy condition at the top of the fuel bed can be overcome by keeping it at a higher temperature. The amount of ash in the coal does not make as much difference as its fusion point does, and even coal with low-fusion ash can be used by applying more steam in the blast.

Mine-run or slack bituminous coal can be used in producers because the coking action at the top of the fuel bed will provide passages for the gas. When anthracite or coke fuel is used, the only openings for the flow of gas through the upper part of the charge will be the spaces between the particles of fuel. Therefore most of the dust finer than $^1/_4$ or $^3/_8$ in. must be screened out. The term "coke breeze" can cover a multitude of sins and, before deciding upon this as a source of gas, it must be positively ascertained that the quoted price covers a fuel sufficiently free of fines to make it usable in a producer. Much of the finer coke is now used at the plants where it is made, in producers for underfiring the by-product ovens, and in steam boilers.

The Gas-Producer Plant

To take its rightful place among other fuels, producer gas must be made at the lowest possible cost, with the minimum amount of labor and operating difficulties. The gas producer is an important item, but it is only one part of the gas-making plant. The best producer cannot make gas without the proper operation and control, and it cannot deliver gas to the furnaces without a proper distribution system. There are few places where proper planning and anticipation of difficulties will have a greater effect on the success of the project than in the design of a producer-gas system. This is particularly true when using bituminous coal.

It is possible to lay out a plant so that one man per shift can take care of either one or two producers, a boiler, and the handling of coal and ashes. He might have to have occasional help in cleaning out dust legs, or in dumping a car of coal, but on the other hand, if the producer is located close enough to the furnace, he may also serve as the furnace operator.

Coal can be discharged from trucks or cars through a hopper, feeder, and bucket elevator to the coalbins. A double-roll crusher should be provided so that mine-run coal can be used even if it is planned to use sized coal. Bins above the producers can be large enough to carry a 2-day supply of coal, which is the preferable arrangement, or the feed bins can be smaller with an auxiliary storage silo. The equipment should be designed so that no hand labor is necessary except in occasional emergencies when coal must be reclaimed from an outdoor stock pile. Segregation of coarse and fine coal in the bins must be minimized. It should never be necessary for an operator to enter a coal-feed bin, as there is always a slight danger that gas may leak up into the bin and the man might be overcome.

The operating floor of a producer plant is really the second floor of the building, level with the top of the producers. All control instruments, motor starters, steam gages, water columns, valves, and air blowers for the producers should be located on this operating floor. The boiler stack can sometimes be combined with the burnout stack for the gas lines. Ashes from producers and boilers should be discharged to a skip hoist or conveyer which delivers them to an overhead ash bin so that no hand labor is necessary.

The lower floor of the building should be enclosed, as the producers do not supply enough heat to prevent freezing around the wet ashes, floors, and conveyers. Floors and pits should be drained so that a hose can be used for cleaning. The operating floor must be well ventilated and should have large doors which can be left open in summer and closed in cold weather. Louvers are usually used in the side walls just underneath the coalbins so that no gas can accumulate in the building. Oxygen apparatus should be available in case a man is overcome with gas, although this would never happen under normal operating conditions. Water-cooled poker tips have to be built up by welding every few weeks, and chain-hoist equipment must be provided for handling them.

Approximately 100 gal of water per ton of coal must be converted into steam for the producer blast, in addition to any heating or power load on the boilers, and 200 gal per hr is needed for cooling the poker, top, and coal feeder of each producer, regardless of capacity. If water is scarce or expensive, the cooling water can be recirculated to a tank on the upper floor of the building. Water-cooled valves in the gas mains have been experimented with but have not proved very dependable.

Bituminous-Type Gas Producer

Gas has been made for years with little improvement in the producing and control equipment, auxiliaries, and operating procedure. Stationary and revolving hand-poked producers gave way to mechanical types, but even today possibly 75 per cent of the producer systems in service have gas-making equipment which requires sledging of clinkers and much hard labor, delivering a gas which varies in heat value and temperature. The old distribution mains are even worse, requiring much labor and weekly burnouts. These things have given producer gas made from bituminous coal a poor reputation in industry, even though the facilities are now available for dependable operation.

The modern bituminous gas producer is a revolving vertical steel cylinder lined with refractory brick, with a stationary water-cooled top through which coal is fed, gas is removed, and pokers are operated. The bottom is sealed by a revolving water-sealed ash pan, which encloses the air-blast hood and plows for continuously removing the ashes. The air blast is usually furnished by a steam-driven turboblower, at a pressure of about 10 in. of water, and gas leaves the producer at a temperature of 1250 to 1500 F, and a pressure up to 1 in. of water.

The producer manufacturers have done a fine job in developing machines which will make good gas with almost no interruptions when operated in a proper manner. They claim, however, with a great deal of justification, that it is almost impossible to get the users to spend the money for the correct flue system and control equipment needed to make the operation clean, dependable, and free from hard labor. The manufacturers have developed a simple rugged machine requiring almost no repairs. They have designed a center blast hood to give proper distribution of air without the use of tuyères in the outer walls. They have removed the arms which formerly obstructed the flow of ashes, and have provided for continuous ash removal, both of which help to maintain an even fuel bed and to prevent the loss of carbon in the ash. They have equalized the flow of air through the bed of hot coke by providing a means for stopping the rotation of the ash pan automatically for a few seconds at a time, while the upper part of the producer continues to revolve. This causes a grinding action in the fuel bed which reduces blowholes and unequal flow of gas. Coal feeders now give excellent distribution and control of feeding rate without leakage of gas. The motion of the water-cooled pokers has been changed to give more frequent and thorough agitation of the upper part of the fuel bed without plastering the hot sticky ash against the walls of the producer. Both the poking and grinding actions are necessary to break up the caking of the coal in the fuel bed, and to prevent channels and blowholes which cause hot spots in the fuel bed and to permit the gas to burn to CO_2 in the producer.

Auxiliary and Control Equipment

The operation of a producer must be kept constant, in the face of continually changing demands for gas, and many variations in fuel and fire bed. This is almost impossible under strictly manual operation.

Gas is made by blowing a mixture of steam and air through a deep bed of incandescent carbon. If air alone were used, the fuel bed would become very hot, resulting in clinker trouble in the producer and a very lean gas.

The fire bed of the producer contains four zones as follows:

1 The ash bed at the bottom, which protects the blast hood from the heat and aids in distributing air from the hood to the fuel bed.

2 The oxidation zone, where the only reaction is the almost complete combustion of carbon to CO_2, with the liberation of 14,550 Btu per lb of carbon. This zone is only about 6 in. thick and is the hottest zone in the producer.

3 The reduction zone above the oxidation zone, where the CO_2 is reduced to CO by the hot carbon, with a corresponding endothermic reaction of 5850 Btu per pound of carbon, and the steam reacts with the carbon to form hydrogen, CO and CO_2, further reducing the temperature of the fuel bed.

4 The distillation zone at the top where the volatile matter in the coal is distilled off and moisture is evaporated.

The fuel requires 2 hr or more to pass through these reactions, but the air, steam, and gas are in contact with the fuel for little more than 1 sec in a bituminous producer, and for possibly 3 sec in the coke type. It is therefore exceedingly important that the various zones are held constant in thickness, "porosity," and temperature, and it is evident that this can only be done with equipment that has been carefully developed for the purpose, with controls made as automatic as possible, and with intelligent operation. When the load varies, these factors become increasingly important. Variations in fineness or caking qualities of the coal, and in the fusion point of the ash, affect the operation.

Air must be delivered to the blast hood in a manner which can be automatically controlled by the demand for gas, in spite of variations in the resistance of the fuel bed. Older producers usually were equipped with steam-jet blowers, but the need for fan-type blowers is now almost universally recognized, and many old producers have been equipped with modern blast equipment. When used on bituminous producers, the blowers are directly connected to small variable-speed steam turbines, and the exhaust steam is connected into the air blast. On coke and anthracite producers, the steam pressure from the water-jacketed shell is not high enough to operate a turbine, and the blower is therefore driven by electric power.

In most plants, particularly where the gas demand is not constant, the volume of the air blast is controlled by a pressure regulator connected to the gas main. The pressure in the main is usually between 0.2 and 1 in. of water. If the furnace operator turns on more gas, the pressure in the main immediately drops and the regulator feeds more steam to the turbine. The small pipe between the gas main and the regulator is kept free from tar and dust by blowing a very small amount of air through it into the main. Variations in resistance of the fuel bed will not affect the accuracy of the control, and the operator can adjust his regulator to allow for the pressure needed in the gas mains. When used with a motor-driven blower, the regulator adjusts a damper in the air line.

The volume of gas leaving a producer cannot be measured, due to the tar and dust, but the amount of air blown to the producer can be indicated and this is a measure of the gas delivered. All producers should be equipped with an orifice plate in the air-blast line, with an indicating or recording differential gage on the instrument panel to show the operator how much air is being fed to each producer. The operator will then know when the furnaces are using more gas, and he can regulate his coal feed and make other adjustments accordingly. He will also know whether each producer is carrying its share of the load. This indication of air volume is used on very few producers, but all operators who have tried it report that it is one of the most valuable instruments in the plant.

Where a producer plant is operating in connection with a single furnace, and both the producer and the furnace are under the control of one man, automatic regulation can be obtained by means of volume instead of pressure. The furnace operator will adjust the volume-control instrument to give enough gas for the furnace, and this instrument will then automatically control the speed of the turbine so that a constant volume of air is fed to the producer, regardless of the resistance against which this air must be delivered. This method has the advantage that the producer

will deliver the required amount of gas, regardless of obstructions in the line between the producer and the furnace.

The amount of steam in the air blast is one of the most important factors in producer operation. In the reduction zone in the producer, the CO_2 is reduced to CO by contact with hot carbon, with a consequent absorption of heat amounting to 5850 Btu per lb of carbon. The hotter the fuel bed, the more rapid and complete will be this reaction, resulting in less CO_2 and more CO in the gas produced. The high temperature also results in more active action between the carbon and the steam. However, the temperature which can be maintained is limited by the fusing temperature of the ash, so enough steam must be introduced to lower the temperature of the reduction zone to a safe point, by combining with the hot carbon to form H_2, CO, and some CO_2.

When the old steam-jet blowers were used, the proportion of steam to air could not be accurately controlled and too much steam was usually put into the producers. When a turbine- or motor-driven blower is used, the amount of steam is adjusted by observing the temperature of the mixture of air and steam. This is usually at some point between 130 and 150 F. When the correct figure has once been determined for a certain coal, it is not difficult for a producer operator to maintain this so-called "saturation temperature." The exhaust steam from the turbine is discharged into the air blast, and some live steam is usually added. When more air is needed the turbine is speeded up, automatically adding more steam to the blast. Automatic temperature control of the blast is often furnished but is not absolutely needed when turbines are used. It is necessary when blowers are motor-driven.

Fig. 1 shows the blast temperatures corresponding to various inlet-air temperatures and pounds of steam per pound of coal. Fig. 2 shows results of tests reported by W. P. Chandler of Carnegie-Illinois Steel Corporation indicating the increase in the quality of the gas when the proportion of steam in the blast was decreased. In practice, however, it is usually dollar efficiency rather than thermal efficiency which counts, and as coals with high ash-fusion temperatures are rarely available, we choose more steam and a poorer gas rather than a job of sledging clinkers out of the producers.

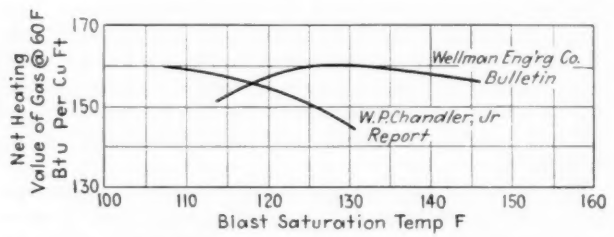

FIG. 1 RELATION BETWEEN STEAM USED PER POUND OF COAL AND BLAST SATURATION TEMPERATURE

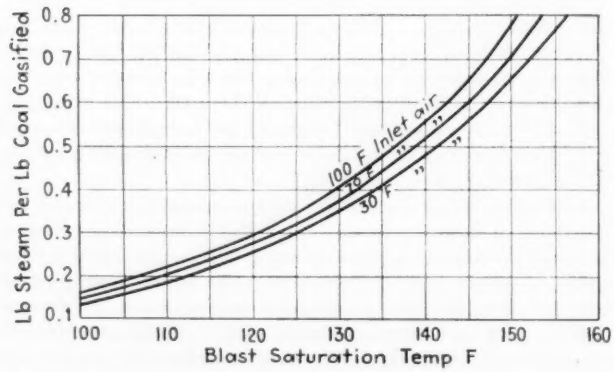

FIG. 2 RELATION BETWEEN HEATING VALUE OF GAS AND BLAST SATURATION TEMPERATURE

Producer gas is a very "lean" gas, due to the high percentage of inert nitrogen introduced with the oxygen in the blast. The use of steam as a reducing agent to lower the temperature of the fuel bed and prevent the formation of clinkers, actually enriches the gas because it adds hydrogen without increasing the amount of inert gases. However, fuel must be burned to generate the steam, and this fuel amounts to about 5 per cent of the coal gasified. Therefore, CO_2 is sometimes used in the blast, to lower the fuel-bed temperature, but this is only profitable where the CO_2 content of the gases is very high, as in the exhaust gases from lime kilns. Proper control of the percentage of CO_2 added to the blast is quite difficult.

High fuel-bed temperatures do not necessarily mean high gas temperatures leaving the producers. Gas temperatures usually run between 1250 and 1500 F, but may be as high as 1800 to 1900 F when used in kilns for burning limestone, where producers are usually located very close to the kilns.

All automatic producers have an adjustable mechanical coal feed. Practically all of these are adjusted by hand. There is a recording thermocouple in the gas stream leaving the producer, and the operator adjusts the coal feed to maintain a reasonably constant gas temperature. If more air is blown through the producer, the top of the fuel bed soon increases in temperature, and the operator feeds more coal to prevent the gas from getting too hot. If the operator is provided with an orifice meter on the air blast, he knows when more gas is being generated without waiting for the temperature to increase, and he can regulate his coal feed accordingly. Automatic regulation of coal feed is now being applied, using the temperature of the gas leaving the producer to regulate the rate of feed. This is very successful, as it re-

TABLE 3 PRODUCER-GAS DATA

Fuel used in producer	Bituminous coal	Anthracite coal	Coke breeze
Fuel gasified, lb per sq ft per hr	30–70	15–30	15–30
Volume of gas at 60 F, cu ft per lb coal	60	65	68
Temperature of gas leaving producer, deg F	1250–1500	550–650	550–650
Lower or net heating values, Btu:			
Coal or coke used, per lb	13500	12500	12000
Steam 0.4 lb per lb fuel (Anthracite and coke producers make own steam)	450	(450)	(450)
Heat input to producer, per lb fuel, Btu	13950	12500	12000
Raw producer gas, per cu ft at 60 F	140	130	120
Sensible heat of gas leaving producer per cu ft	23	10	10
Tar in hot gas leaving producer, 0.0006 lb tar per cu ft gas at 15,000 Btu	9	..	..
Heat output from producer, per cu ft, Btu	172	140	130
Heat output from producer, per lb fuel, Btu	10320	9100	8840
Efficiency of producer, not including losses in boiler or gas lines	73.9	72.7	73.6
Typical analysis of gas, per cent:			
CO	22.5	24.8	26.0
H_2	12.5	15.0	11.0
Hydrocarbons	3.1	0.9	0.7
CO_2	7.4	9.0	7.6
N_2	54.5	50.3	54.7
	100.0	100.0	100.0
Air for perfect combustion, cu ft per cu ft gas	1.17	1.04	0.95
Additional air for combustion of 0.0006 lb tar per cu ft of bituminous gas	0.11	...	...
	1.28		
Products of perfect combustion, cu ft per cu ft gas	2.14	1.83	1.76
Weight of producer gas, lb per cu ft	0.069	0.066	0.069
Weight of air for perfect combustion, lb per cu ft of gas	0.098	0.080	0.073
Weight of products of perfect combustion lb per cu ft of producer gas	0.167	0.146	0.142
Theoretical flame temperature, based upon gas at 60 F, deg F	3170	3150	3000

duces the work of the operator and improves the quality of the gas.

Table 3 gives general information on the different types of producer gas and is useful in the design of distribution systems, burners, and furnaces, and in the comparison of this gas with other fuel.

Distribution System for Bituminous Producer Gas

Raw gas made from bituminous coal is a hot dirty fuel to handle. It contains dust from the fine coal falling into the producer and soot from the cracking of the hydrocarbons. When using slack coal, the dust carried over into the mains may amount to 5 per cent of the weight of the coal. This will fill up a round pipe so rapidly that the flue would have to be cleaned or "burned out" once a week, shutting down the furnaces and producers during the operation.

This gas also contains tar vapors which will condense as the gas cools, gumming up valves and burners, seeping out of cleanout doors, and mixing with the dust to form a cokelike substance. It has a temperature of 1250 to 1500 F, when it leaves the producer, and therefore has nearly twice the volume of gas made from coke or anthracite and 18 times the volume of natural gas for the same Btu value. Consequently, mains and valves are large and costly. As a result, bituminous gas has been most frequently applied to large furnaces located near the producer plant and more rarely used where the gas must be distributed for greater distances and to a large number of burners.

Having outlined the causes of the difficulties encountered in the distribution of hot raw bituminous gas, the next step is to see what can be done to overcome them. In the case of old gas mains already in use, only a little improvement is possible without extensive alterations. Where a new distribution system is to be installed, it is entirely possible to increase the length of time between "burnouts" to 2 months, or even to a year, at the same time conserving the sensible heat of the gas and smoothing out the furnace operation.

Gas mains can be built without any horizontal bottom surfaces on which dust can accumulate. They can be constructed with a saw-tooth bottom, with provision for removing the dust at all of the low points. Dust will sometimes accumulate on the slopes but small openings can be provided for steam lances in the top of the pipe, so that the dust can be blown down into the pockets at the bottom. However, this is a hot and dirty job, and a better scheme is to install soot blowers at every point in the mains where dust can settle, with legs or pockets having double seals through which the dust can be removed while gas is flowing. These blowers can be standard boiler soot blowers, which will withstand the gas temperatures quite well, but are not entirely resistant to the higher burnout temperatures. On the other hand, if burnouts can be greatly reduced or eliminated by the soot blowers, the soot blowers will not be damaged by the burnouts.

The removal of the dust from the pockets is also a disagreeable job, particularly if it must be handled in wheelbarrows. This dust could be sluiced into a stream of water, but this is rarely available. A steam-ejector vacuum system is being used to remove the dust and deliver it in a dampened condition into the ash bin. This dust contains about 75 per cent carbon and 25 per cent ash and is "red hot" when removed from the mains.

To prevent trouble with the tar, the gas temperature must be kept high enough so that the vapors will not condense, or else the gas must be cooled and washed. Insulation of new gas lines is now relatively simple since insulating refractory brick can be used for the complete lining of the mains, and gas can be delivered 100 ft from the producer plant with a temperature loss of not more than 300 deg F, including dust catchers and mains. Washing of bituminous gas has been tried on numerous installations in the past, and there is at least one successful plant in operation today. However, it involves the use of expensive equipment and the loss of sensible heat amounting to 6 to 12 per cent of the total Btu content of the hot gas as well as the loss of the tar. Either the tar must be wasted, or costly recovery and handling equipment must be installed.

Producers and Distribution Systems for Anthracite and Coke Gas

Gas made from coke or anthracite, while higher in first cost, is cooler, cleaner, and easier to handle, and may be washed if necessary with less difficulty and loss of heat. It is comparatively free from dust as it leaves the producer because anthracite producers gasify only one half as much fuel as do the bituminous type, and because the fuel used contains less fines and almost no hydrocarbons, and flows directly from distributing pipes onto the top of the fuel bed instead of dropping through a stream of moving gases. It is entirely free from tar and has a temperature of about 600 F, making it possible to deliver it through steel pipe lines of smaller size, with insulation on the outside of the pipe. No time need be lost in burning out the mains. Higher pressures and velocities can be used and a booster blower can even be connected to increase the pressure of the gas after it leaves the producers. In the past this gas has usually been washed, but in recent installations the velocity has been increased by the use of bowers to the point where dust will not settle out, and gases are distributed in the hot raw condition. Standard valves, fittings, and burners can be used, and the burners require much less attention from the furnace operators.

The producers used for coke and anthracite are quite different from bituminous producers, mainly because these fuels do not contain tar and hydrocarbons. Therefore the fuel bed does not cake to any great extent and no mechanical poker is needed. The bed can be 5 ft deep instead of about 2.5 ft, resulting in cooler gas. The construction is very much simpler than in the bituminous machine, since the shell is stationary, while only the bottom revolves. The blast hood is large and is usually eccentric in shape, so that it grinds the ashes and agitates the fuel bed as it revolves. In some producers it is attached to the revolving ash pan in which case a deep water seal is used and the blast pressure is limited to approximately 20 in. of water. In others, the revolving blast hood supports the fuel bed, and ashes are discharged through the hood into a stationary hopper below. These producers can be operated with a blast pressure of several pounds, since no water seal is used. Coal feeders are either stationary or revolving. The producer shell is water-jacketed instead of being lined with brick and generates enough steam to mix with the air blast.

Refractories

The refractory-brick lining of a bituminous producer is subjected to continuous abrasion from the passage of fuel and ashes, and to occasional destruction from the formation of clinkers and the necessity of breaking them loose from the walls with heavy bars. The temperature of the lining usually is not excessive, but hot spots sometimes develop, due to channeling of the fires. A dense, strong, high-heat-duty brick is required to resist these conditions. The lining can be either $4\frac{1}{2}$ in. or 6 in. thick, backed up with $2\frac{1}{2}$ in. of strong insulation next to the shell. A high-temperature cold-setting refractory mortar should be used, and all joints should be kept as tight as possible. When using coal having a very low ash-fusion temperature a few courses of silicon-carbide brick are sometimes used at the clinker line.

Mains for carrying hot raw bituminous gas do not exceed 1400 F except during burnouts. Steam jets and lances must be used to stir up the dust. Formerly, mains were lined with $4\frac{1}{2}$ in. of

fireclay brick, sometimes surrounded with insulation. The development of lightweight refractory brick which will withstand these conditions has greatly simplified the construction of these mains. The entire 9-in. lining can be built of 2600-deg insulating refractories, or lower-temperature insulating brick can be used in the outer $4^1/_2$-in. portion. This brick is somewhat lower in cost and higher in insulating value. Flue linings usually involve a great deal of complicated brickwork and the use of insulating refractories which can be easily cut, sawed, ground, or rubbed into any desired shape greatly reduces the bricklaying labor cost. A cold-setting mortar should be used, with expansion joints about every 20 ft. No fireclay brick need be used except in the connection from the producer to the dust catcher, and for construction of the valve seats. Cast-iron seats are now seldom used.

Furnaces and Burners

Producer gas is not only a cheap fuel, but is admirably adapted to many heating operations, particularly where a soft luminous flame is desired. As can be seen from Table 3, it has a theoretical flame temperature of about 3100 F, as compared to 3700 F, for natural gas and 3800 F for oil. This makes it especially suited to steel reheating, where the entire furnace must be filled with a hazy slightly reducing flame and "hot spots" must be avoided. The same characteristics, at slightly higher temperatures, make it suitable for burning refractory brick. A glass tank can be completely filled with a luminous flame having the high radiation characteristics so desirable for heating this transparent molten bath. With producer gas, it is easy to get delayed combustion, even when using highly preheated air, an operation that is very difficult when using natural gas or oil.

Bituminous producer gas is used for firing vertical-shaft lime kilns and also rotary kilns for lime and other products where freedom from ash deposits is necessary. Freedom from ash makes it suitable for firing many ceramic products, where both bituminous and coke or anthracite gas are being used.

In many of these furnaces, the fuel requirements are large, and the gas and air are merely admitted through ports in the furnace walls. The air is usually preheated by regeneration or other means, and this preheating becomes very necessary when high temperatures must be reached. It is sometimes claimed that there is no object in keeping the gas hot between the producers and the furnaces, as this may reduce the furnace efficiency because the exhaust gases will not be cooled in the gas regenerators. Intermittent steam jets can be used if necessary in order to keep soot from building up on the reversing valves and burner ports.

Where a number of smaller burners have to be used, bituminous gas is usually fired through a cast-iron burner with a fireclay burner block. The gas flow is controlled by a slide or inverted-cone valve, which has to be opened and closed about once an hour to keep it clean. The air, preferably preheated, often acts as an injector to draw the gas into the burner block. A very short oxidizing flame can be obtained by using enough air and moving the air pipe away from the block. A reducing or delayed combustion flame is produced by using less air and moving the pipe closer to the throat of the burner. These burners must be thoroughly cleaned about once every 24 hr and large cleanout doors must be provided. Since the gas going to each burner cannot be measured, it is advisable to have an orifice and an indicating differential gage in each air line. The air can then be set for any desired quantity, and the gas adjusted to give the required temperature and flame quality.

Producer gas made from anthracite or coke, either washed or in the hot raw condition, can be burned in standard gas burners large enough to allow for the low Btu value of the gas, or it can be regenerated and burned in ports. It is particularly suited to plants where the burners are widely scattered, as in smaller heating furnaces, and in the underfiring of coke ovens.

Everything considered, producer gas made from bituminous coal, anthracite, or coke can be a very desirable fuel if proper consideration is given to the economic, engineering, and operating factors which so materially affect the success of the project.

Pulsation and Its Effect on Flowmeters[1]

By E. J. LINDAHL,[2] COLUMBUS, OHIO

Flowmeter readings are apt to be seriously in error if the fluid flowing through the meter is subjected to rapid recurring variations in velocity or pressure or both. Flow having these variations is thought of as being "pulsating flow." Much thought has been given to pulsating flow or pulsation and much has been written about it. It is the intention of this paper to bring together some of the results which have been published.

Causes and Effects of Pulsation

STEADY flow of a medium exists when the mass rate of flow through a device is constant, when the velocity, pressure, and temperature at any point remain constant, and when thermal equilibrium has been reached by the device through which the medium is flowing. In the case of unsteady flow, one or more of the conditions mentioned does not exist. Pulsating flow can exist when rapid velocity or pressure variations occur and is seen to be a special case of unsteady flow.

The causes of pulsation are numerous. One of the chief sources of pulsation in gas pipe lines is the reciprocating compressor. Another source is water surging back and forth in a low portion of a pipe line. Air enters the intake manifold of an internal-combustion engine having pulsation due to the pumping action of the engine pistons. Clattering check valves and undamped diaphragm regulators in a line are also offenders. Steam flowing to a reciprocating engine has pulsating flow. Any device that causes intermittent flows or pressures is a source of pulsation, since pulsations take place as a result of recurring rapid variations in either velocity or pressure.

One device which is greatly affected by pulsation and which concerns engineers is the inferential meter. While it is true that there are some pulsations which have no effect on the meter reading, there are other pulsations which render the meter reading invalid. Since the measurements which involve large quantities are made with flowmeters, it is extremely important from a dollars and cents standpoint that these meters read accurately. As a result, a great deal of time and money have been spent by concerns in the gas industry to determine means for reducing the errors in meter readings resulting from pulsation. This paper will deal chiefly with the effect of pulsation on meters. In passing, it might be said that at the present time very little study has been made to determine errors in the measurement of liquids having pulsating flow.

It is now generally accepted that any inferential-head meter will measure correctly if the secondary device will measure accurately the differential pressure across the primary element, and if the average of the square roots of the instantaneous readings can be determined. In the case of steady flow these operations are comparatively simple, but when the flow is at all unsteady this is not true.

If the differential is irregular as a result of rapid variations in velocity or pressure the meter is inaccurate because of the fact that most secondary devices are too sluggish to follow the actual changes in differential pressure caused by rapidly changing flow. Furthermore, the differential pressure, indicated by the secondary device, is an approximate average of the maximum and minimum differential pressures. When the square root of this average is taken, the resulting value is higher than the average of the square roots of the instantaneous differentials, and the flow as determined from the meter will be too high.

This can be illustrated by assuming that the flow through a meter varies in a manner such that the differential is, for example, 49 in. during one second and 25 in. the next second. The average rate of flow over this period is proportional to $\frac{(49)^{1/2} + (25)^{1/2}}{2}$ or 6; if the average meter differential is 37, the rate of flow as registered by the meter is proportional to $(37)^{1/2}$ or 6.083. The error due to pulsation is (6.083 — 6.000) /6.000 or 1.4 per cent.

According to most investigators the error is always positive, but cases of negative error have been found which have been attributed by some engineers to pulsation. The magnitude of the error may be up in the hundreds of per cent.

Mathematical Analysis of Pulsation Error

In order to show how pulsation acts to give erroneous meter readings a mathematical analysis of three types of waves will be made. It must be kept in mind that the method of calculating the error due to pulsation is only theoretical and no attempt should be made to apply it in a practical case. It will, however, indicate why pulsation error exists.

Three wave forms, i.e., the rectangular, the sine, and the triangular, will be analyzed. Two assumptions in regard to meter behavior are made in these analyses: (*a*) it is assumed that the pulsations occur with such rapidity that the portion of the meter upon which the differential is impressed cannot follow the rapidly fluctuating differential pressures; and (*b*) it is assumed that the wave is symmetrical and that the meter gives a reading which is the mean between the upper and lower limits of the pulsation wave.

The sine wave would result if a single-cylinder compressor had the connecting rod replaced by a Scotch yoke, as shown in Fig. 1(*a*), since the piston would have simple harmonic motion and the wave displacement assumed to follow the motion of the piston. The wave would then be as shown in Fig. 1(*b*), with p as the maximum displacement of the pulsation wave and with the angular displacement of the crankpin through one revolution plotted as the abscissa.

The rectangular wave form will be first discussed in detail, since its analysis presents less of a problem than the other two.

The differentials encountered are illustrated in Fig. 2(*a*) and apply to one revolution of the crank of a compressor. The phase angle of the crank is plotted as the abscissa and the instantaneous differential as the ordinate. The meter reading (indicated by h) is taken halfway between the maximum differential ($h + p$) due to the pulsation and ($h - p$) the minimum differential, p being the distance between the instantaneous differential and the meter reading. The instantaneous value of the true differential is indicated by H. If K is used to designate all of the constants, such as $(2g)^{1/2}$, velocity of approach factor, etc., then Q_m, the flow as indicated by the meter, is equal to $Kh^{1/2}$. If, instead of

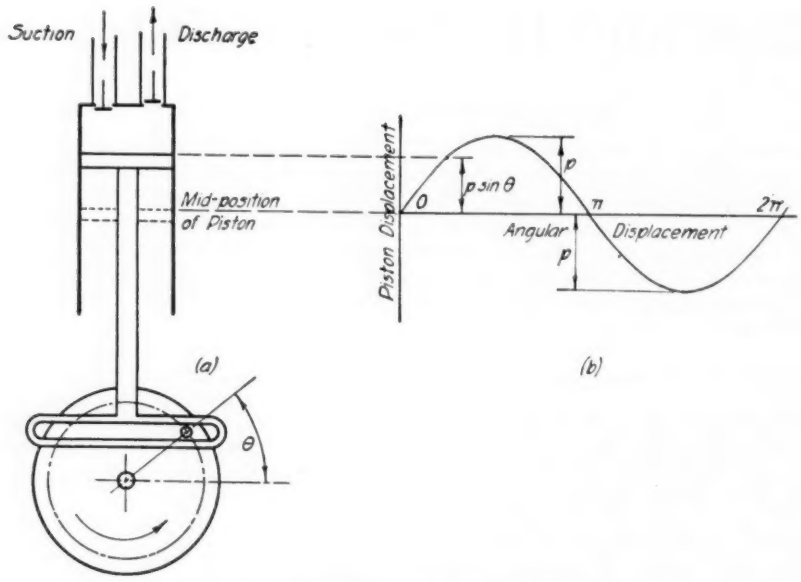

FIG. 1 GENERATION OF PULSATION WAVE

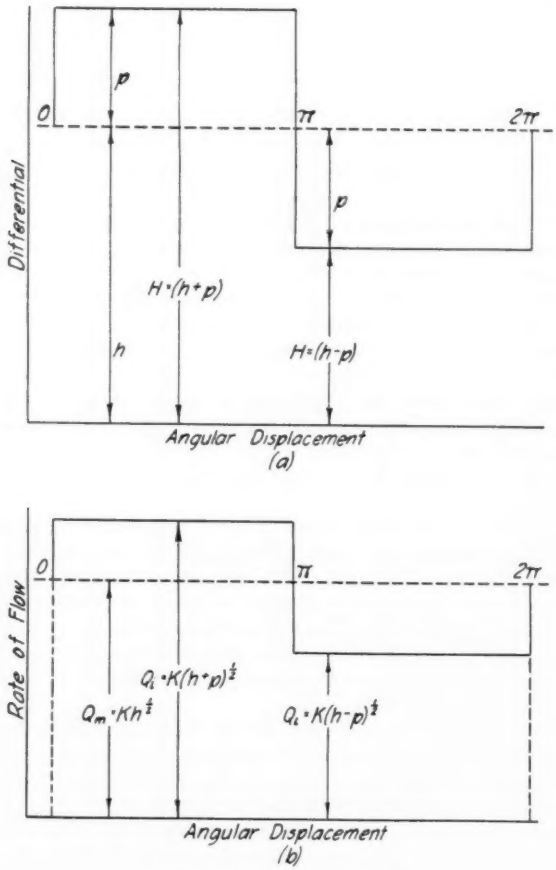

FIG. 2 RECTANGULAR WAVE

plotting the instantaneous differential, the instantaneous flow is plotted, the result is as shown in Fig. 2(*b*). If the area under the curve is taken for one cycle (angular displacement 0 to 2π), and the area is divided by the length of the cycle, there results the average ordinate which is the average rate of flow and

$$Q_a = \frac{K\,(h+p)^{1/2}\,\pi + K\,(h-p)^{1/2}\,\pi}{2\pi}$$

or

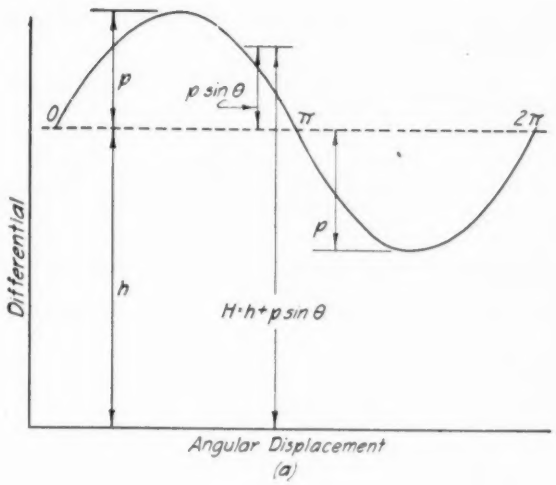
$$Q_a = \frac{K}{2}\,[(h+p)^{1/2} + (h-p)^{1/2}]$$

Then the ratio of the flow as determined by the meter to the actual rate of flow is

$$\frac{Q_m}{Q_a} = \frac{Kh^{1/2}}{\frac{K}{2}\,[(h+p)^{1/2} + (h-p)^{1/2}]}$$

or

$$\frac{Q_m}{Q_a} = \frac{2h^{1/2}}{(h+p)^{1/2} + (h-p)^{1/2}}$$



Sine Wave. As has been pointed out, a sine wave as shown in Fig. 3(*a*) will result theoretically if the connecting rod of a single-cylinder compressor is replaced by a Scotch yoke. Any distance H from the datum to the wave represents an instantaneous value of the true differential which for this particular wave form is $(h + p \sin \theta)$, while the distance h to the horizontal dashed line represents the differential as indicated by the meter. If K is again assumed to be the meter constant, the rate of flow as indicated by the meter is again $Q_m = Kh^{1/2}$, and the instantaneous true rate of flow is

$$Q_i = K(H)^{1/2} \text{ or } Q_i = K\,(h + p \sin \theta)^{1/2}$$

If the instantaneous true rates of flow are plotted the result is Fig. 3(*b*). In order to obtain the true average rate of flow it will again be necessary to determine the area under one cycle of the curve and divide this area by the length of one cycle. The flow which takes place while the crank turns through the angle $d\theta$ is

$$K\,(h + p \sin \theta)^{1/2}\,d\theta$$

and the total flow from one revolution of the crank is

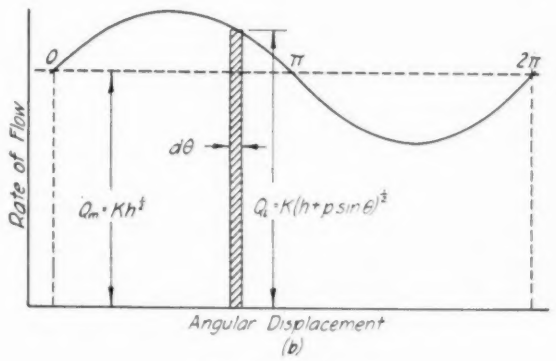


FIG. 3 SINE WAVE

$$K\int_0^{2\pi} (h + p \sin \theta)^{1/2}\, d\theta$$

The average flow over this cycle then is

$$Q_a = \frac{K}{2\pi}\int_0^{2\pi} (h + p \sin \theta)^{1/2}\, d\theta$$

If it is desired to find the actual discharge for pulsating flow from the foregoing equation, the equation must, of course, be integrated. This is done after the portion $(h + p \sin \theta)^{1/2}$ has been expanded by the binomial theorem. The binomial theorem in terms of symbols for five terms is

$$(a + b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{2!}a^{n-2}b^2 + \frac{n(n-1)(n-2)}{3!}a^{n-3}b^3 + \frac{n(n-1)(n-2)(n-3)}{4!}a^{n-4}b^4$$

Then

$$(h + p \sin \theta)^{1/2} = h^{1/2} + \frac{p \sin \theta}{2h^{1/2}} - \frac{1}{8h^{3/2}}p^2 \sin^2 \theta + \frac{3}{48h^{5/2}}p^3 \sin^3 \theta - \frac{15}{384h^{7/2}}p^4 \sin^4 \theta = h^{1/2}\left[1 + \frac{p \sin \theta}{2h} - \frac{p^2 \sin^2 \theta}{8h^2} + \frac{p^3 \sin^3 \theta}{16h^3} - \frac{15\, p^4 \sin^4 \theta}{384h^4}\right]$$

and

$$Q_a = \frac{Kh^{1/2}}{2\pi}\int_0^{2\pi}\left[1 + \frac{p \sin \theta}{2h} - \frac{p^2 \sin^2 \theta}{8h^2} + \frac{p^3 \sin^3 \theta}{16h^3} - \frac{15\, p^4 \sin^4 \theta}{384h^4}\right] d\theta$$

or

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left[\int_0^{2\pi} d\theta + \frac{p}{2h}\int_0^{2\pi} \sin \theta d\theta - \frac{p^2}{8h^2}\int_0^{2\pi} \sin^2 \theta d\theta + \frac{p^3}{16h^3}\int_0^{2\pi} \sin^3 \theta d\theta - \frac{15}{384}\frac{p^4}{h^4}\int_0^{2\pi} \sin^4 \theta d\theta\right]$$

Since

$$\int d\theta = \theta + c$$

$$\int \sin \theta\, d\theta = -\cos \theta + c$$

$$\int \sin^2 \theta\, d\theta = -\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\theta + c$$

$$\int \sin^3 \theta\, d\theta = -\frac{1}{3}\cos \theta \sin^2 \theta - \frac{2}{3}\cos \theta + c$$

and

$$\int \sin^4 \theta d\theta = \frac{-\sin^3 \theta \cos \theta}{4} + \frac{3}{4}\left(-\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\theta\right) + c$$

then the expression for discharge, when integrated is

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left\{\theta - \frac{p}{2h}\cos \theta - \frac{p^2}{8h^2}\left[-\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\theta\right] + \frac{p^3}{16h^3}\left[\frac{1}{3}\cos \theta \sin^2 \theta - \frac{2}{3}\cos \theta\right] - \frac{15}{384}\frac{p^4}{h^4}\left[-\frac{\sin^3 \theta \cos \theta}{4} + \frac{3}{4}\left(-\frac{1}{2}\cos \theta \sin \theta + \frac{1}{2}\right)\right]\right\}_0^{2\pi}$$

Since $\sin 2\pi = 0$, $\sin 0 = 0$, $\cos 2\pi = 1$, and $\cos 0 = 1$ when the limits have been substituted in the foregoing equation, the result is

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left\{\left[2\pi\right] - \left[\frac{p}{2h}\right] - \left[\frac{p^2}{8h^2}\pi\right] + \left[\frac{p^3}{16h^3} \times \frac{-2}{3}\right] - \left[\frac{15}{384}\frac{p^4}{h^4} \times \frac{3}{4}\pi\right] - \left[\left(\frac{-p}{2h}\right) - \left(\frac{p^3}{16h^3} \times \frac{2}{3}\right)\right]\right\}$$

and

$$Q_a = \frac{Kh^{1/2}}{2\pi}\left[1 - \frac{p^2\pi}{8h^2} - \frac{15p^4\pi}{512h^4}\right]$$

or

$$Q_a = Kh^{1/2}\left[1 - \frac{p^2}{16h^2} - \frac{15}{1024}\frac{p^4}{h^4}\right]$$

Then the ratio of the rate of flow as indicated by the meter to the actual rate of flow when the pulsation is in the form of a sine wave, is

$$\frac{Q_m}{Q_a} = \frac{Kh^{1/2}}{Kh^{1/2}\left[1 - \frac{p^2}{16h^2} - \frac{15}{1024}\frac{p^4}{h^4}\right]}$$

or

$$\frac{Q_m}{Q_a} = \frac{1}{1 - \frac{p^2}{16h^2} - \frac{15}{1024}\frac{p^4}{h^4}}$$

It will be observed that if the amplitude of the pulsation p is zero, the flow as indicated by the meter is equal to the true rate of flow. If the meter differential and the amplitude of the pulsation are known the ratio of the two can be found and the percentage of error in the meter reading determined from the expression $\frac{Q_m - Q_a}{Q_a}$ which is equal to $\frac{Q_m}{Q_a} - 1$.

Triangular Wave Form. To take another hypothetical case, assume the wave form to be triangular as shown in Fig. 4(*a*). The reading of the meter is, as before, $K(h)^{1/2}$. The value of the instantaneous differential H in each case is as follows

$$\text{From 0 to } \frac{\pi}{2}: \quad H = h + \frac{2p\theta}{\pi}$$

$$\frac{\pi}{2} \text{ to } \frac{3}{2}\pi: \quad H = h + 2p\left(1 - \frac{\theta}{\pi}\right)$$

$$\frac{3}{2}\pi \text{ to } 2\pi: \quad H = h - 2p\left(2 - \frac{\theta}{\pi}\right)$$

When the instantaneous rate of flow is plotted the curve takes the form as indicated in Fig. 4(*b*) and the rate of flow is as noted in the figure.

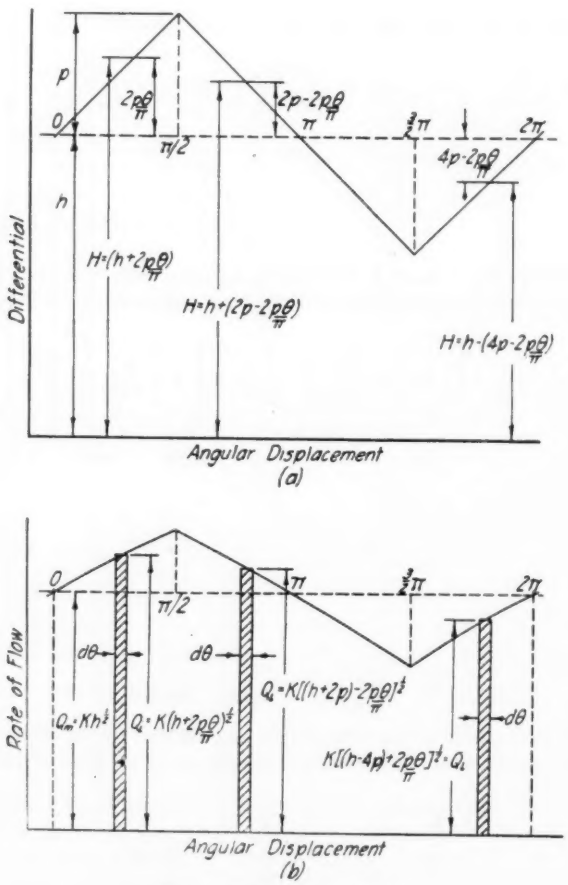

FIG. 4 TRIANGULAR WAVE

The flow during the period that the crank turns through a complete revolution is

$$Q_a = \frac{K}{2\pi}\left\{\int_0^{\frac{\pi}{2}}\left[h + \frac{2p\theta}{\pi}\right]^{1/2} d\theta + \int_{\frac{\pi}{2}}^{\frac{3\pi}{2}}\left[(h + 2p) - \frac{2p\theta}{\pi}\right]^{1/2} d\theta + \int_{\frac{3\pi}{2}}^{2\pi}\left[(h - 4p) + \frac{2p\theta}{\pi}\right]^{1/2} d\theta\right\}$$

This equation is of the form $(a + bu)^n du$ which when integrated is $\frac{(a + bu)^{n+1}}{b(n + 1)}$. Since in this case $n = 1/2$ the form when integrated is $\frac{(a + bu)^{3/2}}{3/2\ b}$.

Then

$$Q_a = \frac{K}{2\pi}\left\{\left[\frac{\left(h + \frac{2p\theta}{\pi}\right)^{3/2}}{3/2 \times \frac{2p}{\pi}}\right]_0^{\frac{\pi}{2}} + \left[\frac{\left(h + 2p - \frac{2p\theta}{\pi}\right)^{3/2}}{-3/2 \times \frac{2p}{\pi}}\right]_{\frac{\pi}{2}}^{\frac{3}{2}\pi} + \left[\frac{\left(h - 4p + \frac{2p\theta}{\pi}\right)^{3/2}}{3/2 \times \frac{2p}{\pi}}\right]_{\frac{3}{2}\pi}^{2\pi}\right\}$$

and

$$Q_a = \frac{K}{2\pi}\left\{\left[\frac{(h + p)^{3/2} - h^{3/2}}{\frac{3p}{\pi}}\right] - \left[\frac{(h - p)^{3/2} - (h + p)^{3/2}}{\frac{3p}{\pi}}\right] + \left[\frac{h^{3/2} - (h - p)^{3/2}}{\frac{3p}{\pi}}\right]\right\}$$

and finally

$$Q_a = \frac{K}{3p}\left[(h + p)^{3/2} - (h - p)^{3/2}\right]$$

Then

$$\frac{Q_m}{Q_a} = \frac{Kh^{1/2}}{\frac{K}{3p}\left[(h + p)^{3/2} - (h - p)^{3/2}\right]}$$

or

$$\frac{Q_m}{Q_a} = \frac{3ph^{1/2}}{(h + p)^{3/2} - (h - p)^{3/2}}$$

THE THEORY OF PULSATION

Numerous articles dealing with pulsation and the effects of pulsating flow have appeared in technical literature from time to time. Most of them deal with the inaccuracy of meters handling fluids subject to pulsation.

Among the first references is one by William Mayo Venable (1)[3] in 1905, which stated that piezometer tubes used in measuring the static head on centrifugal pumps gave values that were abnormally high. He attributed the error to pulsation caused by the limited number of vanes or blades in the pump runner.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

In the 1914–1915 Proceedings of The Institution of Civil Engineers Prof. A. H. Gibson (2) pointed out that "most devices for measuring fluid motion do not record the true mean of a pulsating flow and that the error increases," and that "fluctuations in velocity (are) accompanied by fluctuations in pressure."

In 1916 three interesting and significant articles appeared pointing out the inaccuracy of meters when measuring fluids having pulsating flow. One by Allen Hazen (3) indicated that wide and sudden variations in flow cause errors in the head produced by a Venturi meter and that elastic pipe and too-small air chambers when used with reciprocating pumps cause these errors. Another by E. G. Bailey (4) stated that steam flowing to a reciprocating engine is erroneously measured by a flowmeter because of velocity and pressure variations. F. P. Fisher (5) attributed to pulsation the discrepancy in meter readings when the meters were placed some distance apart in a pipe line from a compressor.

In 1922 the results of an investigation by Judd and Pheley (6) appeared in a bulletin published by The Ohio State University Experiment Station. This was the first real attempt to determine the nature of pulsation and to study methods of eliminating pulsation itself and the detrimental effects of pulsation. The conclusions drawn by Judd and Pheley are still considered sound; in fact, most of the later theorizing and investigating has been based upon the ideas originally brought out by them. Subsequent investigations have served to substantiate their conclusions.

Their studies were made with air on Venturi meters, orifices, nozzles, and Pitot tubes. Among the pertinent conclusions which these two men drew up are the following:

(*a*) Pulsations in pipe lines consist of sudden changes in velocity and pressure of the fluid.

(*b*) Pressure changes cause the largest pulsations.

(*c*) The pressure change is in the form of a wave front resembling a traveling sound wave of low velocity.

(*d*) The pressure wave travels with the velocity of sound.

(*e*) Velocity of pulsation is independent of the velocity of fluid flowing.

(*f*) The effect of pulsation on a flowmeter is to increase the reading. The magnitude of the error is a function of frequency and pulsation, static pressure of the fluid, type of meter, and adjacent fixture in the pipe line.

(*g*) Pulsation must be eliminated or reduced greatly to have the meter read without appreciable error.

It was also pointed out by them and now generally believed that no correction factors can be applied to a meter reading to correct for the error caused by pulsation. In most of the correction equations several things, such as frequency of pulsation, the shape of the wave, the amplitude of the wave, etc., must be taken into account. It is also felt that errors due to rapid pressure change are far more severe than changes in velocity. The fact is that there can be errors caused by rapid pressure changes without the presence of changes in the rate of flow of the mass in the pipe line. This has been illustrated by placing a positive-displacement meter on a dead-ended line. The meter valves will clatter and the meter will register a flow if pulsation is present. Likewise, a reading will be indicated on a manometer across an inferential meter, such as an orifice, when placed in a dead-ended line if pulsation exists.

Studies which have been made indicate that in addition to the primary pressure waves in the fluid between the disturbance and the primary element, there are also pressure waves of different amplitude existing in the primary element on the side opposite from the disturbance; and suggest that these waves might be slightly out of time with the waves on the other side, so that the effect of pressure variation is multiplied at times. Then, in addition to the primary waves, there are harmonics which are affected by the size and shape of the conduit on both sides of the primary element. The differential across the primary element where pulsation exists is thus a complicated varying pressure made up of many elements. This was shown by an electrical instrument developed by S. R. Beitler (7) in connection with the pulsation research sponsored by the American Gas Association and The American Society of Mechanical Engineers.

With the equipment as originally used it was possible to obtain a record of the pressure variations on either side of the primary element. However, a study of these records (along the line of reasoning mentioned) indicated that a knowledge of the differential pressure was desirable, and a special mixing switch was designed which made it possible to secure a record not only of the inlet or outlet pulsation waves but the differential pulsation waves as well. Fig. 5 shows some of the records taken with this instrument under various conditions of pulsation.

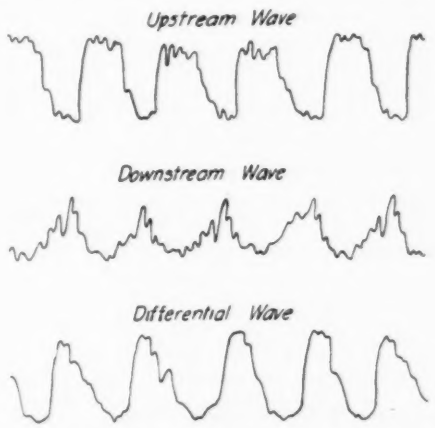

FIG. 5 ACTUAL PULSATION WAVES

A study of these records will show that there is no regularity of pulsation waves, and no apparent relation between the shape and amplitude of the waves on the two sides of the primary element, and that the differential wave bears no similarity to the other waves. These records were made at a gas-compressor station where the pulsation was produced by one compressor running at almost constant speed. The meter was placed directly on the outlet of the aftercooler so that the pulsations would be as nearly constant as possible. Because of the fact that the waves were so irregular it is practically impossible to include the effect of wave form in an equation for correcting the rate of flow.

If the pressure differential could be measured instantaneously, and if the square roots of these two pressures could be averaged, it is possible that a meter would indicate the rate of flow accurately. This would be true, because while the velocity through the primary element does not vary directly with changes in pressure waves, the energy present due to these waves will be used either in accelerating or decelerating the fluid passing through the primary element, so that the decelerations should balance the accelerations. The average flow will be indicated by the average of the square roots of the instantaneous differential pressures across the primary element.

While it is true that each meter installation presents its own problems and that each disturbance creates pulsations which cannot be analyzed, certain general conclusions in regard to pulsation can be drawn. In a paper by S. R. Beitler (8) which reports the results of research conducted at several stations, it is pointed out (*a*) that for a single diameter ratio the error becomes larger for decreasing values of the differential; (*b*) that

with a constant differential the error becomes larger with smaller diameter ratios; and (c) that at any one rate of flow the suction pulsation causes a smaller error than the discharge pulsation;

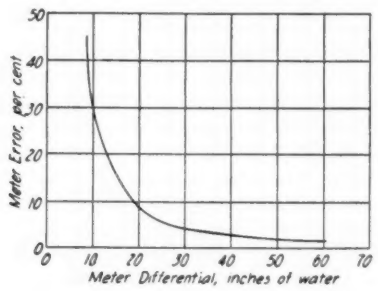

FIG. 6 DIFFERENTIAL VS. ERROR FOR ONE DIAMETER RATIO

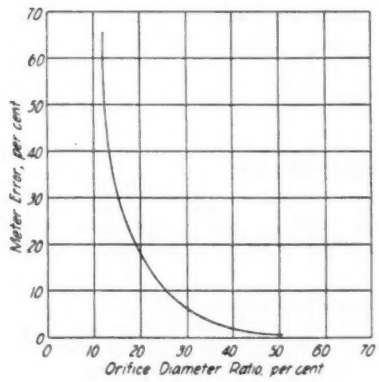

FIG. 7 DIAMETER RATIO VS. ERROR FOR A GIVEN DIFFERENTIAL

In other words, it might indicate severe pulsations while the pulsations might be so slight that the meter error would be negligible. A sketch of Mr. Bean's detector is shown in Fig. 8. The by-pass valve is left open until the pressure in the tank reaches main pressure. The by-pass is then closed, and if the drop of water moves back and forth pulsation is present. Any slight change in static pressure or a pulsation of appreciable magnitude causes the water to be withdrawn into either the gas main or the pressure tank. If the drop of water does not move the flow is certain to be pulsationless.

A device designed by S. R. Beitler (7) and J. E. Overbeck is similar to the one just described and is shown in Fig. 9. In this device the gas-pressure tank is connected to the meter-run line through a $^1/_2$-in. line in which is placed an orifice plate, the diameter of the orifice being $^1/_8$ in. The manometer shown in the figure is then piped up to measure the pressure drop across the

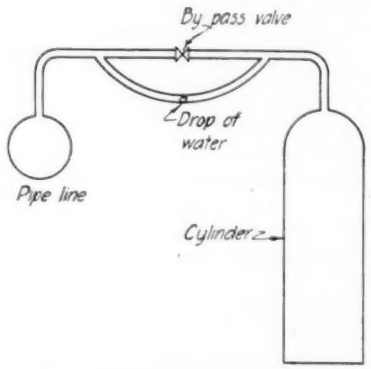

FIG. 8 PULSATION DETECTOR (BEAN)

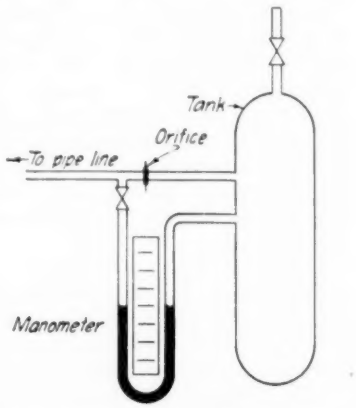

FIG. 9 PULSATION DETECTOR (BEITLER AND OVERBECK)

but suction pulsation is just as serious as discharge pulsation if the amplitude of the pulsation is the same in both cases. These conclusions have been substantiated by other tests. Figs. 6 and 7 show the results of tests reported in this paper.

The magnitude of the error depends upon the quantity of fluid being measured, the resistance and capacity between the disturbance and the meter, and the viscosity and density of the fluid being measured.

According to H. F. Hagen (15) tests on centrifugal- and propeller-type fans are apt to be in error because of erroneous velocity and pressure readings caused by pulsating flow.

Tests (10) that have been conducted reveal that the meters made by several manufacturers gave the same amount of error when tested simultaneously.

METHODS OF DETECTING PULSATION

If two meters are placed in series in a given line at some considerable distance apart and if the one nearer the potential source of pulsation gives a reading which differs from the reading given by the other by an amount greater than the usual discrepancy between meters, then it is certain pulsation has been created.

If a meter is subjected to constant quantity of flow and if the indicator on the meter produces a line which indicates a variable rate of flow by a wavy line, then the presence of pulsation can be suspected. This does not mean, however, that pulsation must exist if the meter charts have wavy lines nor does it mean that every case of pulsating flow will produce a wavy line.

One pulsation detector was devised by H. S. Bean (9) which had only the defect that it was too sensitive for most installations. $^1/_8$-in. orifice. As has been pointed out previously, an orifice subject to pulsations will show a differential pressure even when there is no flow. This device takes advantage of this fact, and a differential reading on the manometer is an indication of the presence of pulsations. This device partially overcomes the defect of Mr. Bean's pulsation detector in that the liquid does not escape so readily but large rapid changes in static pressure will force the liquid out of the manometer. Slight changes of static pressure will cause differentials on the manometer which are not caused by pulsations. As in the case of Mr. Bean's detector, if no differential is shown on the manometer then it is certain that no pulsation exists.

Another instrument, which was electrical and also devised by Professor Beitler, consisted of two diaphragms of stainless steel about 1 in. diam and $^1/_{32}$ in. thick which were connected to each side of the primary metering element by very short connections and so constituted that a pressure variation would be indicated by a very slight movement of the diaphragms. Piezoelectric crystals were used to indicate the motion of the diaphragms, and the voltage produced was amplified and recorded on a recording voltmeter. The whole apparatus gave a record of the wave form at both the inlet and outlet pressure taps. The recorder was capable of responding to very rapid fluctuations of the pressure, and the complete record of the form and amplitude of the pressure variations was made on a high-speed chart. The wave forms shown in Fig. 5 were recorded by this instrument. If no pulsation is present a straight line is drawn. The entire apparatus was constructed of standard types of instruments manufactured by Brush Development Corporation, Cleveland, O.

Another instrument described by T. K. M. Smith and R. E. Morter (10), which was used for detecting pulsation, was made up of a sylphon bellows to which a pen was attached. When pulsation causes the bellows to move the pen makes a mark on a strip chart driven by a spring motor. The record of the variations of pressure is thus made on the chart.

Elimination of Pulsation

Although it is now generally felt that no equation can be written for the error caused by pulsation and no meter can be built that will measure correctly if pulsation exists, many such equations and meters have been devised.

It was pointed out by Judd and Pheley (6) and since found true by others that: (*a*) it is not feasible to apply a correction factor to a meter since the correction factor would probably change with every installation and every condition of flow; (*b*) the laws of pulsating flow are not well enough known to set up an equation for a correction factor; and (*c*) each installation presents different problems. Most of the writers who have developed equations for correction factors have failed to take into account the complexity of the pulsation wave and have treated it as a simple one. Some of those who have devised meters which correct for pulsation have failed to take into account one very important fundamental, namely, that pulsation is the result of pressure variations as well as velocity variations.

Literature which deals with many of these equations and meters will be referred to.

J. L. Hodgson (11) presents the description of a device for metering air with pulsating flow. A vane which oscillates with the pulsations carries a pointer through a hairspring. The pointer indicates the mean of pulsations. The rapid motion of the pointer is damped by vanes in an oil bath. He gives an equation for calculating a coefficient to be used with the reading obtained with the damped reading to obtain the true rate of flow. Mr. Hodgson also has another paper dealing with the subject (12).

Prof. N. P. Bailey (13) discusses a patented device which he indicates will give true-flow air under pulsating conditions. The flow of water through a calibrated orifice is claimed to be proportional to the square root of the air velocity head. Professor Bailey also has discussed similar meters in other papers (14). C. A. Dawley has patented two meters which are claimed to read correctly even if the flow is pulsating; one was patented in 1927 and the other in 1928.

H. F. Hagen (15) describes an instrument he has developed for determining the shape of the pulsation wave created by a high-speed fan.

Equations for determining the error due to pulsation or for the calculation of correction factors to be applied to the flow equation for pulsationless flow have been prepared by N. P. Bailey (14), J. L. Hodgson (12), D. Gilmour (16), and A. H. Gibson (2).

It was thought for a time that the effect of pulsation could be eliminated in a meter by placing obstructions or throttles in the gage lines. In 1922 it was pointed out by H. P. Westcott (17) that this would have no beneficial effect. Tests conducted by Eagle and Daberko (18) at The Ohio State University in 1937 showed that such devices increased the error rather than reduced it.

As far as is known now, the only way to remove every trace of error due to pulsation is to eliminate the pulsation itself. There can, however, be a slight amount of pulsation present which will not seriously affect the meter readings.

Judd and Pheley (6), as a result of their work, set down some conclusions in regard to the practical elimination of pulsation which have since been substantiated. Among them are the following:

(*a*) Because of high velocity of pulsation an excessive length of pipe line would be necessary to destroy pulsation.

(*b*) Throttling is effective, but a great deal of throttling is required to reduce pulsation error.

(*c*) Abrupt volume enlargements in the pipe line will eliminate the error if of sufficient capacity.

(*d*) For the same capacity a volume with a large diameter is better than one of equal volume and smaller diameter.

(*e*) Combination of throttling with a volume forming a muffler device is probably best for mechanically removing pulsations.

(*f*) Revolving baffles are partially successful in removing pulsation.

(*g*) The effectiveness of any quieting device depends upon its ability to dissipate or change the energy of pulsation.

One sure way to reduce pulsation to a negligible quantity is to have sufficient pressure drop between the disturbance and the meter. This can be accomplished by an orifice or a partially closed valve. In tests that have been conducted the pulsation error on the downstream side was insignificant when the pressure drop through the restriction equaled or approached the critical. This, however, in the case of a compressor, is a costly method since the purpose of the compressor will partially be defeated.

A meter placed at a considerable distance from a disturbance will not be subjected to the same degree of error as a meter placed near the disturbance. Edward Sackett (19) points out that in one instance a meter placed 6 miles from a compressor had no error. E. P. Fischer (5) noted that a meter 17 miles from a compressor had no error while one near the compressor gave considerable error. Just how far pulsation will be carried in a transmission line depends upon a number of factors and will probably be different for every installation.

Volumes placed in a line have proved quite effective in reducing pulsation to the point where meter error is no longer appreciable. The fluid having pulsation is discharged into a tank having considerable volume from whence it flows on into the line again. Several modifications of this principle have been used with success. Smith and Morter (10) discuss the use of volume tanks. They also suggest that a tank have a volume of 100 cu ft per million cu ft of gas per 24 hr reduced to actual volume under the existing pressure and that the length of the cylindrical portion of the tank be 1.75 times its diameter. One tank of their design is shown diagrammatically in Fig. 10. The pressure drop through these tanks is very low.

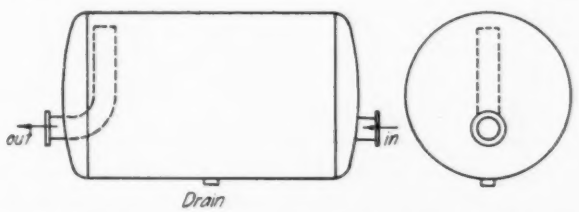

Fig. 10 Pulsation Eliminator Tank (From Smith and Morter)

Tests of volumes were conducted by Eagle and Daberko (18) in which they used the volumes in two different ways. The arrangement of the piping to the tank is shown diagrammatically in Fig. 11. The pulsation was produced by a two-stage compressor having a capacity of 350 cfm. In one series of tests they passed the air from the compressor directly through the tank by closing valve *A* and opening valve *B* (Fig. 11), valve *C* also being open; and in another series of tests they arranged the tank for "breathing" in the manner of a surge tank by opening valve *A* and closing valve *B* with the valve *C* being again open. It was found that the former method (passing the pulsating air directly through the tank) was far more effective in removing the pulsa-

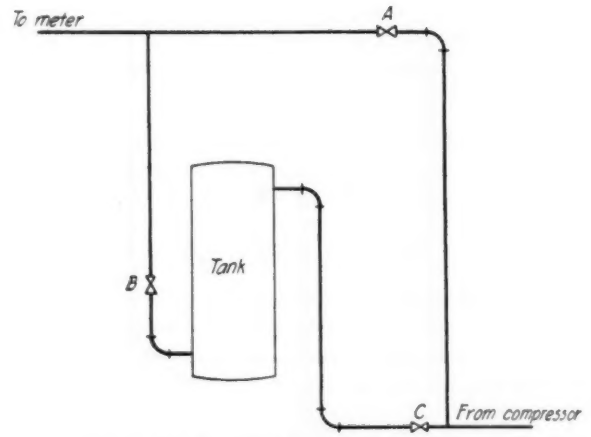

FIG. 11 OHIO STATE TEST TANK ARRANGEMENT

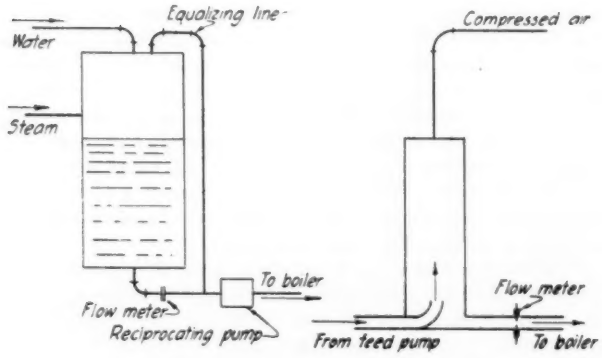

FIG. 12 PULSATION REDUCERS (MELAS)

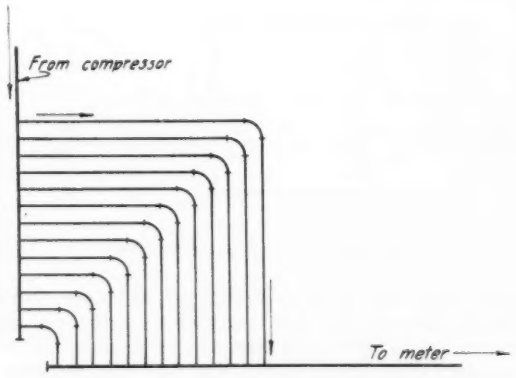

FIG. 13 PIPING FOR PULSATION REDUCTION (FISCHER)

tion than the latter. The tank used in these tests had a volume of 54 cu ft.

They also conducted tests when the air was passed directly through a tank having a volume of only 3 cu ft. They found that the smaller volume was about as effective in removing pulsation as the larger one. They then used the small volume lined with sound-absorbing material and placed baffles of the same material across the path of the air flow. They found that the acoustic material aided in removing pulsation to a small extent but that the acoustic material was destroyed under the action of the pulsation. They also found that the pressure drop through

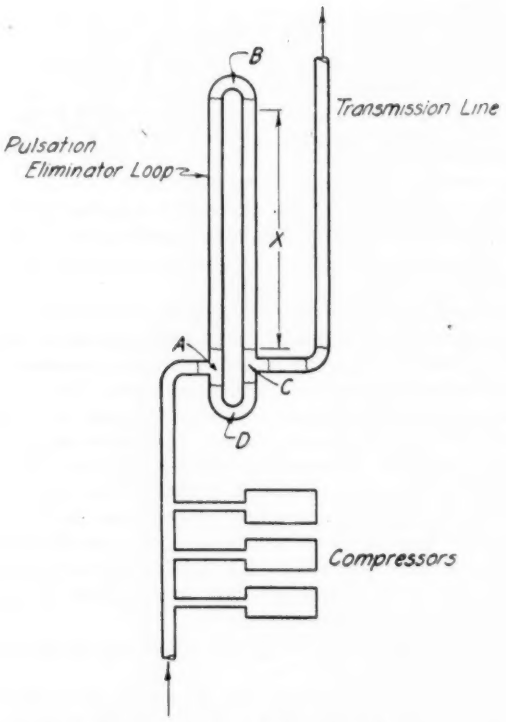

FIG. 14 PULSATION ELIMINATOR LOOP

the acoustical device was slight and concluded that the benefit was due to the sound-absorbing qualities of the device.

Two devices using the surge-tank principle are described by William Melas (20, 21, 22, 23) and shown in Fig. 12. It should be pointed out that these four articles are practically the same. Mr. Melas has used these devices in connection with a meter measuring the flow to a boiler feed pump.

F. P. Fischer (5) constructed a device (Fig. 13) which consisted of piping so arranged that various portions of the fluid under pulsating flow would have paths of different length so that the pulsation waves would interfere with one another as they joined the main pipe. Theory indicated that the waves would be broken up by this method. Elimination of the pulsation proved to be only partially accomplished.

In a report written by William Mosteller to J. T. Cortelyou, both of the Southern California Gas Company, Mr. Mosteller includes a discussion of the pulsation eliminator shown in Fig. 14. He points out that for maximum effectiveness in pulsation elimination, the length of the path *ABC* should equal the path *ADC* plus one half the length of the pulsation wave. Mr. Mosteller also gives an equation for calculating the wave length and the length X in the loop.

Tests made on a pipe line from a compressor before and after the installation of this type of loop indicated that the pulsation downstream from the eliminator was less severe after the eliminator had been installed. The pulsation in the line between the eliminator and the compressor was more severe in some sections of the line and reduced in other sections.

Another device which might be used as an eliminator is mentioned by Mr. Mosteller and is shown in Fig. 15.

After having studied a good many reports of test work, including some of the reports just discussed, L. K. Spink (24) has concluded that meter measurement accuracy may be improved by the following:

(*a*) Operating at a higher differential, i.e., in a multiple-

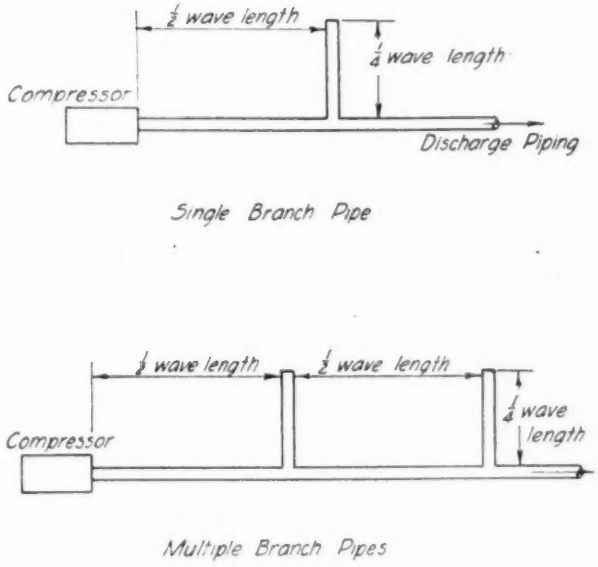

FIG. 15 ELIMINATORS CONSISTING OF BRANCH PIPES

meter run, shutting off one or more runs; or installing a smaller orifice in an existing meter run.

(*b*) Installing a higher range differential gage and changing operating conditions in order to use the increased range.

(*c*) Reducing the pipe-run diameter so as to use a higher orifice-to-pipe diameter ratio, still operating at differentials as high as practicable. Increasing the ratio of the orifice diameter to pipe-run diameter will reduce the pulsation error if the differential remains constant.

(*d*) Installing mufflers, headers, restrictions, or combinations of capacity and pressure drop between primary device and source of pulsation to reduce pulsation amplitude.

(*e*) Locating the primary device at a point where the pulsation amplitude is lower (as on the suction side of compressors).

MEASUREMENT OF PULSATION

Because of the fact that so many variables enter into an equation for pulsating error and because each installation has peculiarities of its own, computation of the error due to pulsation is out of the question. It is therefore necessary to have some instrument to determine the presence and extent of the pulsation error.

A second electrical instrument suggested by S. R. Beitler using piezoelectric crystals was developed in which the amplitude of the pulsation wave was measured by an indicating voltmeter mounted on top of a small box containing the diaphragm holders, the amplifier, and the mixing switch, so that the entire apparatus was self-contained. The power for amplification was supplied by dry cells so that the apparatus was portable. This instrument was also developed and manufactured by the Brush Development Corporation. Operating experience indicated that there was some question about the calibration of the electrical apparatus and, because of its sensitivity to pressure variations, it was extremely difficult to obtain a representative reading. A mechanical device which gives the amplitude of the differential-pulsation waves has been developed by S. R. Beitler (25) and J. E. Overbeck. This device, shown diagrammatically in Fig. 16, is a variation of the indicator and has proved very satisfactory in operation.

In its present form the mechanical pulsometer consists of two cylindrical volumes, *A* and *B*, Fig. 16, separated by a sylphon

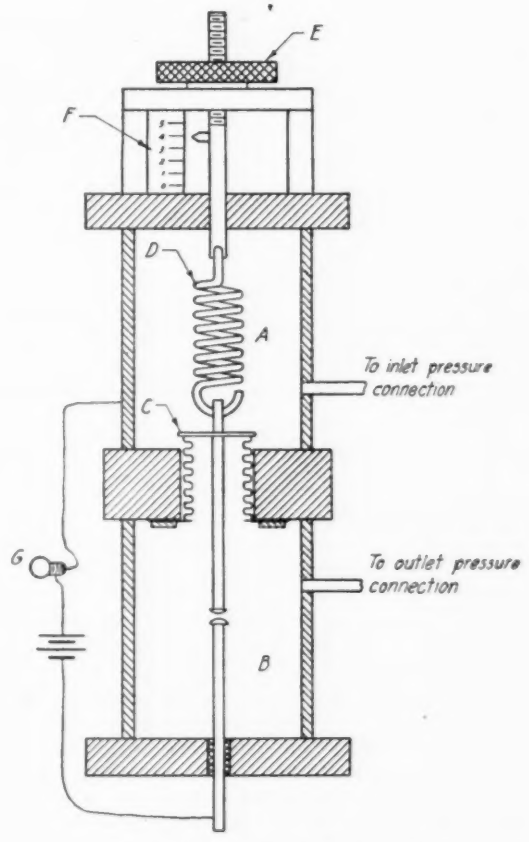

FIG. 16 MECHANICAL PULSOMETER

bellows *C* so that there will be no leakage between the two volumes which are connected to the inlet and outlet pressure connections of the meter, and as close to the primary element as possible. A coil spring *D* is mounted in volume *A*, which volume is connected to the high-pressure tap. The tension on this spring can be changed by turning the handwheel *E* which is outside the instrument. The scale *F* (each division represents $^1/_{16}$ in.) indicates the elongation of the spring. Electrical connections are arranged in volume *B*, which is connected to the low-pressure tap, so that any motion of the bellows caused by differential pressure will be indicated by a light *G* located on the outside of the instrument. During operation the tension of the spring is gradually increased until the light goes out. This indicates that the differential pressure has been equalized by the spring tension. When this occurs the tension of the spring should represent the differential pressure due to the flow plus the maximum amplitude of the differential pressures.

The instrument spring can be calibrated by comparing its scale readings with any differential gage when connected to a setup where there are no pulsations present. When measuring pulsation amplitude the instrument is almost totally unaffected by inertia, since the moving parts are practically at rest when the determination is made.

To determine the correlation between pulsometer reading, meter differential, and meter error a research project was sponsored by the American Gas Association and The American Society of Mechanical Engineers. A special test station, shown diagrammatically in Fig. 17, was constructed near Sugar Grove, Ohio, at the Crawford No. 2 Station of the Ohio Fuel Gas Company. (It was the good fortune of the author to be a member of the research working committee during the period that many of

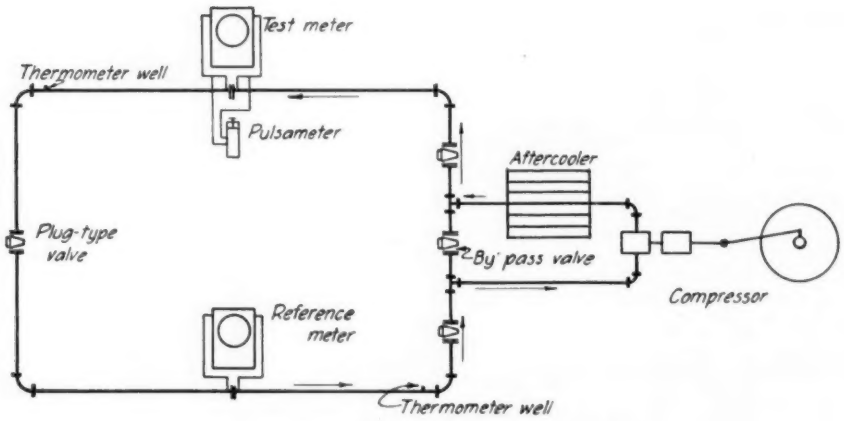

FIG. 17 ARRANGEMENT OF PULSATION TEST PIPING
(Crawford No. 2, Sugar Grove, Ohio.)

the tests were conducted.) This test station was built with two orifice meters in series, one on the discharge and the other on the suction line of a large gas compressor. Gas was supplied to the first orifice directly from the outlet of the aftercooler of one compressor, and after passing through the second orifice meter, was discharged back into the suction of the same compressor.

With this arrangement pulsation could be maintained as nearly constant as possible and the other measured conditions could be easily changed to give the pressures and rates of flow desired. Throttle valves (plug-type valves) were placed in the line between the two meters and also between the compressor and the inlet and outlet of the test setting. By means of these valves it was possible to regulate the pressure on either one of the meters so that it would not be subjected either to suction or discharge pulsations from the compressor.

This meter was then used as a standard or reference meter and the measurement error due to pulsation was determined by comparing the quantity indicated by the meter subjected to pulsation (or test meter) against that indicated by the reference meter. The test meter was equipped with both "flange" and "pipe" taps, and readings were taken on both simultaneously in order to determine what effect the location of pressure taps might have on the test results.

In order to eliminate the effect of small variations in orifice plates and runway construction, so-called "unity tests" were run for each arrangement of orifice plates. In making these tests the flow into and out of the setting was throttled to the extent that there was no pulsation on either meter. By comparing the quantities as measured by the two meters under these conditions, an indication was obtained of how close the meters would check each other when no pulsation was present.

As shown in Fig. 17, the setup is as it was arranged for the determination of discharge pulsation. When the study was made on the effect of suction pulsation the function of the meters was interchanged and the pulsometer was moved to the other meter.

Since changing the speed of the compressor would change the type of pulsation, a by-pass was built into the setting between the inlet and outlet so that it was not necessary to change the speed of the compressor in order to change the rate of flow through the setting. The compressor used was a two-cylinder double-acting Ingersoll-Rand machine having $18^1/_2$-in. × 48-in. cylinders and operating at approximately 70 rpm.

The curve shown in Fig. 18 was determined from the tests at this station. In preparing this curve the results of about 500 tests on orifices with diameter ratios of from 20 per cent to 80 per cent in 2-in., 4-in., and 6-in. lines were studied. It was decided not to attempt to determine any correction factors but to concentrate on the determination of the conditions under which meters would measure accurately. Taking many facts into consideration, it was decided that a meter, subject to pulsation, would be normally within the limits of commercial accuracy when the error was less than 1 per cent. Taking into account spot tests made with commercial setups and recording gages, it was felt that the probable accuracy of any individual test not subject to pulsation was within the range of ±0.5 per cent.

All of the test points were plotted on a large sheet, and the percentage of error was marked on the points. The line was then drawn through the points where the error was approximately 1.5 per cent. Because of the inherent limitations on the accuracy of the tests there were three or four points with an error greater than 1.5 per cent below the curve and ten or twelve points with less than 1 per cent error above the curve. It will be

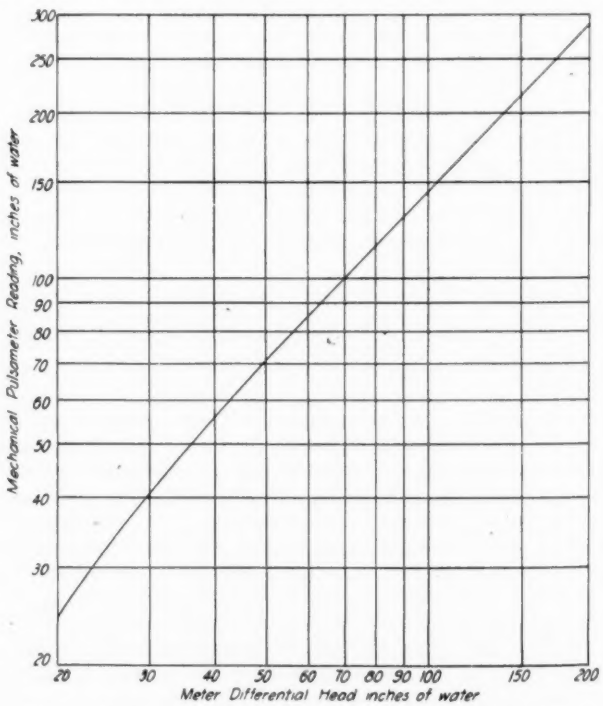

FIG. 18 RELATIONSHIP BETWEEN METER DIFFERENTIAL AND PULSOMETER READING FOR ONE PER CENT ERROR

noted that the same curve applies to both flange and pipe taps.

This curve can then be used to determine whether or not a meter measuring pulsation flow is accurate. It is necessary only to attach the pulsometer to the pressure taps and take a reading on it at the same time that the differential pressure is determined. The calibration curve is then consulted to find the pulsometer reading in inches of water. If the point, when plotted in Fig. 18, falls below the curve, then the pulsation error is less than 1 per cent and the meter is probably within the range of ordinary commercial accuracy. If the point falls above the curve, then the pulsation error is greater than 1 per cent, and the measurement with the meter will not be accurate.

For differential pressures less than 32 in. of water the experimental curve was intentionally curved downward at the lower readings, since operating experience has shown that measurements made at low differentials when the flow is pulsating, are very sensitive to changes in pulsation, and it was felt that the line should be lower than normal to allow the effect of these accidental variations. Because of erratic results the empirical curve was not drawn for differentials below 20 in. of water and if pulsations are present, it is believed better not to attempt to meter the flow where the differentials are as low as that. These curves were plotted on logarithmic paper so that points with the same percentage of error would be approximately the same distance from the curve for any value of the differential head.

In order to make use of the available test results all pulsometers must have the same general dimensions as the one used to determine the effect of pulsation, since the shape and dimensions will undoubtedly have some effect on the instrument reading. This pulsometer is patented and is now being built by the Refinery Supply Company, Tulsa, Okla.

As previously mentioned, the location of the curve drawn in Fig. 18 was determined by experiment, and it was thought that the results might be better understood if there was a rational explanation for drawing it in this manner. In order to see the relationship of the empirical curve to some theoretical curves, Fig. 19 was plotted.

Equations developed in the second section, "Mathematical Analysis," were used in obtaining these curves. Values of the error were found for several values of p/h. Then p/h was plotted against the meter error for each wave form, and the value of p/h for 1 per cent error for each of the three wave forms was determined from the curves. Then a relationship was set up between the pulsometer reading $(p + h)$ and the meter differential (h).

In comparing the theoretical curves with the empirical curve it has been assumed that the pulsometer reading is the sum of the differential plus the amplitude of the pulsation. These curves are all drawn for 1 per cent error. It will be seen that there is a reasonable degree of relationship between the empirical and theoretical curves.

Research to Be Done

Although pulsation has received considerable thought and attention for a number of years and although devices have been built which indicate the presence and others which to a degree indicate the magnitude of the pulsation, considerable work remains to be done.

No use of the pulsometer shown in Fig. 14 has been made in connection with a vapor having pulsating flow. Just how the instrument would behave if the volumes on both sides of the bellows or if the lines leading to the instrument were filled with a liquid remains to be learned through an investigation. At the present time it also seems quite necessary that an instrument be developed for use with meters having low differentials, say, 30 in.

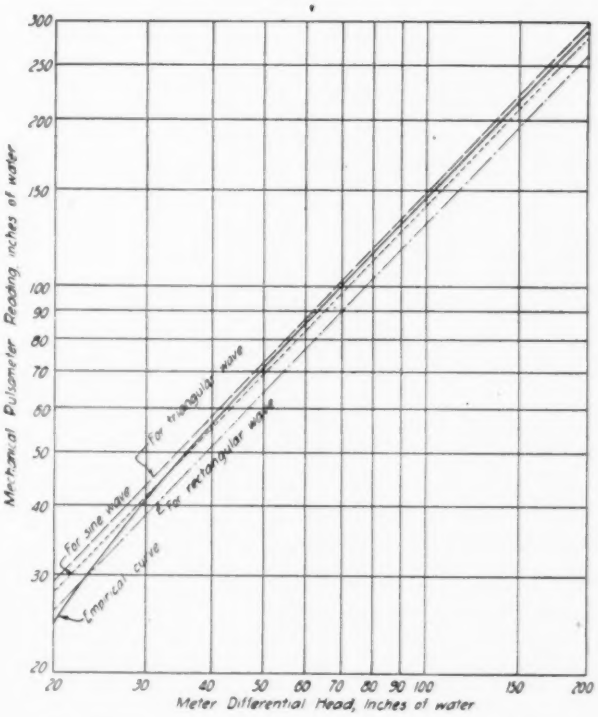

Fig. 19 Theoretical and Empirical Curves for One Per Cent Error

and less. The curve now used, Fig. 18, cannot be used with such low differentials with any degree of confidence.

It is also felt that more of a study of the pulsation theory should be made. Heretofore, pulsation produced by a commercial machine has usually been studied. It would seem to be logical to make a laboratory study of pulsations which could be carefully controlled and varied. In this way the degree of error produced by different devices and with different wave forms could be determined.

The studies mentioned are only a few which need to be made. There are, in fact, many others of equal importance.

Discussion

J. E. Overbeck.[4] The writer has had the good fortune of working on some of the research studies explained, as well as of using some of these research data in practical applications.

If the operating gas-measurement engineers will take full advantage of the information now available, which is set forth in this paper, there is certainly much to be gained. In putting these data to practical application, the first step should be to make a study of all measuring stations to determine which are liable to be affected by pulsation. This can be done by reviewing all stations and determining which ones are located adjacent to compressor stations. The term "adjacent" may mean that the meters are located on the compressor-station lot, or it may mean that they may be up to 20 miles away from the compressor station where there is very little pressure drop or resistance between the measuring station and the compressor station.

Each station suspected should be checked with a mechanical-type pulsometer of the type shown in the author's Fig. 16, to determine whether or not the effect of pulsation is sufficient to cause an error in measurement. Such tests should be made under all of the operating conditions encountered, including rates of flow, number of compressors being operated, lines and connections being used, whether or not the gas is passing through scrubbers, coolers, dehydrators, etc. Generally, the pulsation effect will be the greatest with the least number of compressors being operated and with the least number of connections, etc. It is probable that these tests will eliminate a high percentage of the stations suspected, that is, the effect of pulsation will be within the limits as shown by the author's graph, Fig. 18.

Where the effect of pulsation exceeds these limits and is to be reduced, local conditions surrounding the meter stations are big factors, and which method to use, of course, will depend upon these local conditions. In many instances it may only be necessary to change operating conditions or make only slight changes in the equipment, such as changing orifice size, operating at higher differentials, etc.

From the operating standpoint, the charts shown in Fig. 6 and Fig. 7 of the paper, are helpful in determining whether or not to change the meter differential or change the orifice-to-pipe diameter ratio to obtain the most efficient results. For example, where it is not necessary or practical to change the pipe-run size, it will be found that it is more effective to operate at the highest differential, even though flow conditions require a slightly lower orifice-to-pipe diameter ratio.

For those stations where the pulsation effect is beyond the limits, as shown in Fig. 18, the suggested remedies pointed out by the author will certainly be helpful in reducing the error. Many other types of pulsation dampers have been used. Generally, any change in piping that will, through interference, break up the pulsation waves at the point of measurement will increase the frequency, lower the amplitude, and thus reduce the meter error.

It may be found necessary at some stations to make more than one change, that is, increase the orifice-to-pipe diameter, increase the operating differential range and install some pulsation dampers, or change the arrangement of piping between the source of pulsation and meter.

Author's Closure

The comments by Mr. Overbeck relative to checking and correcting meter installations for pulsation are a valuable addition to the paper.

The author feels certain that there are many others who have something to offer which will shed more light on pulsation. There should be several who have tried eliminators besides the ones shown. There should also be additional references. No doubt the theory of pulsation as given in the paper can be expanded.

The author will appreciate receiving any information on pulsation that any reader may have.

Boiler Design for Extreme Load Variations

By M. H. KUHNER,[1] WORCESTER, MASS.

A summation of required design provisions for boilers adapted to operate under quick demand changes. Reference is made to the quick-pickup boiler in the Harbor Steam Plant of the City of Los Angeles and the steel-mill boiler at the Homestead Works of the Carnegie-Illinois Steel Corporation. The importance of water storage, unrestricted path for water and steam in circulation, steam release with minimum disturbance of water body in drum, steam-temperature control during unbalanced firing, and the effect of each item on the others, is discussed. Recommendations are made for determining required capacity of fuel-burning equipment and fans in reference to the extent and rapidity of steam-load changes.

MOST boilers in public-utility and industrial plants are called upon to carry reasonably steady steam loads. Changes in steam demand are gradual and are often predicted in sufficient time to permit required preparations for load increases or decreases. Boilers of what can be termed standard design usually give a good account of themselves under this type of service.

There are, however, other steam power plants, both public-utility and industrial, in which standard boilers would be quite unsuited. These are the plants where steam demand is unpredictable and where load changes are instantaneous and extreme. Steam-electric plants which stand by hydroelectric stations come under this category.

An outstanding example in the utility field is the Harbor Steam Plant of the City of Los Angeles, where a single boiler and turbine-generator unit must be prepared to pick up loads at the rate of 50,000 to 60,000 kw within seconds and without previous warning, Fig. 1.[2]

In the industrial field the steam power station of the Homestead Works of the Carnegie-Illinois Steel should be mentioned, Fig. 2. A single boiler and turbine-generator unit feeds steam and power into the lines of the entire system of "Big Steel's" Pittsburgh district. Whenever a deficiency in steam or power develops in any one of the steel-mill units, it must be made up by the Homestead Works Power Station. Instantaneous load-rate changes as great as 250,000 lb of steam per hr and 20,000 kw are quite frequent.

In the design of boilers suitable to serve safely and reliably in a power plant with sudden and extreme load variations, the following major points must be given careful consideration:

1 That portion of heat stored in the boiler which will become available at once for steam formation with reduction in pressure.

2 Path of water and steam through circulatory system.

3 Release of steam formed by flashing in the water body.

4 Control of steam temperature while steam output and firing rate are out of balance.

5 Effect of rapid thermal changes in steam, feedwater, and combustion gas on boiler pressure parts.

6 Methods of firing and capacity of fuel-burning equipment.

7 Selection of mechanical-draft equipment and drives as to type, capacity, and control.

8 Construction of setting enclosure for momentary high internal setting pressures.

9 Automatic equipment for control of firing and flow of fuel, air, gas, and feedwater.

Heat Storage

When the steam-output rate of a boiler increases elevenfold in a matter of 4 or 5 sec, as is the case with the Harbor Steam Plant boiler, it cannot be expected that the firing rate can be made to increase proportionately and at the same time. Response of the automatic control naturally lags because the control receives its primary impulse from steam pressure or steam flow. It takes time for the fans to speed up, for dampers to arrive at the new setting and for increased fuel and air quantities to reach the furnace. During this time lag the boiler is required to perform somewhat like a steam accumulator. Steam delivered over and above that quantity generated by the existing furnace heat input must be produced by flashing, using heat stored in the boiler water. Part of this heat is made available with reduction in boiler pressure. Steam is formed in the body of water contained in drums, tubes, and headers. The greater the weight of water below the working level, the more heat is available for flashing of steam and the smaller will be the pressure loss for a given steam output. To have the highest possible pressure and heat head available at the moment of load pickup, it is advisable to control the drum pressure of the boiler rather than the pressure at the superheater outlet or at the turbine throttle. The difference between the drum pressure existing at the moment of the beginning of the load pickup and the lowest drum pressure permissible for the work to be done determines the steaming rate during accumulator operation, and the maximum permissible time lag between start of high steam output and correspondingly increased furnace heat release.

The example of the Harbor Steam Plant boiler is probably best suited to illustrate the importance of heat storage. A standard boiler unit of 650,000 lb capacity at 1000 psig, 900 F usually contains approximately 2500 cu ft of internal cubical space below the working water level in drums, tubes, and headers. The Harbor boiler has 3500 cu ft. Its hourly steaming rate is between 60,000 and 100,000 lb, while it is under stand-by load. The drum pressure is maintained at 1040 psig. It can be assumed that during the low steaming rate of stand-by operation the space below the water line is occupied by substantially solid water, that is, water almost free of steam bubbles. The turbine is constructed so that the peak generating capacity can be maintained with 840 psig throttle pressure. Maximum pressure drop through the superheater, steam-temperature control system, and steam line from boiler to turbine, is approximately 100 psi. The boiler-drum pressure may therefore be permitted to drop 100 psi during accumulator operation before capacity power output of the plant is impaired.

Saturated water totaling 3500 cu ft at 1048 psig, which is the mean pressure between water level and lowest point of the system, equals 160,000 lb. It contains 551.9 Btu per lb, or a total of

(650,000 lb per hr, 1040 psig drum pressure, 915 F steam temperature. Boiler and 65,000 kw turbine generator operate as "spinning reserve" for hydropower. Boiler automatically picks up steam-load rates of 600,000 lb per hr within a few seconds.)

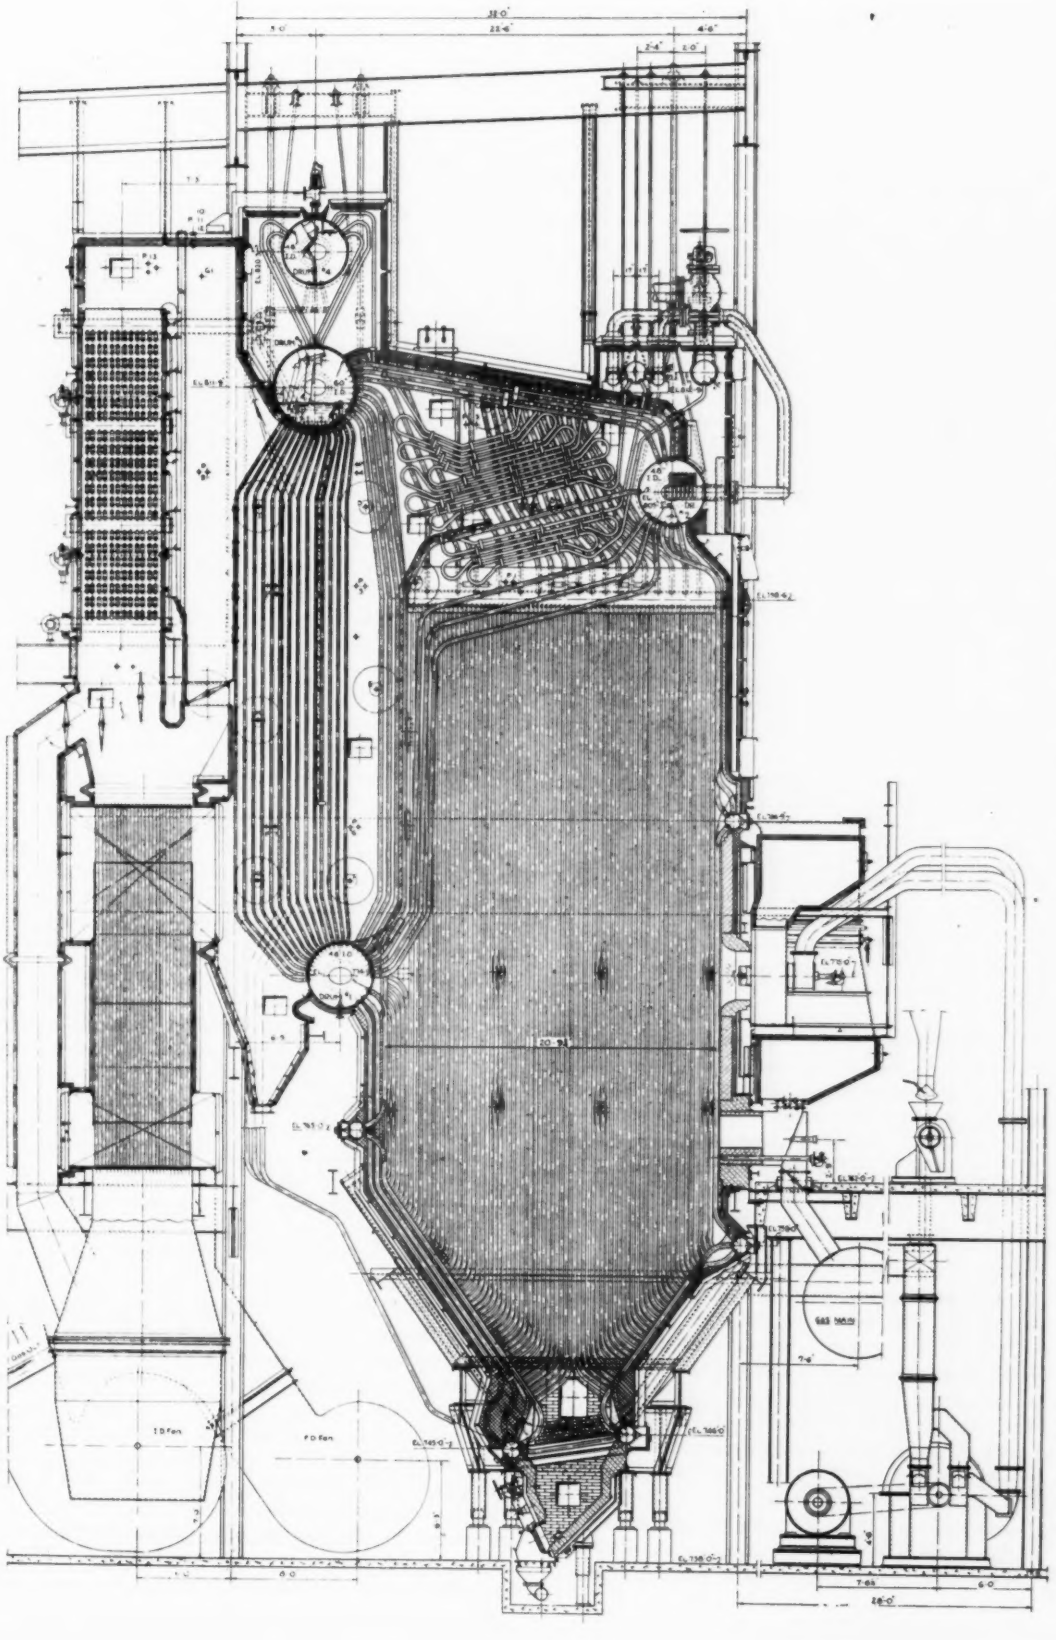

FIG. 2 450,000 LB PER HR BOILER UNIT OF CARRIE FURNACES PLANT, CARNEGIE ILLINOIS STEEL CORPORATION
(Steam-output rates change rapidly between 200,000 and 450,000 lb. Fuel is blast-furnace gas and pulverized coal. Steam temperature automatically controlled by heat-exchanger-type control.)

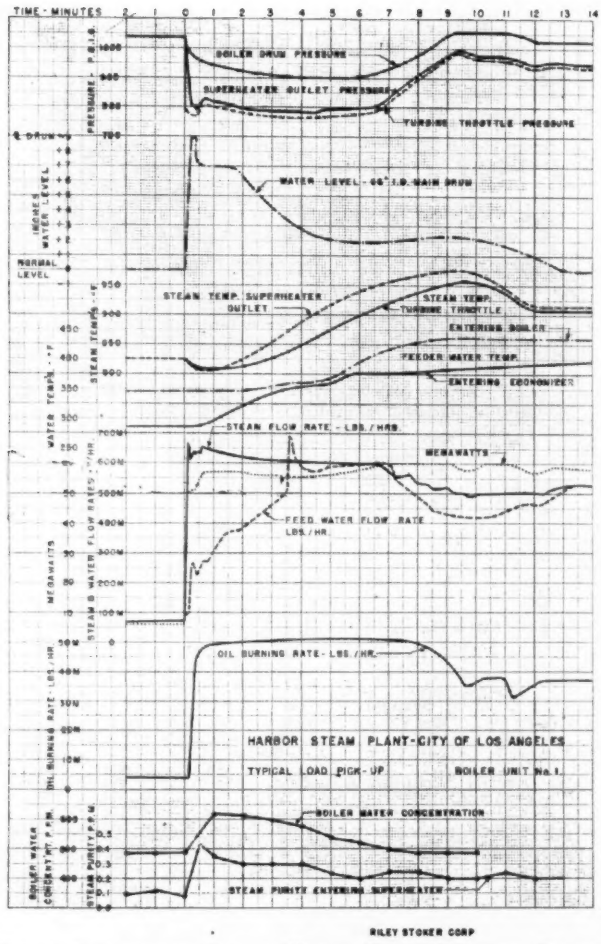

FIG. 3 PERFORMANCE DATA OF HARBOR BOILER RECORDED DURING TYPICAL STEAM-LOAD PICKUP FROM 70,000 LB STAND-BY RATE, TO APPROXIMATELY 650,000 LB PER HR

88,200,000 Btu. If the mean pressure is 100 psi lower, or 948 psig, each pound of water contains 537 Btu and the total heat in 160,000 lb of water is 85,900,000 Btu. The difference, 2,300,000, is available as heat to be flashed into steam.

The heat of evaporation at the mean pressure between the initial drum pressure (1040 psig) and the pressure at the end of the accumulator cycle (940 psig) is 648.5 Btu per lb; 2,300,000 divided by 648.5 = 3550 lb of steam can thus be flashed from boiler water.

The Harbor boiler must deliver steam at the rate of approximately 650,000 lb per hr to develop 55,000 kw output under rapid pickup conditions. The firing rate is established to produce only approximately 60,000 lb per hr prior to the moment the load rise begins. The difference at the rate of 590,000 lb per hr must be made up by flashed steam. A steaming rate of 590,000 lb per hr is 164 lb per sec; 3550 divided by 164 is 22; therefore the heat stored in the boiler water permits the maintenance of 650,000 lb per hr steam-output rate for only 22 sec duration if the firing rate corresponding to 60,000 lb steaming rate is maintained. The boiler-drum pressure will drop from 1040 psig to 940 psig during this period. The 22-sec time lag is usually sufficient for the fuel-burning rate to increase and to meet the new steam-output rate, Fig. 3.

CIRCULATORY SYSTEM

While the design for unidirectional circulation of water and steam is a basic requirement for all water-tube boilers, it becomes much more important where boilers are subjected to rapid load variations. Not only must the design of the system insure that there can be no stoppage or reversal of flow in any of the steaming tubes during a quick load change, but the path of water and steam must be easy and direct. Abrupt changes in internal cross-sectional area within the circulatory system must be avoided.

A sudden change in steam-output rate results in a momentary disturbance of the flow of water and steam in circulation. If the load suddenly rises with a resulting drop in drum pressure, steam is formed in the entire body of water contained in steaming tubes as well as in downflow and feeder tubes, wherever the water temperature corresponds with steaming temperature. The buoyancy of the steam globules formed in the downflow column opposes the downflow of solid water. The rate of circulation is naturally low during low rates of evaporation. If there are restrictions and obstructions placed in the path of natural circulation, a quick load rise will certainly produce stoppage and reversal of flow in some steaming tubes. This may lead to tube failures. If, on the other hand, the circulatory system is designed so that water and steam can find no serious obstruction in their path, full use can be made of the flywheel effect of the mass of water in motion.

It is calculated that the average circulating velocity of water in the Harbor boiler is approximately 2 fps during 60,000 lb per hr evaporation. The momentum of 80 tons of water traveling at this velocity is an effective force opposing the buoyancy of steam flashed in the water during a load pickup. It assures that unidirectional flow is maintained in all tubes. This boiler has been subjected to a number of rapid load pickups during the past 3 years. The performance recorded by curves, Fig. 3, is typical for such surges. No circulation difficulties were detected.

STEAM RELEASE

Releasing the steam generated in the open drum space of the main boiler drum above the water level prevents geysering and turbulence of the water body in the drum and seesawing of the water level. In general, this method effects rapid separation of steam from water. A design incorporating this provision is an advantage for all boilers regardless of type and service.[3]

Rapid steam-load changes are accompanied by water-level variations because the steam formed in the body of water during a sudden load rise, not paralleled by corresponding increase in heat input, tends to lift the water level. The volume of the fluid below the water level increases in direct proportion to the volume of steam formed in the water body. Conversely, a sudden reduction in load, accompanied by a slight rise in boiler pressure, causes steam globules already formed, to collapse, resulting in a shrinkage of the volume below the water line and a drop in water level.

It is important therefore that the drum in which steam is released and in which the working water level is to be maintained, be unusually large. The maximum rise in water level must not reduce steam-release space to the point where there is danger of water carry-over, and the drop in water level must not be such that the entrance to the downflow system becomes exposed and steam, in place of solid water, is permitted to enter the downflow column.

When the drum is equipped with a steam-cleaning and drying device the efficiency of this apparatus is usually dependent upon the height of the water level in the drum. If the level is too high the steam-purifying system may become flooded; if too low, dirty steam and boiler water may by-pass the purifier with disastrous results for superheater and turbine. Because large changes in water-level elevation cannot be prevented during

[3] "How Steam Is Released in Water-Tube Boiler Drums," by Max H. Kuhner, *Power Plant Engineering*, vol. 48, September, 1944, pp. 92–94.

sudden large changes in steam-output rates, it becomes necessary to study carefully the placement of steam-purifying equipment and a larger than normal drum diameter, or a separate steam-purifier drum is indicated.

The Harbor Steam Plant boiler is equipped with a 66-in-ID steam-release drum plus a 36-in-ID steam drum placed above at 14 ft vertical center distance. The volume of water contained in the 66-in-ID drum with the water line at normal elevation is 350 cu ft while the steam space above the water line is 1110 cu ft, Fig. 4. The normal water level is established at 9 in. below the horizontal center line of the 66 in. drum. The water level may rise 11 in. from normal during a load pickup or may drop 6 in. below normal with a sudden steam-load reduction before steam release, steam purification, and water supply to downflow column are affected. The effectiveness of this arrangement is indicated by the steam purity recorded during load pickups. The solids carried away in the steam usually increase momentarily from approximately 0.1 ppm to 0.5 ppm, Fig. 3.

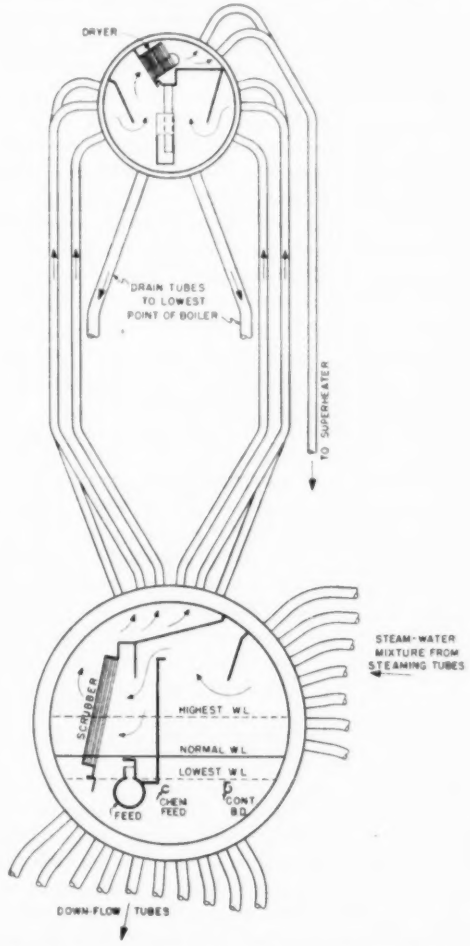

FIG. 4 STEAM-PURIFYING SYSTEM HARBOR STEAM PLANT BOILER NO. 1

STEAM-TEMPERATURE CONTROL

During normal operation of a central station or industrial boiler final temperature of steam delivered by the superheater is influenced by moisture content of the steam entering the superheater, steaming rate, length of flame, excess air used for combustion, type and kind of fuel, cleanliness of furnace wall and water heating surfaces placed ahead of the superheater, and cleanliness of the superheater surface. These are all factors which can change the steam temperature of an installation. A relatively simple system of steam-temperature control is usually sufficient to produce a workable steam-temperature characteristic in spite of the factors of normal operation mentioned. A system based on control of gas flow over superheater surface or on partial desuperheating is often sufficient to prevent a rise in steam temperature to the point where superheater and turbine are endangered, because each individual factor, or a combination of those mentioned, will not so seriously influence the final steam temperature that the range of a correctly designed control is exceeded.

With a quick-load-pickup boiler additional factors must be considered as affecting steam temperature. During a sudden load rise, and while the firing rate lags 20 to 30 sec behind the increased steam output, very little heat is applied to the superheater surface and a drop in steam temperature must be expected. On the other hand, steam temperature will rise sharply with a sudden drop in steam demand because the firing rate, corresponding with the higher load, continues several seconds after the load decrease has taken place. More heat is therefore applied to the superheater surface than can normally be carried away with the steam. Conditions are aggravated for a purely convection superheater because its normal characteristics produces a steeply rising temperature gradient with increasing steaming rate. A superheater designed so that part of the heat is received by radiation and the remainder by convection, produces a more uniform steam temperature over a wide range in load. Obviously therefore a superheater of this design insures a higher steam temperature at the beginning of the load-pickup cycle, and the effect on steam temperature by the unbalance of steam flow and firing rate at the moment of a sudden load drop is not as pronounced as with the purely convection superheater.

In addition to the points mentioned as affecting superheater performance there is one factor identified with quick-load-pickup boilers only which has a severe effect on steam temperature. Heat removed from boiler water by flashed steam, with the reduction in pressure, must be restored after the high steaming rate is established and while pressure is raised to normal. The fuel-burning rate is therefore not only that required to generate the steam delivered by the boiler, but in addition, that necessary to restore the heat to the boiler water and thus re-establish the normal operating pressure. The heat input to the superheater is considerably greater during the time pressure is being restored

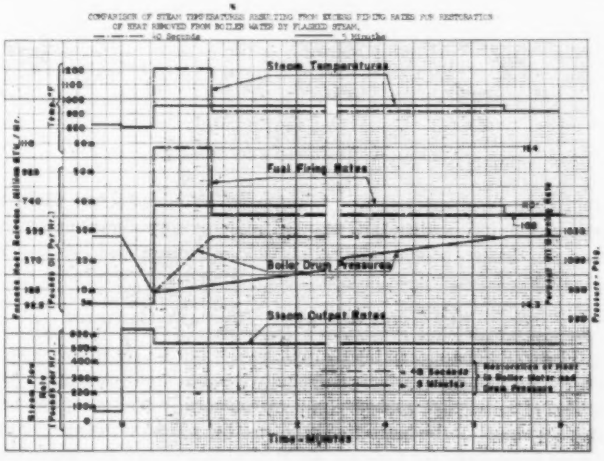

FIG. 5 COMPARISON OF STEAM TEMPERATURES RESULTING FROM EXCESS FIRING RATES FOR RESTORATION OF HEAT REMOVED FROM BOILER WATER BY FLASHED STEAM

than required for normal steam temperature at the existing steam flow. During this period steam-output rate and firing rate are out of balance with the firing rate a considerable percentage greater than needed for the steam output. The result is high steam temperature. The excess rate of firing is, of course, in inverse proportion to the time permitted to restore the heat in the boiler water and to establish normal drum pressure, Fig. 5. The maximum permissible steam temperature usually limits the excess rate of firing and thus controls the time required for restoring normal drum pressure.

Gas by-pass dampers for controlling steam temperature are too sluggish to be effective at the moment of a rapid load increase. The heat-exchanger type of control, or one employing direct-contact water sprays, is more suitable because its action is almost instantaneous if it receives its impulse automatically from the steam temperature, and especially so if the control anticipates a steam-temperature rise by receiving its primary impulse from steam flow.

Thermal Changes

It is apparent that rapid load changes produce rapid temperature changes in feedwater, steam, and combustion gas. Fig. 3 shows that during an instantaneous load pickup by the Harbor Steam Plant unit from 70,000 to approximately 630,000 lb steaming rate, the feedwater temperature rose from 270 to 380 F in less than 6 min, while the steam temperature dropped from 825 F to approximately 800 F in 45 sec, then rose to 975 F in 8 min. The increase in firing rate, from approximately 4000 lb of oil per hr to over 50,000 lb in less than 1 min, naturally produced a rapid rise in the temperature of combustion gas passing over the heating surfaces.

Rolled tube joints and welded pressure connections must be insulated against direct impact of combustion gas to prevent damage from temperature shocks. Feedwater entrance connections must be designed to prevent water of rapidly varying temperature from contacting the drum steel, Fig. 6. The entire pressure system must be suspended in a manner which permits free thermal expansion and contraction without placing unpredictable strains and stresses on pressure parts, setting enclosure, and supporting members.

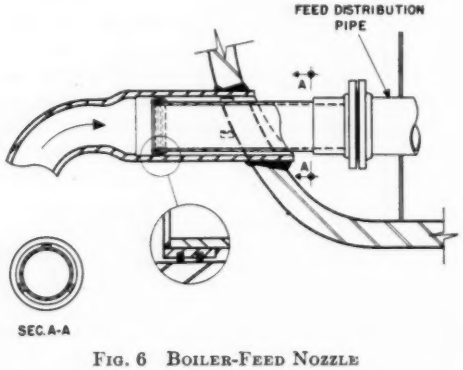

Fig. 6 Boiler-Feed Nozzle

Fuel-Burning Equipment, Type and Capacity

The rapid changes in heat-input rates required by widely varying steam demands call for extremely flexible fuel-burning equipment. Liquid and gaseous fuels are naturally well adapted for this service but burners must be of the wide-load-range type. There is no time for lighting additional burners or for changing burner tips or guns at the moment of load pickup. Neither will the available time permit taking burners out of service or making manual adjustments during a sudden drop in load.

In the case of the Harbor Steam Plant, where oil is the principal fuel, all ten burners are in service at all times. The combined burning rate is only approximately 4000 lb of oil per hr during stand-by operation, but in case of a load pickup the burning rate will have increased to more than 50,000 lb of oil per hr in less than 1 min, Fig. 3. A maximum burning rate of 60,000 lb per hr can be maintained.

Where coal must be burned stokers are usually not suitable because their operating characteristics prevent the required flexibility of heat liberation for quick steam-load changes. Pulverized-coal-firing is better adapted. Although response to load changes is rapid with correctly designed pulverized-coal equipment, the wide range of burner performance easily obtainable with oil and gas is usually not secured. A supplementary fuel, such as gas or oil, may have to assist the maintenance of stable ignition where the load swings to extremely low points.

An outstanding example of this method of operation is the steam-generating unit of the Rankin steam-electric station of the Carnegie-Illinois Steel Corporation, Fig. 2. This unit, of 450,000 lb per hr design capacity, is fired by blast-furnace gas as the main fuel, with pulverized coal to make up any deficiency. Sudden changes in steam demand at the rate of 250,000 lb per hr take place, and because the supply of the blast-furnace-gas fuel cannot be changed as rapidly as necessary to parallel steam demands (whatever quantity of blast-furnace gas remains from other operations in the steel mill must be burned under the boiler), the load swings must be handled by pulverized coal.

The typical steel-mill load of this plant differs from the spinning-reserve service of the Harbor Station. While Harbor receives its high load demands without warning as, for example, in case of a break in the transmission lines coming from the Boulder Dam hydroelectric station, the Rankin plant is usually informed of a major load change a few minutes in advance. If a load pickup is announced, pulverizers are started and remain spinning without coal. As soon as the steam demand exceeds the available supply of blast-furnace gas, raw-coal feeders start delivering coal to the mills, and within a few seconds a pulverized-coal flame is established in the furnace. The pulverized-coal burners contain oil pilots permanently maintaining an oil flame sufficient for instantaneous ignition of the pulverized coal and for support of the flame at extremely low burning rates.[4]

The capacity of fuel-burning equipment for boiler units subjected to extreme steam-load variation must be greater than for a standard boiler installation, because the heat to be released in the furnace immediately following a sudden load increase is not only that necessary to produce the steam actually generated in the boiler, but in addition, that necessary to restore boiler pressure and to replace the heat taken from boiler water while the boiler operated as a steam accumulator. This excess fuel-burning capacity must be determined by the time permissible, or available, starting with the moment of load pickup until full boiler pressure is restored. Fig. 5 shows that in the case of the Harbor Steam Plant unit an excess fuel-burning rate of 64 per cent would be required if it were necessary to restore full boiler pressure in 40 sec, whereas if 5 min were permissible, only approximately 10 per cent excess burning capacity would be necessary. This boiler is actually equipped with 28.5 per cent greater fuel-burning capacity than that required for the continuous steaming rate of 675,000 lb per hr

Mechanical-Draft Equipment

The selection of type, capacity, and driving method of fans is governed to a large extent by the required or desired rapidity and magnitude of steam-load changes for which the installation is designed. The construction of forced- and induced-draft fans must,

[4] "Modern Boilers for Steel Mill Plants," by M. H. Kuhner, *Power*, vol. 87, 1943, pp. 650–657.

in any event, be such that mechanical failures caused by the high stresses produced by the torque required for acceleration are prevented. The drive best suited for the requirements should be selected on the basis of the following considerations:

1 Direct-connected constant-speed alternating-current motors. Gas and air flow controlled by dampers or fan-inlet vanes. Quickest response to load change. High power consumption. High rate of wear and tear of fans and dampers. Operating units for dampers must be extra powerful.

2 Direct-connected variable-speed wound-rotor induction motors. Speed range only 50 per cent of maximum. Dampers required for accurate flow control. Power consumption relatively high, but lower than (1). Slower response to load changes.

3 Constant-speed alternating-current motors with hydraulic or electromagnetic couplings. Power consumption less than (1) and (2). Considerable time required for response to load changes. Dampers required for flow control in low load range.

(4) Direct-connected adjustable-speed direct-current motors, variable-voltage control (or electronic control when available for large motors). Economical power consumption. Quick response to load changes. Speed range corresponding to entire steam-load range. No dampers necessary for flow control. Motor generator set required. High investment cost. (Used with Harbor Steam Plant boiler).

The determination of capacity of mechanical-draft equipment must, of course, be governed by the capacity of the fuel-burning equipment. (Refer to section "Fuel-Burning Equipment, Type and Capacity.")

Boiler Settings

It cannot be expected that ten to twelvefold acceleration of burning rates, often taking place in less than 20 sec, will in every case occur without some disturbance of furnace conditions. In spite of the most carefully adjusted combustion control there is always the possibility that the increased fuel flow reaches the burners a fraction of a second in advance of the corresponding air supply. This may result in a furnace puff or, under severe conditions, in a light furnace explosion. One of the fans may speed up faster than the other, creating momentary high positive or negative pressures in furnace and gas passages.

It is evident that greater than ordinary care must be taken in the design and construction of the setting enclosure and gas and air passages. The setting must be strong enough to withstand minor gas and fuel explosions. It must remain tight under this severe service but it must also be sufficiently flexible to absorb internal shocks and damp them so that they are not transmitted to the supporting structure of the boiler and building. This calls for an entire steel shell enclosing the complete unit, reinforced and supported by a system of steel buckstays and girders which is independent of the main supporting structure. Permanent tightness of the joints of casing panels must be insured by flanges with closely spaced bolts, or by complete welding.[5]

The steel casing of the Harbor boiler is constructed to resist internal pressures up to 100 psf (approximately 19 in. water gage) without noticeable deflection. Air and gas passages are arranged for the most direct flow between furnace and fans.

Control Equipment

A reliable system for automatically controlling firing rate, air and gas flow, steam temperature, and feedwater flow must be in use with boilers operating under extreme load variations. It is impossible to attempt manual control of fuel, air, draft, steam, and water because all adjustments are required simultaneously and in step with the variation in steam demand.

It is not within the scope of this paper to recommend the type of control equipment to be used, but in selecting the equipment it must be kept in mind that the time lag of the control mechanism has a very important effect on the performance of the boiler equipment. The time consumed from the moment the control receives its first impulse of a load change, until the control has repositioned the equipment governing flow of fuel, air, gas, steam, and water, must be as short as mechanical limitations permit. If the response is fast the period during which the boiler must perform as a steam accumulator is short and the reduction in drum pressure is small. In this connection it is desirable to study the design of the equipment to be controlled because speedier response may be obtained by having the apparatus to be controlled designed for the least inertia. For example, multiple-leaf and louver dampers in air and gas passages have less inertia than large single-leaf dampers.

The combustion control receives its primary impulse either from steam pressure or steam flow. Because the time element of response to sudden steam-flow changes should be measured in fractions of a second, an arrangement whereby the primary impulse is received from power demand at the output side of the generator rather than from steam demand at the turbine throttle, might be worthy of consideration. Obviously the control mechanism must be self-compensating to avoid vicious hunting cycles.

It is demonstrated that the water level of a boiler rises sharply during a sudden load increase and drops as fast if the steam-output rate is suddenly reduced. The accumulator performance of a boiler and utilization of heat stored in the boiler water, are discussed in the section "Heat Storage." Keeping these facts in mind, it is readily apparent that it would be quite undesirable to have large quantities of relatively cold feedwater enter the boiler at the moment of a load surge. Cold feedwater would not only reduce the heat available in the boiler water for flashing steam, but would tend to raise the water level still further. On the other hand, the entrance of large quantities of colder feedwater is desirable when it immediately follows a sudden drop in steam demand. The water level is then below normal. Excessive heat in the boiler raises the pressure. Safety valves may start to pop. If there is heavy feedwater flow during this critical time the water level will be promptly restored to normal, and part of the excess heat in the boiler water will be dissipated in the fresh feedwater. It is indicated therefore that feedwater flow should be controlled solely by the working water level if the boiler is subjected to rapid load changes. With feedwater flow so controlled, the entrance of fresh water into the boiler is almost entirely interrupted during a sudden load rise and, conversely, large quantities of fresh feedwater will enter the boiler immediately after a sudden load drop. This action effectively stabilizes the water level and reduces the required distance between highest and lowest working levels.

Conclusion

A thorough analysis of the change taking place in a boiler during sudden and extreme steam-load variations must precede the design of the equipment. Expected magnitude of load swings and time permitted for restoring normal conditions in the boiler must be considered in determining the required volume below normal working level and the necessary capacity of fuel-burning equipment and fans. More time is available for response of control equipment when heat storage in boiler water is liberal, but large-diameter costly water drums and headers are required. A study will show whether large accumulator capacity of the boiler can be justified, or if the use of a more conventional boiler equipped with unusually large firing and fan equipment, and controls of extreme speed of response, is more economical.

[5] "Steel Encased Settings for Modern Steam Generating Units," by Max H. Kuhner, A.S.M.E., unpublished paper No. 716, 1940.

In conclusion it can be mentioned that a large number of the design points discussed as being important for boilers handling extreme load changes are equally desirable for boilers operating under more conventional central-station and industrial loads. Other points become of greater or lesser importance, proportionate to the range and rapidity of load changes. The problem thus narrows down to an intimate study of the plant load cycle, a clear understanding of what happens in a boiler during the expected changes in steam demand, and the solution of each problem thus developed by common-sense design.

Discussion

A. G. Ericson.[6] In this paper the author has capably analyzed and co-ordinated the major design factors to be considered in building a boiler for operation under extreme load variations. The importance of a large heat-storage capacity, made available by substantially increasing the size of the main boiler drum and by increasing the weight of water carried below the working level, is readily appreciated. This feature perhaps marks the essential difference from boilers of standard design and is a fundamental requirement for stable operating conditions. The quantity of heat available for flashing of steam within the allowable pressure drop sets the maximum permissible time lag between start of higher steam output and corresponding increased furnace heat release following rapid load rises. As discussed in the paper, the larger quantity of water circulating also assures that unidirectional flow will be maintained during rapid load pickups, and the larger drum size allows the necessary leeway to offset variations in water level accompanying load swings, preventing water carryover during load rises and entrance of steam to the downflow columns during load reductions.

Installation of rapid and reliable control equipment is particularly important as the time required for adjusting the burners, damper settings, feedwater flow, and fan speeds results in a heat deficiency that must be supplied by flashing, and extended lags result in proportionately greater steam-boiler temperature and pressure losses.

The author refers to the 450,000-lb per hr boiler in the No. 3 powerhouse at Carrie Furnaces, Rankin, Pa., as an example of a quick-pickup boiler in the industrial field. Although the boiler was designed for this service, the extreme load variations originally contemplated have not developed in actual operation. This powerhouse is the most efficient in the "Monongahela Valley Power System" of the Carnegie-Illinois Steel Corporation and functions as the major generating unit with an average load rating of 85 per cent of rated capacity. Flexibility of operation is essential, for although the operators are informed in advance of general power requirements, there are inevitably some load swings that cannot be foreseen.

Operation of this boiler, described by the author, through load swings of 100,000 lb per hr has been quite satisfactory. Depending upon boiler-operating conditions at the time, the steam pressure will vary up to 50 psi and the steam temperature rarely varies more than 15 deg F. The steam quality remains good and excessive variation in the water-level, geysering, or turbulence of the water body does not occur. Following a decrease in steam load, the temperature of the superheated steam is effectively regulated by a heat-exchanger type of control. This type of control has a slight disadvantage in imposing additional resistance to the flow of steam through the superheater, therefore causing a greater differential between boiler drums and line pressure. However, it is rapid and accurate and the high-temperature element of the superheater is protected against overheating.

In this respect, it may be added that superheat is one of the most important items requiring control in the modern power plant. Excessive steam temperature is likely to cause damage through creep stresses or loss in tensile strength in both the piping and turbine parts. In addition, fluctuation in steam temperature causes opening up of the joints in the high-pressure unit and steam chest of the turbine, resulting ultimately in leaks.

The benefits to be realized from careful and efficient application of the design features discussed in this paper are dependent principally upon the degree of accuracy with which future load cycles are analyzed and power requirements foreseen.

Dan Gutleben.[7] It is refreshing for an operator of a small sugar-refinery steam plant to learn that a condition can arise which requires a public-service plant to give thought to sudden large load fluctuations. Fortunately, the problem submits to logic and arithmetic in the hands of an experienced engineer. The sudden swings were once considered an unavoidable evil visited only upon the sugar-house engineer whose plant was beset with sugar boilers endowed with untold stupidity. The public-service plants, which set the pattern for steam-plant design, accomplished an amazing job and made empirical design facts available to industrial plants long before the bondholders were repaid for the cost of their full-size research. In 1931 when the Pennsylvania Sugar Company in Philadelphia installed two boilers of 250,000-lb per hr capacity and 400 psi pressure, there was a limit to the size of forged drums, besides their cost; and welding had not become available. Accordingly, the boiler designer's talents for meeting the specification of large and sudden swings did not include accumulator operation. That existed only in the good old Scotch marine boiler of revered memory. The design staff (to which the author was attached) answered our clamor for a steam flywheel by providing a six-drum design, two of the drums being on the economizer. The steam-separating drum was forged 51 in. in diam to suit an available mandrel.

Under a premeditated test, with one boiler on base load at 400 psi pressure, the second one was increased in output by 105,000 lb per hr in 2 min with no pressure drop discernible on the gage, and with a rise of 6 in. in the water level. With the thoughtlessness of the sugar-boiler operators this was improved. Early on a Sunday morning, as the demand tapered off, one boiler was shut down and then the boys phoned that the week-end job was complete. Suddenly a large quantity of thin sweet water was found that required to be concentrated and the hour for adjournment was at hand. Without notice, the flowmeter skyrocketed. The steaming rate jumped from 75,000 lb per hr to 225,000 lb. in two minutes, accompanied by a 15-inch spear in the water-level chart. In a public-service plant such a jump in water level would wreck some turbine blades, but in a sugar refinery allowance is made for stupidity, which is a "gift from heaven." Our plant is equipped with a steam accumulator which can provide an instantaneous supply of 40,000 lb of steam for the pans, but this "dinosaur egg" happened to be empty.

H. J. Klotz.[8] The subject of this paper is most timely, as indicated by the recent increase in the number of proposed power-station installations required to operate under wide load variations. The author is to be commended for his logical analysis of the problem and his clear-cut treatment of the various factors which have important influence on the successful operation of equipment under the severe conditions described. In fact, the success achieved in developments such as he has described has en-

[6] Chief Engineer, Homestead Steel Works, Carnegie-Illinois Steel Corporation, Munhall, Pa.

couraged operators, never noted for their backwardness in asking for the impossible, to demand even greater load changes in smaller time intervals. Whereas the Harbor Steam Plant is required to handle a load increase at the rate of about 10 to 1 in a matter of seconds, operating conditions on some utility systems make it desirable to increase the ratio to 20 to 1. The resourcefulness of boiler and other equipment manufacturers, as typified by the work behind this excellent paper, leads the operators to expect that the increased severity of their requirements will be met.

Of the various factors involved, it would seem that all of the features described by the author, with the exception of the fuel-burning facilities, could be expected to be adapted without too great difficulty for the higher ratio of load increase. As pointed out in the paper, only gas and fuel oil are suitable for the minimum rates of firing required by installations of the type under consideration, and where pulverized coal is the basic fuel, supplemental use of the former fuels would be a necessity. A range in firing rates of 20 to 1 is a severe requirement which imposes serious problems in the achievement of a satisfactory design for burning even such flexible fuels as gas and fuel oil. Also, in this connection, a furnace arrangement suitable for stable combustion at the minimum firing rates is of great importance, especially in cases where pulverized coal is to be the basic fuel. Maintenance of stable combustion of course is the factor which prevents pulverized-coal firing from having the required maximum load range without use of supplemental fuel.

C. C. McKee.[9] The author has selected a subject that well deserves considerable attention; especially for those utilities which depend upon hydropower for the major portion or all of their electric supply. Usually in these systems, after installations are complete, the cost of hydropower generation, particularly secondary or dump power, is lower in the hydroplant. For this reason the power produced from steam plants is held at a minimum to reduce fuel cost. Under such circumstances steam plants are required to operate at minimum loads or about enough power to supply all auxiliary drives.

Then when a major disturbance occurs, such as loss of a transmission line, it is necessary for the steam plant to assume full load, without any previous warning, and with automatic controls to bring the steam generator into action, not only to meet all turbine requirements, but also to replace energy lost from the unit by the accumulator action while the automatic controls were bringing combustion and combustion equipment from low load to maximum capacity.

There are points of interest shown in Fig. 3 which are not indicated in the text of the paper. A study of the pressure-drop curves shows there was a slight indication for a return to normal between 30 and 40 sec. This indication was shown to much better advantage when these curves were plotted to a larger scale. The further drop following this point was caused by the feedheating system going into action at that time. This early increase of feedwater flow has been corrected and a recent test for quick pickup indicates that increased flow of feedwater was delayed for about 1½ min after application of load. There was little, if any, secondary pressure drop; however, the load picked up was less than that shown in Fig. 3 by about 5000 kw.

There is no rebuttal to the question that the boiler for such service must be designed to meet the severe demands; but automatic controls must also come in for their share of praise in their ability to be adjusted, timed, and synchronized to bring all steam-generating equipment to overload capacity in less than 25 sec.

Another interesting item which was checked in particular in our recent quick-pickup test is that the temperature of the feedwater entering the economizer was higher than that leaving, by some 10 deg. In the test data obtained for the curves in Fig. 3 the temperature readings for economizer feedwater in and out were read and indicated this condition, but they were considered unreliable. There was a reluctance to show this condition before checking it thoroughly. During the recent test this particular item was checked carefully, with the result that there is no hesitancy in saying that for a period of 2 to 2½ min, the temperature of the incoming feedwater is actually higher than the outgoing feedwater from the economizer. Our estimate of the reason for this condition is that it takes about that long to move the cold water through the economizer.

W. C. Rowse.[10] The writer, who is in charge of the Steam Design Section of the Los Angeles Department of Water and Power, set forth the fundamental requirements for a steam plant which must operate in parallel with hydroelectric plants in an article which appeared[11] before the first unit of the Harbor Steam Plant went into operation. In that article it was stated that the plant should have the ability to operate over a wide range of load factors with reasonably good economy and in addition, the ability to pick up full load instantly when floating on the line at a light load, which latter requirement affected the design of the boiler.

In his paper the author clearly sets forth the boiler-design problems and how they were solved, together with the results of the first quick-pickup test with special fast-recording instruments made on October 12, 1944. The writer's discussion of the paper will consist of a brief statement of actual experience in operation.

Following the usual ups and downs incidental to placing a new unit in operation, particularly the first unit of a new plant, by March 1, 1944, the plant settled down to regular operation, except for the 4000-kw house turbine-generator unit which was appropriated by the Federal Government and shipped to Russia. Since that date the plant has been subjected to all kinds of loads from a minimum output of 64,000 lb of steam per hr continuously to a maximum output of 723,000 lb of steam per hr for 1 hr, all under full-automatic control with all burners on and including quite a few cases of quick pickup of load in emergencies. The most publicized of these was the occasion on March 18, 1946, when two airplanes collided, cutting conductors on two circuits from Boulder Dam, thus cutting off 300,000 kw of generating capacity furnishing energy for the total load of 533,000 kw being carried at that time. Although the frequency at the Harbor Steam Plant dropped momentarily to 40 cycles and continued for 10 min at 50 cycles, which shut down the fans three times, the plant picked up 55,000 kw immediately and 75,000 kw within a few minutes and carried this 75,000 kw for 1 hr. The value of the accumulator effect of the boiler was abundantly demonstrated by the ability of the boiler to supply steam even during the fan outages. These fan outages were due partly to the low frequency of energy for auxiliaries which will not occur again because the turbine-driven house generator is now installed, and partly to the setting of the protective thermorelays on the fan drives, which latter has been corrected. Since March 1, 1944, the only unscheduled outages of the steam-generating unit were for three leaks in economizer welds which were repaired over week ends.

An exhaustive test was made of this boiler during the first part of 1944, under the supervision of Mr. Sheppard T. Powell, primarily to check circulation and to recommend boiler-feedwater

[9] Mechanical Engineer, Department of Water and Power, City of Los Angeles, Calif.

[10] Engineer of Steam Design, Department of Water and Power, City of Los Angeles, Calif. Mem. A.S.M.E.

[11] "Some Features of the Harbor Steam Plant of the Los Angeles Bureau of Power and Light," by W. C. Rowse, *Mechanical Engineering*, vol. 64, 1942, pp. 773–776.

treatment and control procedures. At first a total of over 100 readings and analyses were made on each shift. As knowledge of the circulatory and other characteristics of the boiler increased, some of these readings and analyses were discontinued until, after about 6 months, a normal feedwater-control procedure was evolved. One important result of these tests was to demonstrate clearly that the boiler had been properly designed especially as to positive circulation and delivery to the superheater of steam of the required purity.

On April 24, 1946, the installation of the 4000-kw house turbine was completed, and on May 8, 1946, a quick-pickup test was made, with adjustments to the automatic controls which resulted in holding back boiler feedwater longer, and in faster opening of the fuel-oil valve. The method of increasing the load instantly is interesting. One unit at Boulder Dam was loaded with the exact load which the Harbor Steam Plant was to pick up. The 4000-kw turbine-generator unit at the Harbor Steam Plant was carrying the auxiliaries, the main turbine-generator unit was carrying 10,000 kw on the low governor block, the high governor block was set for the load to be picked up and the governor was set for a slightly higher speed than 3600 rpm. When the circuit-breakers at the Boulder unit were opened, the momentary drop in system frequency tripped the low block on the Harbor unit which picked up the load instantly with only a momentary change in system frequency. Although the load picked up (48,000 kw) was not as large as the engineers desired, the results showed a great improvement in every way over the previous test of October 12, 1944. The time required for return to normal conditions was shorter, and the maximum steam temperature lower (only 925 F at turbine throttle) than the previous test. It should be noted that both tests were made under full automatic control.

The over-all efficiency of the plant has been better than the expected efficiency. A Willan's line, in which barrels of oil per month are plotted against kilowatt-hours net output per month, results in a formula of 5250 bbl of oil (6,250,000 Btu per bbl) per month for zero net output plus incremental oil at the rate of 595 kwhr net output per barrel of oil. This results in an over-all efficiency of 11,250 Btu per kwhr net output at rated capacity (62,000 kw net output), as compared with an expected value of 11,400 Btu.

Author's Closure

It is very gratifying to have the correctness of the conclusions reached with this paper verified by the actual performance experiences with quick load pickup boilers reported by Mr. Rowse, Mr. McKee, and Mr. Ericson. These discussers' comments are of specific interest because they point the way to further improvements in steam plants required to operate under unusual load conditions.

Progress in any field is gradual and if the steps forward are not too large the result of the future step can be predicted with reasonable accuracy by the experience with the present. A boiler load increase of 1 to 10 taking place in a few seconds and without trouble was considered quite hazardous only a relatively short time ago. Mr. Klotz mentions the future requirement for load pickups in the ratio of 1 to 20. A safe boiler design for this condition is today entirely feasible if the Harbor Steam Plant experiences are made the basis for this next step.

Mr. Gutleben's reference to the human element in steam plants points to the importance of the correctly designed complete automatic-control system mentioned by Mr. McKee, but the steam-plant operator is well advised not to take the designation "automatic" too literally. Automatic control cannot replace human thought. It is especially important in plants subjected to extreme load variations that the men in charge know intimately the sequence of the various operations normally performed by the controls. The operators must be trained to take over and operate manually in case of failure of the automatic controls. Several of the pickup tests referred to by Mr. Rowse were performed to acquaint the Harbor Plant operators with all that can happen during a bona fide pickup and to instill confidence in the equipment.

The valuable supplementary data and information supplied by the discussers are gratefully acknowledged.

Acid-Cleaning of Boilers and Auxiliary Equipment

By S. T. POWELL,[1] BALTIMORE, MD.

Acid-cleaning of equipment has been demonstrated over a long period as a useful and economical means for removing encrustations from boilers and many other types of power-plant equipment. This paper explains the use of various cleaning reagents and inhibitors, the procedure which should be followed, and the precautions to be taken to safeguard both personnel and equipment from the hazards inherent in the process.

THE use of acid to remove deposits from metallic surfaces has been practiced for many years and in widely divergent industries. Such processes have been and still are extensively employed for the removal of mill scale from sheets, plates, tubes, and other products in mills making steel and copper alloys, and enormous quantities of acid are used for such services. The economy and speed gained in removing deposits in this manner have directed attention to many applications, and the treatment has been extended to the cleaning of oil wells, water mains, heat-exchange equipment, boilers, and other equipment. The extensive acidizing of oil wells to improve yields, by removing deposits and opening the formations, did much to attract interest and suggest other applications.

One of the most interesting acidizing projects,[2] which was performed more than 25 years ago, was the cleaning of the entire piping system in The Bankers Trust Building in New York City, a 35-story office building. After 12 years of service the pipe lines throughout the structure were seriously clogged with corrosion products. It was estimated that repiping would cost from $100,000 to $300,000 and could be done only at serious inconvenience to the tenants. Sections of the piping system were cleaned by means of inhibited muriatic acid in about 8 hours, after the offices were closed on Saturdays. It is surprising that this novel method of cleaning pipe lines did not receive more widespread interest at that time since the basic principle of the procedure has much merit. It is obvious that removal of deposits is merely a temporary expedient and must be followed by other forms of corrective treatment to avoid their recurrence.

The removal of scale from boiler surfaces was a logical development after the practical application of acidizing for other uses was demonstrated. The most rapid expansion of this method of boiler cleaning, however, has occurred within the past 4 or 5 years because of the need for reducing boiler outages to a minimum, and because of the shortage of labor during the war period. The effectiveness of acid cleaning is demonstrated in Fig. 1 which shows the heavily encrusted tubes of a chemical evaporator. Fig. 2[3] shows the same evaporator after being cleaned.

Thousands of boilers and miscellaneous equipment units have been cleaned by acid during the last few years and a majority of these treatments have been successful. It is a recognized fact, however, that even though inhibitors may be used, these compounds do not completely prevent corrosion, but merely reduce the rate and extent of the attack. Under ordinary conditions the corrosion of the surfaces is relatively minor if an effective inhibitor is used, if the temperature is satisfactorily controlled, the contact time limited, and subsequent washing out and neutralization of remaining acid properly performed.

Considering the large number of boilers which have been acid-cleaned, there have been only a relatively few cases where noticeable corrosion has taken place; however, there is no accurate record of the extent to which all acid-treated equipment has been corroded. From our personal experience we are inclined to believe that where the temperatures have been properly maintained and if the acid was thoroughly removed from the surfaces after cleaning, the extent of attack has been minor, and repeated acidizing may be undertaken without seriously damaging equipment. The primary object of this paper is to direct attention to the potential possibility of serious damage if the work is performed carelessly and without proper regard to precautionary measures required to insure satisfactory results.

Although acidizing of boilers is most widely practiced in power plants, still there are many other applications in this field. These may be broadly classified as follows:

1 Boilers, economizers, superheaters.
2 Deaerators, vent condensers, and stage heaters.
3 Surface condensers and heat exchangers.
4 Feedwater-treating equipment.
5 Valves and miscellaneous equipment.

Each of these applications requires special study and the treatment must be selected and applied to meet the conditions encountered.

Mechanism of Effect of Inhibitors on Acid Corrosion

There are two general concepts regarding the mechanism by which inhibitors protect steel or other metals when in contact with acid solutions. One group of investigators[4] suggests the following mechanism: Iron goes into solution at the anodic regions, forming ions, while hydrogen is discharged in equivalent amount at the cathodic areas. The cathodic areas occur principally in the narrow spaces of grain boundaries in steel or between the slag and metal in wrought iron. Most inhibitors are bases or positively charged colloids which, when present, travel to the cathodic areas and are deposited and adsorbed on the surface. The electrochemical process is stopped when the reaction at either pole is stifled, and the inhibitor thus retards corrosion. It has also been stated that the presence of the inhibitor raises the hydrogen overvoltage above any potential which can exist in the acid-metal system.

A second explanation is that the inhibiting compounds serve to blanket the entire metal surface by a protective layer of the

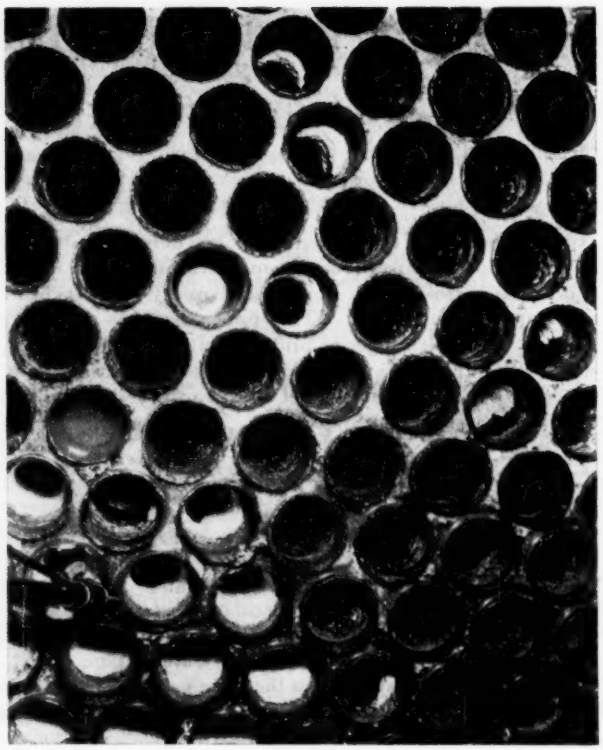

FIG. 2 CONDITION OF EVAPORATOR TUBES, SHOWN IN FIG. 1, AFTER ACIDIZING

organic compound used. This occurs as simple adsorption of the inhibitor ions on the metal surface, through the nitrogen atom which is a component in most organic inhibitors. The stereochemical structure of the inhibitor determines its effectiveness because the structure controls the degree of concentration that will occur.

Others have gone further and contend that inhibiting substances form a nonpermeable blanket through which the hydrogen cannot diffuse and which is limited to the metal surface, as contrasted to the oxide surface.

One investigator has submitted data to show that the action of inhibitors cannot be explained by the electrochemical or overvoltage theory nor by the formation of an impervious pore-free film on the oxide-free metal surface. Test results have been submitted to indicate that inhibitors are adsorbed simultaneously on both metal and oxide surfaces; however, the concentration is heavier on the clean metal surface. The film which forms increases the electrical resistance from liquid to metal, but the film is porous, being built up of molecule aggregates or micelles spaced closely together, similar to a pincushion filled with pins. The theory developed from these studies is that the long-chain molecules thus form long narrow channels similar to capillaries or gel structures. This condition is reflected in reduced diffusion velocity and migration velocity of the hydrogen and sulphate ions which are active in the corrosion of iron in sulphuric acid. The net result is a reduction in the corrosion of the metal, and inasmuch as a more concentrated film is present at the clean metal surface, the oxide is attacked relatively faster than the metal. This results practically in removal of the oxide and preservation of the metal surface.

It has been contended that the corrosion of some boilers during cleaning with inhibited hydrochloric acid is due largely to the formation of ferric chloride which, in itself, is a highly aggressive salt and against which the common inhibitors are not effective. According to this theory the inhibitors will retard the electrochemical reaction involving the displacement of the hydrogen of HCl by iron, but they will not prevent the oxidation-reduction reactions by which ferric chloride oxidizes metallic iron and copper to the ionic form. If metallic copper is in the sludge, ferric chloride attacks it as it does iron, producing cupric chloride which is also an oxidizing agent and a second source of trouble. It is held that the plating out of copper, or its solution to form a chloride, depends upon concentrations of the various ions present.

To limit the concentration of ferric chloride it has been suggested that the solution be constantly circulated and thereby avoid raising the ferric chloride to a level where active attack is possible. There is no assurance that circulation will bring about this desirable condition. If ferric chloride pockets or otherwise concentrates at surfaces and remains in a quiescent or semiquiescent state, it may react more slowly if only diffusion is available to carry away and remove the products of the reactions.

To support the foregoing theory, corrosion has been produced experimentally with dilute solutions of ferric chloride containing no hydrochloric acid except that resulting from hydrolysis.

It should be pointed out that if inhibitors retard corrosion by covering the entire surface and preventing contact with the acid, they should be equally effective against solutions of ferric or cupric chloride. If the impervious-film theory of inhibitor mechanism is correct, any specific vulnerability of the film to certain solutions would seem doubtful, but if the film leaves certain areas exposed, they could be attacked by oxidizing agents in the absence of an opposite electrode reaction. It is a known fact that inhibitors do not give complete protection, and the actual over-all attack which occurs may no doubt be aggravated by oxidizing agents. Whatever the role of ferric chloride and copper may be, it remains true that with proper care equipment can be acidized repeatedly without hazard.

Practical Effect of Acid-Cleaning on Boiler Steel

Studies of metal which has been repeatedly acid-cleaned show that some corrosion occurs each time, but the rate of attack is not sufficiently rapid, generally, even after many cleaning cycles, to cause serious concern. In some instances acidizing has been blamed for active attack on the metal when this treatment has not actually been responsible but has merely revealed the presence of corrosion which occurred previously and passed unnoticed because the pits and surface etching were filled and coated over with iron oxide or encrustations which the acid removed.

The effect of acidizing may be best evaluated by meticulously cleaning the surfaces before the acidizing, either by wire-brushing or local application of weak acid, and inspecting the metal for pitting, under low magnification and with tangential illumination. The same surface should be similarly cleaned and inspected after the entire unit has been acidized. The pitting shows up on stressed metal, hence for these inspections it is best to select the rolled ends of boiler tubes, the heads or nuts of highly strained bolts, the bends of angle irons, welded zones, etc. In most cases such scrupulous before-and-after inspections have not been made owing to the need for returning the equipment to service as quickly as possible after the cleaning has been completed, or because the operators were unaware of what to look for.

It is a well-known fact that the rate of attack on metals by acid or any other electrolyte is greatly affected by the internal stresses in the material. Examination of boilers which showed corrosion after acid-cleaning demonstrated that the most severe attack was on metal which had been greatly stressed. This condition was particularly pronounced on the flared end of tubes where stresses of large magnitude occurred as the result of cold-rolling. This is illustrated in Fig. 3 which shows the "honeycomb" type of attack that is characteristic in units where corrosion developed during acid-cleaning. A photomicrograph of a section of tube which has been attacked by acid is shown in Fig. 4. The honeycomb or lace form of deep pitting is more clearly demonstrated by the photomicrograph. Inspection of numerous boilers has further demonstrated that cold working of the metals used in the fabrication of internal appliances within the drum are also readily attacked by inhibited acid, even when the unstressed metal has shown no corrosion.

Fig. 3 Corrosion Resulting From Acid Attack on Stressed Metal at Flared End of Cold-Rolled Tube
(*A*, This shows honeycomb type of attack.)

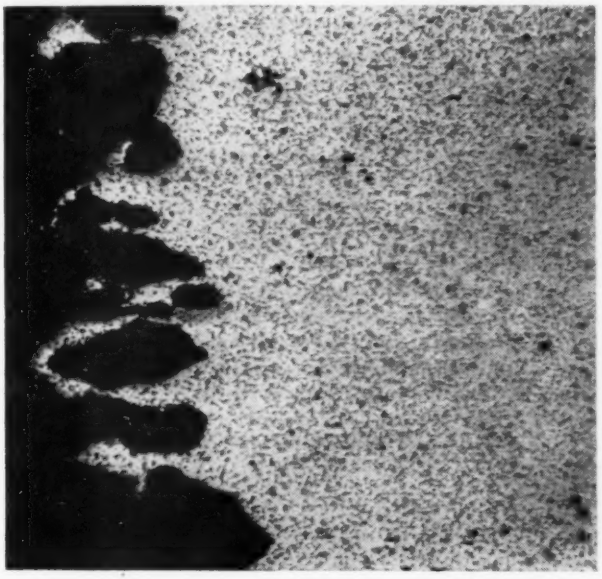

Fig. 4 Photomicrograph of Section of Boiler Tube Taken From Rolled End, Showing Honeycomb Attack During Acid-Cleaning

This type of attack has been observed by the author in a number of installations. Some of the boilers referred to had been acid-cleaned and the temperature of the acid solution was relatively high. In one case the attack was probably due to the effect of an acid contaminant in the feedwater and not to acid-cleaning. The pattern of the corrosion, however, was identical to the type and pattern of attack which was noted in acid-cleaned boilers. This occurrence tends to demonstrate that all corrosion of tube ends may not be the result of acid-cleaning, but may have resulted from some contaminant present in the feedwater. This observation suggests the need for an intensive investigation to determine all conditions which may be responsible for corrosive attack, and the avoidance of unwarranted criticism of acid-cleaning, which in the final analysis may not be responsible.

Some concern has been expressed as to the possible intercrystalline attack on steel due to the penetration of hydrogen into the steel during or subsequent to acid-cleaning. Although relatively large amounts of hydrogen may be generated during the cleaning period, investigations have shown no attack on the intercrystalline structure or any evidence of embrittlement attendant with such form of corrosion. Such investigations have not been extensive, still it seems reasonably safe to predict that embrittlement will not occur if temperature and strength of acid used is within the safe limits, and if the acidized units are thoroughly washed and acid adhering to the surfaces is completely neutralized.

Factors Influencing Effectiveness and Safety of Acidizing Equipment

There are numerous conditions which require control during

acidizing of any equipment in order to insure effective removal of encrustations from the surfaces and a minimum of corrosive attack on the metal. It is not possible to list specifically all of the many conditions which may be encountered, since there are a multitude of variables which may alter the effectiveness of the acidizing process. In general, however, the items which should be considered, and controlled if possible, are as follows:

1 Composition and concentration of acid.
2 Nature and composition of inhibitor.
3 Additional chemicals employed for their wetting, catalytic, or special solvent properties.
4 Temperature of the metal and of the solutions.
5 Circulation, mechanically induced or by diffusion.
6 Composition of the metal.
7 Physical and chemical composition of the scale to be removed.
8 Procedure followed, from taking equipment out of service through removal of acid and washing down and neutralization of acid remaining on the surfaces after treatment.

Time does not permit complete discussion of all the foregoing items, nor would it be appropriate to elaborate on all of them here, since many of them involve complex chemical reactions which are outside the scope of this paper. However, there are certain items in the list which may be profitably discussed as they are of interest to mechanical engineers and others responsible for acidizing of power-plant equipment.

Type and Concentration of Acidizing Solution. It is a common misconception that the cleaning of equipment requires merely the addition of a mineral acid, to which has been added a chemical inhibitor for the purpose of slowing down the rate of attack on metal surfaces. In some cases such treatment may effect the desired results provided temperature control and other conditions are adequately maintained. There are, however, certain types of encrustations occurring in boilers, condensers, and heat exchangers which completely resist solution by muriatic, sulphuric, or other common mineral acids. For instance, the silicate, sulphate and other scales, either alone or combined with other types of encrustations, are not appreciably soluble in muriatic acid. Where such compounds are encountered, hydrofluoric acid or other sources of the fluoride ion must be used to insure their removal.[5] Certain metallic deposits also resist solution, and where such are present, specific solvents must be employed. If oils or greases are encountered, special solvents are necessary for their removal, and effective acidizing results cannot be secured without first removing such materials.[6]

Experience has demonstrated, also, that in addition to the inhibiting chemicals, other compounds improve the effectiveness of the acidizing process. Most of these treatments involve trade secrets, and their use and application are the result and outgrowth of research and development, coupled with practical experience over a wide range of conditions encountered.

The strength of acid to be used should be governed by the time available for cleaning the equipment and the chemical composition of the acidizing solution. In the past the strength of the acid employed has been as high as 15 per cent. Recently, however, there has been a marked trend to the use of acid of lower strength, even though the cleaning takes more time. Concentrations now generally used are from 4 to 7 per cent.

Composition of Inhibitor. The technical literature on the subject of acid-cleaning and pickling of metal contains a long list of organic and inorganic substances which have been used as inhibiting agents to repress the attack on the metal, but which will permit the solution or removal of oxides or other deposits on the surface. A partial list of some of the materials which have been used is shown in Table 1. This list includes only a very small percentage of compounds which are available or have been employed. Actually, there are thousands of organic and inorganic substances which are known to have inhibiting properties. The relative effectiveness of these products varies widely, and they have specific adaptabilities for different services. Most inhibitors are harmless, but others are hazardous and should not be used. In this group are compounds of arsenic, cyanide, and some of the coal-tar by-products. At least one fatality has occurred from the use of an arsenic inhibitor. Operators should be warned against such materials and be informed of their potential danger.

TABLE 1 PARTIAL LIST OF MATERIALS USED OR INVESTIGATED FOR INHIBITING CORROSION OF METALS BY ACIDS

Niter cake	Aniline
Sumac leaves	Pyridine
Formaldehyde	Coal-tar extracts
Glue	Slaughterhouse wastes
Flour	Ethyl iodide
Starch	Paramethylaminophenyl sulphate
Gelatine	Carbozole
Glucose	Cyanide
Thiourea	Quinoline ethiodide
Arsenious oxide	Barium salts

NOTE: The inhibiting effect of the compounds listed, and many other substances, varies greatly as does their cost and availability. Some of these materials possess slight inhibiting value and some are dangerous to use. No inhibitor should be employed without specific information as to its effectiveness and the potential hazard involved in its use.

Practically, the selection of the inhibitor should be left to experts in this field, who should be advised in complete detail about the design of the equipment and the physical and chemical nature of the deposit to be removed. Organic inhibitors are marketed for cleaning operations (such as pickling) which can safely be handled by plant operators. For complex jobs involving major equipment units of the magnitude of boilers and heat exchangers, it is best to rely on the experienced contractor performing the work to select and prepare the acid solution, if the operating personnel in charge of the plant are not informed on the subject.

Temperature. Possibly the most controversial factor with regard to acidizing is the temperature at which the process is carried out, and there is fairly definite evidence that corrosion has occurred in a number of instances where temperatures have been high during cleaning. Many boilers have been cleaned at temperatures ranging from 170 to 180 F, and in one case the temperature was well above the boiling point of the solution and much damage was done. It is a known fact that the inhibiting effect of all chemicals used for retarding corrosion in acid solutions is rapidly reduced as the temperature is elevated. As the result of corrosion of equipment by acidizing at too high temperatures, there is now a trend toward maintaining the temperature of solution during the cleaning period between 140 and 160 F. If sufficient time is allowed for the cleaning, proper removal of the encrustations can ordinarily be effected at the lower temperatures.

In Fig. 5 is shown the extent of corrosion which occurred on the face and edge of caps in waterwall headers. It is probable that the relatively high temperature was responsible for the condition.

Circulation. Various schemes have been used requiring special equipment for applying the cleaning solution to the boiler. In some instances the operators merely inject the chemical into the top drum, while others prepare the solution in a tank and pump it into the boiler and recirculate from the tank back into the boiler. In the final analysis there is not now available sufficient evidence to prove that either circulation of acid by means of a pump, or circulation induced merely by diffusion current is a preferable scheme to use. Both procedures have been followed, in

[5] "Chemical Removal of Scale From Heat-Exchange Equipment," by F. N. Alquist, C. H. Groom, and G. F. Williams, Trans. A.S.M.E., vol. 65, 1943, p. 719.

FIG. 5 CORROSION ON FACE AND SIDE OF CAP SHOWING HONEYCOMB TYPE OF ATTACK

large groups of boilers cleaned, without active corrosion occurring in either case.

Composition of Metal. The composition and the cleanliness of the metal are important factors in resisting or accelerating corrosion during acidizing of equipment. It has been observed repeatedly that low-grade steel containing slag inclusions or other impurities has been readily attacked during acid-cleaning, while the drum and tubes were not affected. In one installation the tops of practically all the acorn nuts used in the fabrication of the internal baffles were destroyed, and a similar condition was noted in a number of other units. To what extent the acid was responsible has not been fully determined, but it undoubtedly accelerated the rate at which the metal was attacked. It is a well-known fact that the material from which such nuts are constructed is low-grade metal, as might be expected, especially during the war years.

Ordinarily, black iron pipe, especially if cold-worked, is readily

(Exact cause for selective corrosion not accurately determined but probably presence of slag inclusions or change in metal structure due to flame-cutting. Note wasting and honeycomb type of attack.)

TABLE 2 TYPES OF DEPOSITS WHICH HAVE BEEN FOUND IN BOILERS, AUXILIARIES, AND MISCELLANEOUS POWER-PLANT EQUIPMENT

Principal ion	Common name	Mineralogical name	Formula determined by x-ray analysis
Group A Boiler and Superheater			
Barium	Barium carbonate	Witherite	$BaCO_3$
	Barium sulphate	Barite	$BaSO_4$
Calcium	Calcium carbonate	Calcite	$\beta CaCO_3$
	Calcium sulphate	Anhydrite	$CaSO_4$
	Calcium sulphate	Hemihydrate	$CaSO_4.0.5H_2O$
	Calcium hydroxide		$Ca(OH)_2$
	Calcium phosphate	Hydroxyapatite	$Ca_{10}(OH)_2(PO_4)_6$
	Calcium phosphate	Whitlockite	$\beta Ca_3P_2O_8$
Magnesium	Magnesium hydroxide	Brucite	$Mg(OH)_2$
Sodium	Sodium sulphate	Thenardite	$Na_2SO_4(V)$
Silicates	Silicon oxide	Quartz	SiO_2
	Sodium-iron-silicate	Acmite	$Na_2O.Fe_2O_3.4SiO_2$
	Sodium-alumina-silicate	Analcite	$Na_2O.Al_2O_3.4SiO_2.2H_2O$
	Sodium-alumina-silicate	Natrolite	$Na_2Al_2Si_3O_{10}.2H_2O$
	Sodium-alumina-silicate	Noselite	$Na_8Al_6Si_6O_{24}.SO_4$
	Sodium-calcium-silicate	Pectolite	$Na_2O.4CaO.6SiO_2.H_2O$
	Calcium silicate	Wollastonite	$\beta CaSiO_3$
	Calcium silicate	Xonotlite	$5CaO.5SiO_2.H_2O$
	Calcium-alumina-silicate	Cancrinite	$4Na_2O.CaO.4Al_2O_3.2CO_2.9SiO_2.3H_2O$
	Magnesium silicate	Serpentine	$3MgO.2SiO_2.2H_2O$
Iron	Iron oxide	Ferrous oxide	FeO
	Iron oxide	Hematite	Fe_2O_3
	Iron sulphide	Triolite	FeS
Group B Condenser, Evaporator, and Heat Exchanger			
Calcium	Calcium sulphate	Anhydrite	$CaSO_4$
	Calcium sulphate	Gypsum	$CaSO_4.2H_2O$
	Calcium carbonate	Aragonite	$CaCO_3$
	Calcium-sodium-silicate	Pectolite	$4CaO.Na_2O.6SiO_2.H_2O$
	Calcium-magnesium-carbonate	Dolomite	$CaCO_3.MgCO_3$
	Calcium fluoride	Fluorite	CaF_2
Copper	Copper sulphide		CuS
	Copper carbonate	Malachite	$CuCO_3.Cu(OH)_2$
	Copper iron sulphide		$CuFeS$
	Copper oxide	Cuprite	Cu_2O
Magnesium	Magnesium silicate	Forsterite	Mg_2SiO_4
	Magnesium hydroxide		$Mg(OH)_2$
	Magnesium silicate	Serpentine	$3MgO.2SiO_2.2H_2O$
Iron	Iron oxide	Magnetite	Fe_3O_4
	Iron oxide	Goethite	$Fe_2O_3.H_2O$
Sodium	Sodium-aluminum-silicate	Noselite	$Na_8Al_6Si_6O_{24}.SO_4$
Group C Steam and Condensate Line			
Ammonia	Ammonium bicarbonate	Teschemacherite	NH_4HCO_3
Iron	Iron carbonate	Siderite	$FeCO_3$
Sodium	Sodium sulphate		$Na_2SO_4(III)$
Group D Miscellaneous Power Plant Equipment			
Calcium	Calcium carbonate	Calcite	$\beta CaCO_3$
	Calcium carbonate	Aragonite	$\lambda CaCO_3$
	Calcium aluminate		$3CaO.Al_2O_3.6H_2O$
	Calcium phosphate	Phosphate	$Ca_2P_2O_8.H_2O$
Magnesium	Magnesium hydroxide	Brucite	$Mg(OH)_2$
Group E Turbine			
Copper	Copper sulphite	Chalcocite	Cu_2S
Nickel	Nickel oxide	Bunsenite	NiO
Silicates	Silicon oxide	Quartz	SiO_2
	Silicon oxide	Cristobalite	SiO_2
	Silicon oxide	Opal	SiO_2
Sodium	Sodium sulphate	Thenardite	$Na_2SO_4(V)$
	Sodium-carbonate-sulphate	Burkeite	$Na_2CO_3.2Na_2SO_4$
	Sodium chloride	Halite	$NaCl$

attacked by acid even though better grades of metal show no visible attack. The type and extent of the attack are illustrated in Fig. 6. This shows a nipple used as a spacer in the construction of internal baffles in a boiler which had been acid-cleaned. An identical type of corrosion was observed in a number of other units employing the same grade of material.

Corrosion of such parts in boilers or in other equipment is not of major importance and is presented here merely to illustrate the susceptibility to corrosion by acid when the metal in contact with the solution is not metallurgically clean.

Active corrosion occurred on manhole covers in two boilers operating under different conditions. The pattern of the attack is shown in Fig. 7. In one instance it was indicated that the metal may have been fairly hot when the boiler was acidized. In the second case the unit was relatively cold, but the feedwater had been contaminated with an acid compound prior to acidizing. It is believed that the condition of the surface of the metal may have made it more susceptible than other portions of the boiler. These conditions were noted on boilers supplied by different manufacturers.

Composition of Deposits. Table 2[7] shows a number of scales which have deposited in boilers and appurtenant power-plant equipment. Frequently such scale will be composed of several formations, each having specific solution characteristics. Furthermore, the composition and extent of the deposit will vary widely in different positions of the same equipment. This condition is demonstrated by the analysis of the encrustations removed from tubes in two sections of the same unit.

Procedure for Acid-Cleaning Boilers. There is no standardized procedure for acid-cleaning of equipment and no standard solution may be employed. It is obvious that the treatment must be guided and adjusted to meet the many variables encountered. Where the work is performed by a commercial company, the job is taken by contract and the contractor furnishes all the necessary appliances and the material for the complete acidizing, including washing down and neutralizing the residual acid when the cleaning of the equipment has been completed. Generally, it is preferable to have the work done by a trained and experienced contractor rather than to attempt the work by local operators, unless

[7] Acknowledgment is made to Dr. F. N. Alquist, of The Dow Chemical Company, who supplied much of the data included in Table 2.

the necessary trained personnel have been developed who can employ the proper technique for effective cleaning and prevention of the industrial hazard involved in such work.

The program of operation which is usually followed when cleaning boilers consists of the following steps, in the order given:

1 Drain the unit, cool, and inspect.

2 Adjust the temperature of the metal to the desired level by the addition of feedwater.

3 Drain.

4 Fill with inhibited acid.

5 Soak for a predetermined period.

6 Continue tests to determine reduction in strength of acid If concentrations drop rapidly and continue to fall, draining and refilling with the solution may be required.

7 When soaking period is completed, drain the unit.

8 Flush two or three times by pumping feedwater into unit and draining as the pH of the test samples indicates the necessity.

9 When flushing is completed, drain boiler and refill with 1 to 2 per cent solution of alkali (soda ash or caustic soda).

10 Drain, then fill with feedwater above the level in the top drum which was reached by the acid, and then drain to the normal water level.

11 Heat with a slow fire and steam at 10 to 25 psi for 2 hr or more.

12 Empty boiler completely if unit is to be inspected, otherwise lower concentration to desired point by blowing down, furnishing feedwater as required.

Whenever possible, boilers should be drained and inspected after acidizing, and a record kept of the condition of the surfaces for future reference and comparison with conditions observed at subsequent inspections.

There may be many deviations from the foregoing operation, but the general plan is indicative of the steps which should be followed to lessen the danger of corrosion.

Hazards

Since all mineral acids are highly corrosive, especially when concentrated, it is obvious that much care should be exercised to protect both the personnel performing the work and the equipment which is being cleaned. If the treatment is carried out by experienced operators who are cognizant of the dangers involved and take the necessary precautionary measures, the resulting hazards should be negligible Aside from the danger of the corrosive characteristics of the acid, the treatment involves a very definite hazard of fire and explosion if the hydrogen generated is not effectively removed and steps taken to prevent its discharge into the atmosphere. Extreme care should be used, also, to prevent hydrogen from pocketing in any equipment which is being acidized.

How many accidents have occurred from explosions from hydrogen during or subsequent to acidizing is not known but during the past 2 years three accidents of this kind have been reported. In one instance two workmen were killed and extensive damaged resulted from an explosion of a boiler. The accident was caused by failure to vent the gas from the boiler drum, the pocketed hydrogen being ignited by a spark from a flashlight used after the boiler was opened for inspection.

This accident demonstrated the extreme danger of acidizing equipment by persons not thoroughly informed of the reactions which occur when the acid is in contact with steel. The two other accidents reported were also explosions resulting from ignition of accumulated hydrogen gas. These accidents were not fatal to personnel, but resulted in appreciable damage to the equipment.

A number of injuries to personnel, resulting from burning or gassing, have come to the attention of the author. There is one case on record during the past year where an operator cleaning a boiler by inhibited acid was killed by arsenious oxide released by the inhibitor which contained an arsenic compound. This type should never be used, although such inhibitors are quite effective for retarding corrosion.

Conclusions

Experience clearly demonstrates that acid-cleaning of equipment is a useful and economical means for removing encrustations from boilers and many other types of power-plant equipment. However, it should never be undertaken or practiced by inexperienced persons who are not fully aware of the dangers involved. Furthermore, acidizing should be practiced only if and when such treatment is necessary. It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule. Such a program is unwarranted both from the standpoint of cost and over-all depreciation of equipment.

No equipment should be treated with acid unless there is assurance that the acid used can be completely removed after the cleaning process has been completed. Most powerhouse equipment is susceptible to cleaning by flushing and flooding with neutralizing alkaline solutions. However, there are certain appliances that are so constructed that adequate removal of acid cannot be effected, or can be done only with great inconvenience and at appreciable cost. In this group the nondraining superheater is an example of apparatus which does not lend itself to acid-cleaning. In some cases where the superheaters may become badly fouled with deposits which are not water-soluble, acid-cleaning may be practiced. If such work is undertaken it should be attempted only when there is assurance that adequate provision has been made for flushing and neutralization when the work is completed and before the unit is returned to service.

Discussion

F. N. Alquist.[8] The acid-cleaning of boilers and auxiliary equipment has been called to the notice of the Society several times in the past few years. Briefly, attention is directed to a discussion by C. H. Groom, G. Williams, and the writer,[9] on scale removal from heat-exchange equipment. Before this publication and since, we have been working in close contact with the power industry and many others on cleaning problems. The present paper is a valuable contribution to the literature on the subject. Data are also given in a paper by J. L. Wasco and the writer.[10]

Acid-cleaning is an economical method of cleaning power-plant equipment. However, the hazards of the acid-cleaning process should be fully recognized so that only experienced persons will be entrusted with cleaning. All engineers recognize that acidizing should be done only when necessary.

The author's statement, "It is a very questionable procedure for any plant to acid-clean equipment as a routine maintenance schedule," requires further discussion. For example, when should a high-pressure boiler be cleaned? The proper answer is to turbine selected tubes to find the extent of fouling. If the fouling rate thus determined is such that annual cleaning is re-

[8] Organic Research Laboratory, The Dow Chemical Company, Midland, Mich.

[10] "Chemical Removal of Calcium Sulfate Scale," by J. L. Wasco and F. N. Alquist, *Industrial and Engineering Chemistry*, vol. 38, April, 1946, pp. 394–397.

quired, then the plant is acid-cleaned annually on a routine maintenance schedule. These decisions are made by the plant engineers on the basis of cost and over-all depreciation values. The practice of the writer's company on its boilers shows variable times for extent of fouling depending upon water treatments and loads.

It is well that the power industry be made aware of the distinction between corrosion due to operation and corrosion due to improper cleaning procedures. A proper conclusion to be drawn is to maintain treating temperatures as low as possible during cleaning and as stated, preferably between 140 and 160 F.

The author has ably discussed the theories of inhibition. Fifteen years of research by the writer's company on acid inhibitors indicates that both the inhibitor and the acid concentration must be selected so as to give a low corrosion rate under cleaning conditions.

Experience gained on thousands of installations where forced circulation has been compared to circulation by convection, shows that forced circulation is only occasionally necessary.

That the effect of inhibited acid varies as the metals differ in composition has been known in the art for a long time. Power-industry engineers have found that operation corrosion as well as corrosion in cleaning depends upon the composition of the metals involved. Considering Figs. 3, 4, 5, 6, and 7 in the paper, no statement can be made as to how much corrosion is due to operation and how much is due to cleaning.

The steps outlined under procedure for acid-cleaning boilers are good but, under the war-emergency conditions, these steps were not always used because of lack of time; however the engineers of the power industry now follow them more closely.

Finally, the hazards of handling acids and venting the hydrogen that may be produced during the cleaning operation are well known both to the chemical and power industries. With proper safety precautions and helpful papers such as this one, the power industry can take economic advantage of acid-cleaning methods

R. E. Hall[11] and C. E. Kaufman.[12] We are in agreement with the general facts on acid-cleaning of boilers as developed by the author. More incisive analysis of some of the factors involved brings to light some significant considerations that require emphasis.

Acid used for the process is supplied with an inhibitor, that is, a substance whose purpose is to minimize or prevent attack of the acid on the boiler steel, while not interfering with its dissolving effect on other substances such as the calcium carbonate and phosphate, the iron oxide, etc., comprising the boiler sludge and scale. Concentration of the inhibitor in the acid-cleaning solution is a function of the type of inhibitor used, concentration of acid employed, and temperature at which the job of acid-cleaning is done. Thus one can depend upon the inhibitor to protect against direct attack of the metal by the acid within rather generous temperature limitations, if the concentration of inhibitor required in relation to the acid is consistently maintained, and if the products of reaction of the acid with the boiler sludge or scale are not of themselves potent in their attack on the metal, regardless of the inhibitor.

As a matter of fact, these products of reaction divide into two classes, one of which is innocuous as regards the boiler metal; the other of which is highly aggressive in attack on the metal, even with any usual inhibitor present in the acid solution. Materials which give rise to the first class comprise the calcium and magnesium salts of the boiler sludges and scales; those giving rise to the second class are the iron oxides, either magnetite or hematite. Whether formed in the feed line by the action of dissolved oxygen and thence entering the boiler, or whether formed in the boiler itself by reaction of boiler metal with the bonded oxygen of the boiler water, these oxides represent high oxidizing capacity. Concentrated bit by bit as the boiler is operated and held harmless by the insolubility of the oxides in the boiler water, they await only the trigger action of the acid solution which dissolves them to bring this concentrated oxidizing capacity into play against the boiler metal. Metallic copper, so frequently associated with the iron oxides, may enter into but cannot initiate the oxidation reactions, nor can it contribute thereto. In fact, by plating out on the metal it may even be protective in some measure.

Let us explore conditions in a thin layer of the acid-cleaning solution adjacent to the metal when the sludge or scale consists primarily of insoluble calcium and magnesium salts, and the normally quite low percentage of iron oxide. The acid dissolves the deposit, forming calcium and magnesium chloride, both of which are stable salts devoid of oxidizing capacity. Because of this, they originate no attack on the metal, and the protection provided by the inhibitor in the acid remains intact, unless undue temperature elevation has adversely affected protective conditions. Barring undue temperature, whether flow of the acid-cleaning material over the surfaces is provided for by means of circulating the solution or whether there is or is not considerable agitation of the solution by dissolving such material as carbonate, a protective concentration of the inhibitor in relation to the acid content of the solution prevails at the surfaces.

Let us now explore conditions in the thin film of acid-cleaning solution adjacent to the boiler metal, when the sludge in the boiler is mainly magnetic oxide Fe_3O_4, which dissolves forming ferric and ferrous ions. It is readily demonstrated that the ferric ion is the most important factor in promoting attack.

Fundamentally the aggressiveness of solutions containing ferric ion can be explained on the basis of the following reaction

$$2Fe^{+++} + Fe \longrightarrow 3Fe^{++} \quad \ldots\ldots\ldots\ldots [1]$$

It will be noted that this process does not intrinsically involve the disappearance or formation of an acid or a base. Therefore it might be presumed that the inhibitors customarily employed to stifle acid attack on steel would not be well adapted to minimize the reaction of ferric ion with metal. Laboratory tests have confirmed this point.

In the laboratory we have run a number of agitated-solution tests at 150 F, for 6 hr, in which the reality of ferric-ion attack is clearly apparent. For example, when 1 per cent Fe_3O_4 was added to an inhibited acid solution, attack on an inserted steel strip was increased nearly threefold as measured by weight loss. The loss, representing about one third of the potential attack as just defined in Equation [1] was undoubtedly limited by the incomplete solubility of the added iron oxide, behavior which of course may be found in full-scale cleaning operations. When the ferric material was present in considerably greater concentrations and as completely soluble chloride, without acid but with a standard inhibitor present, attack actually considerably exceeded that predicted from reaction [1].

In the removal of deposits from boilers by acid-cleaning, when magnetic iron oxide, for example, goes into the circulating acid, what quantitative potential has it for producing damage? If it is assumed that 1000 gal of cleaning acid builds up to contain homogeneously distributed in solution 1 per cent or 83.3 lb of material originally Fe_3O_4, 20 lb of iron can be dissolved if Reaction [1] goes to completion. If, for example, the dissolution of iron is assumed to take place evenly within 3-in. tubing, the general loss of metal will amount to less than 0.001 in. If, however, the ferric ion is not homogeneously distributed in the acid solution, but rather is selectively concentrated in localized areas

[11] Hall Laboratories, Inc., Pittsburgh, Pa. Mem. A.S.M.E.
[12] Hall Laboratories, Inc.

rich in magnetic oxide, then serious pitting or wastage in such areas may be expected.

Avoidance of such corrosion we believe is best effected by steadily maintained circulation of the acid-cleaning fluid so that localized high concentrations of ferric chloride cannot occur, and by limiting concentration of ferric chloride in the acid-washing solution through adequate blowdown and replenishment of acid solution, thus protecting against too much loss of metal in general corrosion of the surfaces by even the homogeneously distributed ferric chloride which develops mainly at the surfaces or in particular spots in the boiler. Satisfactory control of ferric-ion concentration can be established by analysis.

For the boilers that develop magnetic oxide by the bonded-oxygen process in regions where high heat release renders intolerable any decrease in circulation, acid-cleaning does a specially significant job, in that by cleansing the surfaces of iron oxide, and thus bringing back the original designed circulation in the tubes, the conditions for reaction of the bonded oxygen of the boiler water with the tube metal are minimized. Thus periodic acid-cleaning as required can keep circulation at these points maintained at a level where any formation of iron oxide will be slight, and the boiler will be dependable.

Naturally, acid-cleaning should not be looked upon as something to supplant normal careful procedure in taking care of the boiler. Nevertheless, especially in cases such as those comprised in the circumstances just discussed, it can play a very effective part. Likewise, alkaline-cleaning processes in some instances, dependent upon the composition of material to be removed, are more feasible than acid-cleaning.

No mention has been made of acid-cleaning operations involving nonferrous metals. It would be interesting to know if such cleaning has been conducted and the general types of inhibitors, if any, which proved useful.

L. E. Hankison.[13] This paper is especially valuable because it tells of the dangers that may be encountered, not only to the equipment being cleaned, but also to the personnel engaged in doing the cleaning. The definite warning given by the author that acid-cleaning should never be undertaken or practiced by inexperienced persons who are not fully aware of the dangers involved, should not be ignored. It is evident that this work should be done either by someone commercially in the acid-cleaning field, or by someone who is professionally able to prescribe the proper acid to be used, its strength, the inhibitor to be used, the proper temperature and the length of time for its contact, and then the best way to dispose of the partially spent acid, as well as the proper material and method of neutralizing or removing the residual acid from the equipment. This service presumably can be had only at a cost which must be charged against the benefits that may be obtained by acid-cleaning.

There is another, and probably a much greater cost that must be borne by those who indulge in this means of keeping their equipment in service. It is the loss in efficiency and capacity of the equipment from the time the surface begins to foul until the deposit is of sufficient magnitude to justify removing the equipment from service for acid-cleaning. By using the average between the clean condition and the fully fouled condition as the approximate continuous loss, it can readily be appreciated that this cost is quite considerable and should be avoided if at all possible.

It is our belief that it is much cheaper and very much more satisfactory to secure the services of competent water-conditioning consultants whose aim is to avoid the necessity of any cleaning rather than to acid-clean and bear the costs that have just been outlined. We believe that with this consulting service and properly trained operating personnel to carry out their recommendations, acid-cleaning, or any other type of cleaning that requires equipment outages is unnecessary. Of course, this implies properly designed equipment operated at ratings so that steam pockets, hideout, or reverse circulation is not experienced.

Acid-cleaning has a very important place in power-station operation when the equipment is run at ratings beyond the normal ability of the heat-transfer surface to function. In this case the surface may oxidize or change to form an insulation to a point where overheating and failure will follow. Acid-cleaning may remove the deposit that has been formed and prevent the equipment from failing.

There is another situation where acid-cleaning is beneficial and, in fact, is the only practical means of restoring equipment to serviceable operating condition. During the war, when materials such as condenser tubes and the personnel for their installation were very hard or impossible to obtain, condenser leakage allowed silica to build up in some of our boilers to a point where it was deposited as an incrustation that caused tube failures. Acid-washing restored the boilers to good operating condition, where they have continued to function with the aid of the proper water-conditioning previously mentioned.

One other acid-cleaning experience should be mentioned. Due to water leakage through the packing of the boiler feed pumps into the bearing cavities, it was found difficult to keep oil in the bearing reservoirs. An oil-company representative recommended that the straight mineral oil which had always been used be replaced with a compounded oil that would not float out so easily. This was done and the bearing situation was remedied, but this oil was emulsifiable and such oil as did leave the bearing reservoirs would not separate out in the drip collectors but was carried through into the boilers. There it mixed with the boiler sludge forming a tarry mass containing a small percentage of oil that adhered to the surfaces and caused burnouts. It was thought that increased alkalinity would dissolve this mass but it was not cleared up by this means, so we decided to acid-clean to dissolve the embedded sludge. Acid-cleaning partially dissolved this mass. It also removed much of the protective coating of iron oxide and probably other iron compounds that had been formed on the water surface of the tubes by some reaction of the treating chemical, and which are considered beneficial and desirable.

The presence of this iron compound can be well illustrated by our boiler-gasket experience. Due to scarred or cut hand-hole-seat surfaces, it was considered necessary to use solid copper gaskets to make these parts tight. It was recognized that copper gaskets between the iron or steel surfaces and in the presence of the alkaline boiler water as the electrolyte were not conducive to long gasket life, yet we were never able to find even the slightest attack on these gaskets and they were considered entirely satisfactory. After the boilers were acid-cleaned new gaskets would not last 3 months and we have records of heavy new gaskets practically entirely disappearing in 2 months of operation. This caused us temporarily to abandon copper gaskets. We now believe that the protective coating has been restored by the continued use of treatment, and are trying a few copper gaskets which we hope will again give satisfactory service.

As a further indication that acid-cleaning is detrimental in removing the beneficial iron-compound coating, our experience with corrosive barnacles should be related. After the boilers were acid-cleaned, large quantities of iron-oxide scale were found lodged in the tube headers and also in the tubes that had sluggish circulation. Frequent boiler outages were necessary until all this scale was removed from the system. These outages allowed the internal boiler surfaces to be exposed to atmospheric air, and

[13] Superintendent, Efficiency Department, West Penn Power Company, Pittsburgh, Pa. Mem. A.S.M.E.

small rust spots were formed. These rust spots may have provided the insulation that promoted barnacle growth and boiler-tube failures resulted. This is being given further study. It is now believed that the protective surfaces previously described have been fully restored, as failures of this type have not been experienced during the last 1½ years.

While it is agreed that cleaning with acid is beneficial under certain extraordinary conditions, we wish to emphasize the part of the author's conclusion which says, "It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule." We believe that good housekeeping, coupled with intelligent water-conditioning to eliminate the need for acid-cleaning, is the preferred method of operating power-station equipment.

W. R. LaMotte.[14] The writer's company has been particularly interested in the cleaning of boilers by this method. It was first tried in 1939 to clean one of the 350-psi boilers at Kearny generating station. The results were so gratifying, both from the standpoint of low cost and degree of cleanliness obtained, that acid-cleaning has been standard practice at that station ever since. In 1940 the practice was extended to the 1250-psi boilers in the Public Service system. These high-pressure boilers were first acid-cleaned at half yearly intervals, but more recently they have been cleaned annually. As a result, some of them have been cleaned ten and eleven times.

This experience tends to confirm what the author has written concerning the precautionary measures which are advisable in the use of acid for boiler cleaning. The best inhibitor procurable should be used and solution and metal temperature should be kept well below the temperature at which the manufacturer states the inhibitor will break down, the time of contact should be limited, and the various hazards should be recognized and adequate protection provided.

In fact, we differ only with the following statement of the author: "It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule. Such a program is unwarranted both from the standpoint of cost and over-all depreciation of equipment." We look upon acid-cleaning as the normal and best way to clean periodically the internal surfaces of high-pressure boilers. Nothing so far discovered has indicated that measurable harm has been done during the past 5 years.

Perhaps one reason for the foregoing has been the practice of using low acid concentrations, in the range ½ to 1 per cent HCl, as contrasted with the range of 4 to 15 per cent discussed by the author. These satisfactory results have been achieved using presently available inhibitors, and certainly improvement in inhibitors can be expected in the future. High-pressure boilers now on order are so designed that the tubes cannot be cleaned by conventional methods; only by the use of liquids can the internal surfaces be reached. It has been our experience that the art of treating the boiler water has not progressed sufficiently to dispense entirely with internal cleaning.

E. L. McDonald.[15] Our company was one of the early users of inhibited acid for cleaning power-plant equipment. For years we have acid-cleaned various heaters, feed lines, pumps, economizers, etc., all under the guidance of the station chemist.

Much was learned from our early experience. For example, do not try to clean old equipment too fast or too well with any scale-removing compound. Scale removed from the tube sheet of a steam-crane boiler by trisodium phosphate exposed loosely rolled tubes and caused a great number of leaks that did not exist when scale covered them. Scale removed from the cast-iron junction boxes of an economizer by acid-cleaning exposed porous spots in the box that did not leak before the removal of scale.

When the shortage of labor during the war first prompted us to employ a commercial acid-cleaning company, we had the idea we could pump the acid to the boiler through the blowoff line which emptied into a sewer at a convenient location for tying-in the acid truck, thus saving the cost of an acid feed line. After a short period of time the acid pumped through the line removed the scale and a great number of leaks developed, which again were not evident when the scale protected them.

All of this is in keeping with the author's statement to the effect that acid is frequently blamed for corrosion which actually existed before the acid was applied and was not evident until the acid removed the scale. The writer has observed corroded surfaces, similar to the type shown in the paper, in boilers and turbine casings that had not been acid-cleaned.

While we have made substantial savings by acid-cleaning with our own crew and equipment, we have not found acid-cleaning of large steam-generating units, as performed by a commercial cleaning company, to be very cheap. The average on five boilers with about 20,000 sq ft of surface each was $84 per 1000 sq ft of surface. This was about 40 per cent higher than the previous mechanical cleaning cost. On these five boilers a 5 per cent acid solution was used. On three boilers cleaned at a later date, using 3½ per cent solution, the cost dropped to $52 per 1000 sq ft of surface. This was still about 15 per cent higher than the previous mechanical cleaning cost. However, two items definitely favored acid-cleaning, i.e., a shorter boiler outage, and a better job of cleaning. The fact is that it is practically impossible to clean the modern steam-generating unit mechanically.

Mention has been made that the control of acid temperature is important. A thermometer in the acid line can tell a false story. High "spot" temperatures can exist in a boiler if heat is transmitted from brickwork not previously cooled before acid treatment is applied.

The author comments on the possible metal loss due to acid-cleaning; however, it should be remembered the old rotary tube cleaner also removed metal and, before water treatment reached its present stage, more than one boiler tube had to be replaced due to this metal loss. Also, in our own case, we believe the loss of metal, due to corrosion and erosion on the outside of the tube, would exceed any loss of metal on the inside. During acid-cleaning, metal test strips have been hung in boilers, carefully weighed before and after the acid-cleaning, and have given us an idea of the possible metal loss.

Mention is also made of the hazard of generating hydrogen gas when acid-cleaning, and the author comments on a particular boiler explosion. A very serious explosion also occurred last year when acid-cleaning a condenser at the Wichita Station of the Kansas Gas & Electric Company. Details of this are covered in an article by E. D. St. John,[16] which should certainly be read by anybody contemplating acid-cleaning of such equipment.

While acid-cleaning of any equipment has merit, it should not be undertaken except under the guidance of a competent chemist or other competent help.

F. U. Neat.[17] In connection with acid-cleaning, the writer believes that considerably more importance should be attached

[14] General Superintendent of Generation, Public Service Electric and Gas Company, Newark, N. J. Mem. A.S.M.E.

[15] Kansas City Power & Light Company, Kansas City, Mo. Mem. A.S.M.E.

[16] "Repairs to Steam Turbine Unit Following Hydrogen Explosion," by E. D. St. John, *Power Plant Engineering*, vol. 50, no. 3, March, 1946, pp. 64–68.

[17] Assistant to Superintendent of Power Production Stations, Consolidated Gas Electric Light & Power Company, Baltimore, Md.

to the possibility of hydrogen embrittlement. Pickling embrittlement is too well known in the steel world to lead us to do anything but go well on the safe side with regard to removing hydrogen. Particularly in the case of boilers, it is quite possible that we may open up crevices in seams and around tubes and these crevices must be stopped. However, if we should permit the rerolling of tubes or calking of joints without making certain the removal of occluded hydrogen, then we are guilty of negligence. The writer's practice is to rinse the boiler thoroughly, after which a solution of 2 to 5 per cent soda ash is boiled in the boiler for 8 to 12 hr at from atmospheric pressure to 50 psi under open vents before the boiler is opened for inspection and certainly before any cold-working of the boiler metal is permitted. This boiling procedure accomplishes reasonable removal of hydrogen gas from the boiler and occluded hydrogen from the metal, largely prevents after-rust, and partially re-establishes the protective coating of magnetic oxide. It may also assist in the loosening of remaining scales which are incompletely soluble in acid.

Attention is also called to a remark by the author which may be misconstrued. In his discussion of the hazards involved he states that the discharge of hydrogen to the atmosphere must be prevented. The writer feels certain that the author really meant that the vents must be piped to the outside in such a manner as to make reasonably sure that discharged hydrogen may not re-enter the building and that these vents be taken from as near the top of the equipment as is possible. If vents are left open during the fill and drain-rinsing operations and then during the boiling-out procedure, we are assured nearly complete removal of hydrogen in the equipment.

H. B. Oatley.[18] Deposits on the heat-transfer surfaces of several types of vessels are very generally recognized by designers as well as users. This is particularly true for vessels or pipe lines conveying liquids at increasingly higher temperatures and pressures.

Attention has been given to the use of purification systems for the removal of these undesirable elements which cause failure of the apparatus. Acid-cleaning has been used with beneficial results by those who, like the author, realize the dangers of such use. The reverse is also true.

The paper has called attention to the outstanding features of this acid treatment and the dangers of such cleaning are clearly and emphatically stated in the author's conclusions.

The increasing severity of operation has brought the designer to the doorstep of the metallurgists for better material, which is to be more highly resistant to deteriorating effects resulting from impeded heat transfer. It may also be said that the chemical industry is looked to by those who require more effective and less dangerous scale-removing methods, entailing the use of chemical inhibitors.

W. F. Ryan.[19] The development of inhibited acids for the cleaning of metal surfaces is just another example of the fact that many of us were born 30 years too soon. When the writer recalls his filthy and laborious efforts to clean boilers and oil coolers in the old 74th Street Station, he wishes that the Dow development engineers had not been so dilatory in the development of acid-cleaning. His successors in the operating field can have these jobs performed with less labor and worry than he experiences when he sends his shirt to the laundry.

In saying less worry, he is not relying entirely on the fact that it may be easier to replace a boiler than to get a new shirt. The author's precautionary remarks are timely and well taken but, on the other hand, the hazards are very slight if one is willing to pay somebody else to worry about them. Most of the adverse experience with which the writer is familiar, has arisen from misguided efforts to save a few dollars by doing the job without experienced supervision or adequate equipment.

In addition to the routine cleaning of boilers, there are special conditions under which the use of acid-cleaning may pay tremendous dividends; for example, in a paper mill it was discovered that the two high-pressure boilers had accumulated an unusual amount of sludge due to changes in the raw-water supply. One tube was blistered and concern was felt for the rest of the heating surfaces. One would not ordinarily think of using acid to remove sludge, but based upon previous experience it was anticipated that a production loss equivalent to one half of the mill's output for at least 7 days would be involved in shutting down the boilers, allowing them to cool sufficiently, cleaning them thoroughly, and getting them back on the line. This was at a time when the mill output was heavily oversold and such a loss of production would be a major catastrophe. Dowell Incorporated was consulted regarding the practicability of using acid in this situation and found that both boilers could be cleaned in a single day. The two boilers were satisfactorily cleaned by circulation of inhibited acid and the entire operation consumed less than 19 hr. The cost of the acid-cleaning was of the order of $500, while the production hours that were gained were worth many thousands.

Another instance of high return on a small investment was experienced in the cleaning of cooling coils in large process tanks. For years these coils which are used with raw hard water, were installed with 3 times the calculated surface in order to compensate for the gradual accumulation of scale. At the end of 2 or 3 years the coils were removed and replaced. The coil itself was not extremely expensive, but the replacement required draining and cleaning the tank with attendant loss of valuable materials. By the use of acid the coil can be cleaned in place with no loss of production or of materials. Life of the coil will be at least equal to that of the tank, and when new tanks are installed the cooling coils can be designed in correct proportion to the demand for heat transfer.

The use of acid-cleaning in power plants and process industries is still in its infancy, with new time-saving and money-saving applications arising every day. Every operating or maintenance engineer who is confronted with the periodic cleaning of metal surfaces should investigate thoroughly what can be accomplished by this method.

H. G. Thielscher.[20] We have acid-cleaned eleven boilers in our plants with satisfactory results. The work has been performed by a commercial chemical company. The strength of the acid solutions used was 5 per cent, the length of time contained in the boilers varied from 5 to 14 hr, and the temperature of the boiler metal and acid solution ranged from 150 F to 190 F. Forced circulation of the solution was not used. We do not know the nature or composition of the inhibitors used as this is considered secret information by the commercial companies. Subsequent examination of these boilers has not revealed any definite evidence of acid corrosion.

Included in the boilers, which were acid-cleaned, was a new 525,000-lb per hr 675-psig 900 F total steam temperature 3-drum boiler, which was acid-cleaned immediately after the conventional boiling and drying-out period. The results obtained were excellent, and an appreciable saving was effected in the time

[20] Mechanical Engineer, Potomac Electric Power Company, Washington, D. C. Mem. A.S.M.E.

and labor ordinarily required to prepare the drums for Apexiorizing. In addition, we believe a more permanent Apexior job was obtained because of the cleanliness of the metal surfaces after acid-cleaning. We expect to continue this practice of acid-cleaning new boilers before they are placed in service. The superheater in this boiler was the vertical nondraining type and was filled with clean warm water before admitting the acid solution to the boiler. In some of our older boilers we had deposits of analcite. The acid-cleaning did not remove these deposits but did soften them up so they were readily removed by turbining.

We agree with the author that there are corrosion and explosion hazards attached to the acid-cleaning of equipment, but, like him, we believe these hazards are negligible when proper procedures and precautions are observed.

G. F. Williams.[21] This paper gives an exceptionally clear picture of chemically removing scales and sludges with acid-base solvents. The author is to be congratulated on this excellent paper which so ably relates the history of acid-cleaning and points out that its effective application involves a careful consideration of all pertinent factors. When one considers the complexity of the questions involved, which deal not only with chemical engineering but also with metallurgy, electrochemistry and other sciences, it is even more apparent that all factors must be carefully weighed by one thoroughly trained and experienced in this line of work in order that the accumulated scale may be removed safely.

It is interesting to note that over 25 years ago the entire piping system of a large building was successfully cleaned of scale by the use of acid-base solvent but, as the author points out, "It is surprising that this novel method of cleaning pipe lines did not receive more widespread interest at that time since the basic principle of the procedure has much merit." Possibly the difficulties experienced on this job were sufficiently serious to deter this type of work in the immediate future and the present commercial use of acid-cleaning may be due in no small degree to the experience gained in using millions of gallons of inhibited acid-base solvents during the last few years for increasing the flow of oil wells.

In only a few cases has any corrosion been noted in boilers following acid-cleaning, and in most of these there was considerable evidence that the corrosion could have taken place during operation of the equipment rather than during the cleaning job. Our company, during the last 10 years, has made over 50,000 separate treatments using inhibited acid-base solvents on oil wells and industrial equipment, and in less than 0.1 per cent of these jobs has any question been raised concerning the possibility of corrosion due to the use of inhibited solvent. In fact, it is the opinion of many operators of large steam-generating equipment that the metal loss from cleaning with acid-base solvents is less than that which results from mechanical cleaning methods.

The manhole cover, shown in Fig. 7 of the paper, showed definite corrosion upon inspection following an acid-cleaning job, but as this unit was not inspected immediately prior to cleaning, there is room for considerable uncertainty as to the cause of the corrosion. Representatives of the writer's company were present with the author and others at the time this inspection was made. Other places on the edges of the manhole covers in this boiler showed occasional large corrosion "pits" much deeper and much larger than anything shown in Fig. 7. It seems practically impossible that such a large amount of metal could have been removed from such a small area in the few hours' time in which acid was in contact with the metal. Probably factors other than cleaning with inhibited acid-base solvent contributed to this corrosion.

One of the conclusions to this paper, viz., "It is a very questionable procedure for any plant repeatedly to acid-clean equipment as a routine maintenance schedule," might be clarified. Certainly any preconceived schedule for periodical cleaning without any knowledge of the rate at which scale is formed would be questionable, but whenever there is sufficient scale accumulation to warrant its removal, acid-cleaning is the best and sometimes the only feasible way of removing it. After the deposition rate of scale in a boiler is known and therefore the frequency with which it must be removed, it seems entirely reasonable that acid-cleaning could be done on a routine maintenance basis.

[21] Development Engineer, Dowell Incorporated, Tulsa, Okla. Mem. A.S.M.E.

Author's Closure

The comments presented on the author's paper by the several discussers are constructive and justify much consideration by those interested in the subject.

The theory on the mechanism of corrosion, as brought out by Messrs. Hall and Kaufman, requires consideration and indicates the need for further research along these lines. Although there is much disagreement among engineers as to the relative merits of circulation to avoid concentration cells, as suggested by Dr. Hall, this is a desirable procedure under some circumstances and, where it can be carried out in a practical manner, circulating the solution may conceivably overcome the tendency to cause spotty corrosion of the metal. Regardless of the advantages offered by circulation during cleaning of apparatus there are many cases, especially those involving cleaning of large boilers designed with complex circuits, where circulating the solution can not be readily affected. It is obvious that uniform circulation through a large unit is difficult and it is doubtful if pumping the solution through units will insure much better movement of the solution over the metal than may be obtained by normal thermal circulation which occurs during the cleaning process.

Regardless of these apparent operating difficulties to carry out the procedures for avoiding corrosion as suggested by Dr. Hall, the problem warrants further study. It is hoped that the Hall Laboratories, Inc., and other interested groups will continue to study and develop means for overcoming many of the troublesome problems encountered in the acid-cleaning technique.

Dr. Alquist's statement that "The effect of inhibited acid varies as the metals differ in composition" has been known in the art for a long time. Power-industry engineers have found that corrosion during operation as well as corrosion in cleaning depends upon the composition of the metals involved. This has not been fully appreciated by many operators. Why some metal corrodes during acid cleaning to a greater extent than others, when the cleaning procedures are practically identical, is not clearly understood but no doubt is related to the composition of the metal and other metallurgical characteristics.

The instructive and informative research now being carried out by The Dow Chemical Company under the guidance of Dr. Alquist and his associates should reveal much valuable information and place acidizing of equipment on a much more exact basis than is now possible with our limited knowledge. It is hoped that this and other organizations carrying on research in this field will release their findings from time to time. Such dissemination of data should serve as an invaluable guide to the profession.

The author is in agreement with many of the comments made by Mr. Hankison, since our experiences have paralleled his regarding a number of difficulties described. The acid attack on copper gaskets during cleaning of boilers has been encountered

many times with varying degrees of severity. These difficulties and other precautionary remarks mentioned by Messrs. Hankison, LaMotte, and MacDonald and the other discussers, demonstrate the need for intelligent planning and control for safe and effective treatment of any equipment by inhibited acid solutions.

With regard to Mr. Neat's comments, namely, "Attention is also called to a remark by the author which may be misconstrued," the author's precautionary remark, of course, related to adequate venting to the outside atmosphere. We regret if our statement in the text has been misconstrued by others. It is presumed to be obvious that the avoidance of a fire or explosion hazard would require complete and adequate venting outside the building by suitable facilities.

The aim and purpose motivating the preparation and presentation of the author's paper was to direct attention to the economic and practical value of acidizing boilers and other auxiliary equipment. The very favorable comments by so many engineers and chemists indicate that designers and operators agree with our viewpoint, differing only in details of application of the process. There are a number of unsolved factors which are not well understood and therefore may not be adequately evaluated. It is hoped that our effort has focused attention on these matters and will stimulate further study of the problem.

The Theory of Plasticity— An Outline of Work Done in Russia[1]

By W. W. SOKOLOVSKY,[2] MOSCOW, U.S.S.R.

The theory of plasticity as an important part of the mechanics of continuous materials has occupied the attention of many Russian workers in recent years. In the first paper in this field[3] published in 1935, by S. Sobolev (17)[4] the propagation in time of a plastic zone was investigated around a circular hole in an infinite plate. The plastic zone was assumed to have a polar symmetric shape. Based on the works of L. Prandtl, Th. von Kármán, R. von Mises, H. Hencky, A. Nadai, and others, more recently, a group of young Russian engineers have investigated further the theory of plasticity and added many new developments to it. While the investigations abroad and in Europe, outside of Russia, were being aimed at establishing the validity of the theory of plasticity, most of the papers appearing in the literature in Russia were devoted to the solutions of concrete problems. This review does not attempt to discuss broadly the work done in the theory of plasticity. The author confines himself to certain parts of the theory which have been developed in Russia. Naturally those closest to his own scientific interests have been selected for treatment.

Plastic Stress-Strain Relations—Theory of Viscous Bodies—Stability Questions

THE equations expressing the state of strain beyond the limits of elasticity have been the subject of investigation by a number of scientists, among them, N. Belayev (1), L. Kachanov, A. Ilyushin, and A. Ishlinsky. These studies constitute a development of the Mises-Hencky theory of plasticity, which has won general recognition.

Hencky gave the equations for the components of deformation expressed through the components of stress; of considerable interest are the inverse expressions. The latter were obtained by L. Kachanov (14) both for the case of ideal plasticity according to the Mises conditions, and for the more general case of a strain-hardening material according to the Schmidt conditions. L. Kachanov strengthened the validity of the Mises-Hencky theory and investigated in detail the equations of equilibrium and of motion of a plastic body by basing them on a number of interesting energy theorems derived from the principles of the calculus of variation (13, 15).

A. Ilyushin (5) contributed new equations, valid for the process of unloading, to the Mises-Hencky theory of plasticity. He assumes that the intensity of the shearing stresses is proportional to the unit shears. This makes it possible to consider problems dealing with the active process of "loading," as well as the passive process of "unloading." The results obtained are particularly important in their application to stability beyond the limit of elasticity, of which examples will be given later.

The theory of viscous materials was evolved in Russia by A. Ilyushin (4). In addition to the well-known hypothesis of Saint Venant of the coincidence of the maximum rate of shear with the greatest vector of the shearing stress, this theory is based on the assumption that the maximum shearing stress in flow is always larger than a constant σ_s and is a linear function of the maximum rate of shear. For example, in the case of a circular bar, Fig. 1, the normal stress σ_z is assumed equal to

$$\sigma_z = \sigma_s + \mu\dot{\epsilon}_z \quad \text{(see footnote[5])}$$

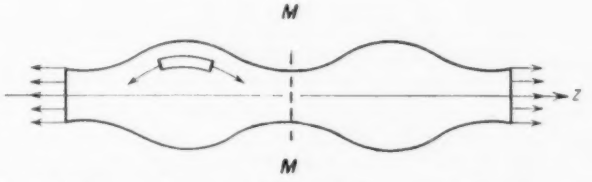

Fig. 1 Assumed Shape of Bar for Discussing Stability of Deformation in Tension

where μ is the coefficient of viscosity and $\dot{\epsilon}_z$ the rate of strain.

The most interesting problems in the theory of deformation of such viscous bodies, which were raised by A. Ilyushin and solved by him and other authors, are those dealing with the stability of stretching or compression of strips, bars, and plates.

The problem was solved by A. Ishlinsky (8) for the case of a cylindrical bar of circular cross section with the radius a. He reduced the problem to an equation which he integrated by means of Bessel's functions.

He found, for example, for a bar having the small deviation

[1] This is a brief summary of an address which was made by Dr. Sokolovsky on June 21, 1945, at a meeting of the Institute of Theoretical Mechanics in Moscow during the Science Congress of the Allied Nations which was held in Moscow and in Leningrad in commemoration of the 220th anniversary of the founding of the Academy of Sciences of the U.S.S.R. The writer of this introductory note has been privileged to present an English translation of the original manuscript to the Journal of Applied Mechanics. This translation which was received in Moscow by the writer on June 29, 1945, was prepared by N. Talickish, editor of the *Journal of Applied Mathematics and Mechanics*. American readers will be grateful to Dr. Sokolovsky and to Mr. Talickish for acquainting them with a number of recent remarkable investigations by Russian engineers into the theory of plasticity which otherwise would have remained unknown in this country owing to the difficulties of the language.—A. Nadai.

[2] Professor, Institute of Theoretical Mechanics of the Academy of Sciences in the U.S.S.R.

[3] Papers on the application of the theory of plasticity to bars in building mechanics appeared somewhat earlier. Reference to these will be omitted in this review.

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[5] A viscous substance having a definite yield stress deforming when the stress is larger than a certain stress σ_s, "yield value," was postulated long ago in the United States in "Fluidity and Plasticity," by Eugene C. Bingham, McGraw Hill Book Company, New York, N. Y., 1922, p. 440 (p. 217; fig. 78, p. 219), and his assumption was used to explain the behavior of many actual substances in applications; also, "Ten Lectures on Theoretical Rheology," by M. Reiner, published by Rubin Mass, Jerusalem, Palestine, 1943, p. 133. (This note added by A. Nadai.)

$\delta \cdot \sin nz$ from the form of a circular cylinder which is subjected to stretching, that the ratio of this deviation to the radius of an undisturbed cylindrical surface tends either to increase (unstable deformation) or to decrease (stable deformation). This depends on the velocity of deformation. An analogous phenomenon takes place when strips or plates are deformed. The causes of this phenomenon may easily be ascertained, Fig. 1. The rates of strain in the narrower cross sections $M-M$ of a bar must be larger than in other sections, since the true stresses in them are larger, and hence these cross sections will decrease the more quickly. On the other hand, the curvatures of the trajectories of the main stresses level out the deformations. These factors taken together determine the process of deformation as a whole.

Stability of deformation depends on whether the expression

$$J_1(\gamma h)\, J_0(\bar{\gamma} h) + J_1(\bar{\gamma} h) J_0(\gamma h)$$

is positive or negative. In this expression $h = na$ and γ and $\bar{\gamma}$ are a complex number and its conjugate value, which depend on the velocity of deformation and on the constants σ_s and μ. It is interesting to note that conditions may be set up in which the relative deviation of the form of the bar from that of a cylinder may be increased owing to compression. A. Ilyushin has proved this phenomenon experimentally.

Elastico-Plastic Bending of Plates and Shells

An interesting section of the theory of plasticity, which has been considerably developed in Russia, is the theory of the elastico-plastic bending of plates and shells. This theory is based on the Kirchoff-Love hypothesis of the "rectilinear element" and is a generalization of the theory of the bending of beams.

The starting point in this problem is the condition of ideal plasticity of Mises

$$\sigma_\alpha^2 + \sigma_\beta^2 - \sigma_\alpha \sigma_\beta + 3\,\tau_{\alpha\beta}^2 = \sigma_s^2$$

where σ_α, σ_β are the normal components of stress, $\tau_{\alpha\beta}$ the shearing stress, and σ_s the yield stress.

Or the condition of the more general form may be postulated

$$\left| \sqrt{\sigma_\alpha^2 + \sigma_\beta^2 - \sigma_\alpha \sigma_\beta + 3\tau_{\alpha\beta}^2} \right| = F\left(\left| \sqrt{\epsilon_\alpha^2 + \epsilon_\beta^2 + \epsilon_\alpha \epsilon_\beta + \frac{1}{4}\gamma_{\alpha\beta}^2} \right| \right)$$

($\epsilon_\alpha, \epsilon_\beta$, and $\gamma_{\alpha\beta}$ are the components of strain) where the z-axis is normal to the middle surface of the shell, β = const and α = const are curvilinear co-ordinates on the middle surface, and F is a power function. This latter condition takes the strain-hardening of the material into consideration.

Both of the conditions mentioned are somewhat simplified by neglecting the shearing-stress components $\tau_{\alpha z}$, $\tau_{\beta z}$ and the unit shears $\gamma_{\alpha z}$, $\gamma_{\beta z}$ in comparison with σ_α, σ_β, and ϵ_α, ϵ_β.

A. Ilyushin (5) considered the rotationally symmetric plastic state set up in circular cylindrical shells loaded by normal pressures uniformly distributed along a range of the generatrix.

Fig. 2 shows the distribution of the plastic zones over the meridional cross section of a cylindrical shell. A completely plastic state throughout the thickness of the shell may be set up along a range of the generatrix. This is an important feature distinguishing this problem from that of the bending of beams; for in the bending of beams a completely plastic state may arise only at points on the axis of the beam and not throughout a range.

The author (21) has investigated the elastico-plastic state in a

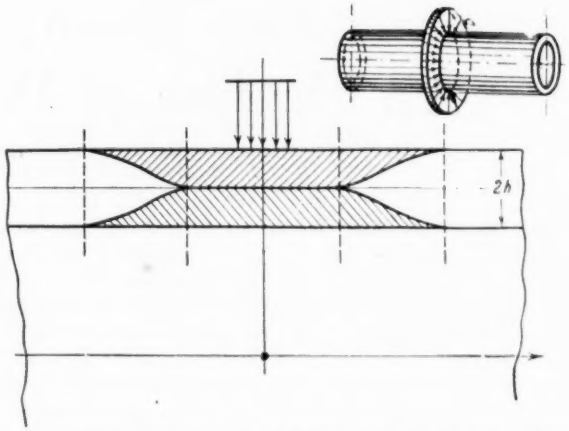

Fig. 2 Distribution of Plastic Zones in Wall of Cylindrical Shell

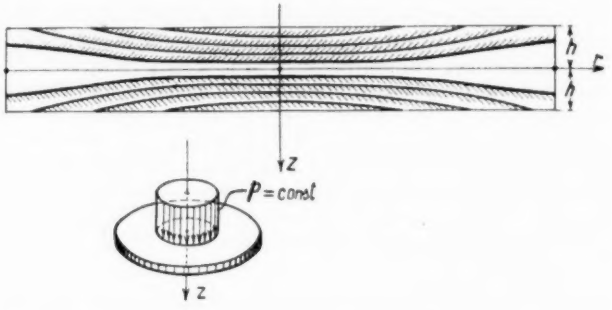

Fig. 3 Successive Expansion of Plastic Zones in Circular Plate

circular plate of radius a, subjected to the action of a rotationally symmetric distribution of an arbitrary load.

Fig. 3 shows the successive growth and expansion of the plastic zones through the thickness of the plate in a meridional cross section due to an increase of a uniformly distributed load over the surface of the plate p = constant.

When

$$p = 6.58\, \sigma_s \frac{h^2}{a^2}$$

($2h$ = plate thickness, a = radius of plate, σ_s = yield stress in tension) a pure plastic state (a completely plastic state throughout the thickness of the plate) arises at the center, and simultaneously the entire plate passes into a pure plastic state. The same phenomenon takes place when the load is distributed over any one of the concentric circles of the plate. This is an interesting feature distinguishing this problem from that of the bending of beams, for the rise of a pure plastic state at one point of the beam does not induce a pure plastic state throughout the beam.

Fig. 4 represents the relationship between the value of the deflection f in the center of the plate and the value of the increasing load p.

A. Ilyushin obtained the finite relationship between the stress resultants T_α, T_β, S and moments M_α, M_β, H for a completely plastic state of a shell. This condition arises out of the Mises condition of plasticity and may be expressed in terms of two parameters.

This finite relationship between resultants of stress and moments may be applied to the solution of problems of the com-

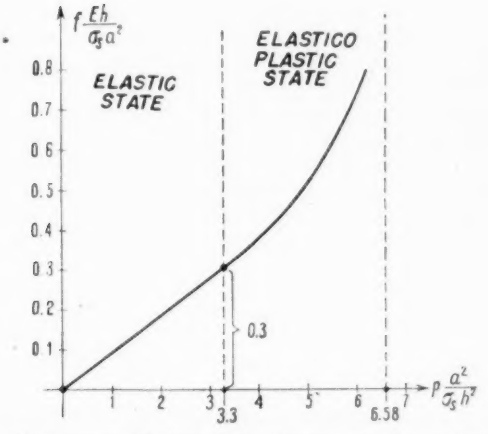

FIG. 4 DEFLECTION VERSUS LOAD CURVE FOR PLATE SHOWN IN FIG. 3

pletely plastic state by means of the methods of the calculus of variations.

In the particular case of rotationally symmetric deformations without axial stretching, the resulting formulas take the form

$$T_\alpha = \pm \frac{\sqrt{\xi}}{2} \ln \frac{\sqrt{1+\xi}+1}{\sqrt{1+\xi}-1}$$

$$M_\alpha = \pm \frac{2}{\sqrt{3}} \left(\sqrt{1+\xi} - \frac{\xi}{2} \ln \frac{\sqrt{1+\xi}+1}{\sqrt{1+\xi}-1} \right)$$

where ξ is a parameter.

These formulas give the relationship between the values of the longitudinal stress resultant T_α and the bending moment M_α in case of a pure plastic state of a shell.

Stability of compressed bars beyond the limit of elasticity was investigated by Th. von Kármán in 1909. Von Kármán's formula for plasticity with linear strain-hardening gives the following value for the critical length l_{cr} of the bar (beyond which the bar loses its stability) beyond the limit of elasticity

$$l_{cr} = i\pi \sqrt{\frac{K}{\sigma}}, \qquad K = \frac{4EE_1}{(\sqrt{E}+\sqrt{E_1})^2}$$

where K is the so-called von Kármán or reduced modulus of buckling, E is the modulus of elasticity, and E_1 is the modulus of linear strain-hardening (i is an integer).

For the case of ideal plasticity, $E_1 = 0$, the critical length of the bar is equal to zero

$$l_{cr} = 0$$

A. Ilyushin (6) investigated the stability of plates and shells beyond the limits of plasticity; his starting point was the Mises-Hencky theory of plasticity and the law of unloading. For the sake of simplicity the material was assumed as incompressible in both the elastic and plastic zones (Poisson's ratio $\nu = 1/2$).

Loss of stability lies in the fact that for certain magnitudes of the external forces, besides the initial state of equilibrium, another state of stress

$$\sigma_\alpha + \delta\sigma_\alpha, \sigma_\beta + \delta\sigma_\beta, \tau_{\alpha\beta} + \delta\tau_{\alpha\beta}, \epsilon_\alpha + \delta\epsilon_\alpha, \epsilon_\beta + \delta\epsilon_\beta, \gamma_{\alpha\beta} + \delta\gamma_{\alpha\beta}$$

becomes possible and that (excluding eccentrically applied loads) the transition from the first state into the second occurs with no change of forces.

If the plate is in a pure plastic state prior to loss of stability, then after loss of stability, generally speaking, two zones form throughout the thickness of the plate; in one of them loading will continue and it will remain plastic, and in the other unloading will begin and it will become elastic. On the boundary between these two zones the intensity of the shearing deformation is constant.

A. Ilyushin expresses the increments of the moments and forces in terms of the deflection of the middle surface of the plate and derives the basic differential equation of stability, which is a generalization of Bryan's equation for elastic cases. He investigated a number of interesting particular cases of stability, among them the case of instability of a rectangular plate with two free edges compressed by a load uniformly distributed along the two other edges.

It is interesting to note that if a material with ideal plasticity is assumed, the calculation proves the existance of a plastic zone only in the plate after loss of stability (the elastic zone vanishes). It was found that the critical length of the plate is not zero but, when $2h$ is the thickness of the plate, is equal to

$$l_{cr} = \frac{\pi}{3} h \sqrt{\frac{E(1-\psi)}{\sigma_s}}$$

where σ_s is the yield stress, and ψ is a variable, increasing in the process of flow from 0 to 1. At the beginning of flow $\psi = 0$, and the critical length will be one half of the corresponding critical length in the elastic state.

The application of this theory to shells made it possible to investigate the rotationally symmetric case of the stability of a circular cylindrical shell compressed by external pressure and an axial force.

Mention must also be made of simpler elastico-plastic problems. Among these are the cases of plastic equilibrium of a hollow sphere, of a hollow cylinder, and the torsion and simultaneous stretching of a circular bar. These problems, which have wide practical application, were studied by Smirnov-Alayev (16), N. Belayev (2), and the author (20).

In solving these problems, the Mises-Hencky theory was employed, under the assumption of the incompressibility of the plastic material. This assumption has a strong influence upon the value of the displacements and does not permit satisfying completely the conditions of the continuity of all the components of stress and displacements on the boundary between the elastic and the plastic zones.

An objective of recent work is to avoid these defects of the theory. This requires employing the exact theory of Mises-Hencky by taking into consideration the compressibility of the material in both the elastic and the plastic zones.

The method evolved for the solution of this problem may be applied to the condition of ideal plasticity of Mises-Hencky or to the Schmidt condition of strain-hardening of the material. The solutions of these problems are given either in closed form or reduced to one of the usual nonlinear equations of the first order.

PLASTIC STATE OF PLANE STRAIN AND PLANE LIMITING STATE OF EQUILIBRIUM OF A SOIL

The starting point for the theory of the plastic state of plane strain (strain $\epsilon_z = 0$) may be the Saint Venant theory of plasticity or the Mises-Hencky theory; while the starting point for the theory of the limiting cases of equilibrium in loose materials may be Koetter's equation.

The condition of plasticity, according to the Saint Venant and the Mises-Hencky theories, has the form

$$(\sigma_x - \sigma_y)^2 + 4\tau_{xy}^2 = 4k^2 \quad \ldots\ldots\ldots\ldots [1]$$

where for the Saint Venant theory $k = \sigma_s/2$ and for the Mises-Hencky theory $k = \sigma_s/\sqrt{3}$ where σ_s = yield stress for tension.

The condition of limiting equilibrium, according to the Koetter theory, is

$$(\sigma_x - \sigma_y)^2 + 4\,\tau_{xy}^2 = \sin^2\rho(\sigma_x + \sigma_y + 2\,k\,\operatorname{ctg}\rho)^2 \ldots [2]^6$$

where ρ is the angle of internal friction and k is the coefficient of cohesion.

The two equations of equilibrium

$$\frac{\partial\sigma_x}{\partial x} + \frac{\partial\tau_{xy}}{\partial y} = X, \quad \frac{\partial\tau_{xy}}{\partial x} + \frac{\partial\sigma_y}{\partial y} = Y \ldots\ldots\ldots [3]$$

together with conditions of Equation [1] or [2], comprise a system of three equations for determining the three unknowns σ_x, σ_y, and τ_{xy}.

The system of Equations [1] and [2] has been investigated by a number of scientists, among them M. Levy, H. Hencky, L. Prandtl, H. Reissner, H. Geiringer, W. Prager, A. Nadai, and S. Christianovich. These equations belong to the hyperbolic type and hence possess two families of characteristics (lines of slip) which are orthogonal curves in the x, y-plane. Equations [1] and [3] may be reduced to two linear canonic equations (if both families of characteristics are curvilinear), or, as was shown by S. Christianovich, have integrals with an arbitrary function (if one of the families of the characteristics consists of straight lines).

Continuing the interesting work of Geiringer and Prager, Christianovich (24) solved the boundary-value problem for the distribution of stresses in the plastic zones outside and within a closed contour, assuming that the stresses are given along this contour. The problem can be reduced to the Cauchy boundary-value problem for the canonic equations mentioned, for given values along a segment of a curve in certain auxiliary planes represented by means of the characteristic curves.

For obtaining numerical solutions to these boundary problems of Christianovich and of the theory of loose materials, the Massot method was employed in which the solution of the corresponding equations is reduced to defining the magnitude of the functions sought in a finite number of the points of intersection of the characteristics. In addition a number of important theorems on the properties of these solutions were derived.

The system for Equations [2] and [4] was set up by Koetter and investigated by Nadai, H. Reissner, and the author (19). It belongs to the hyperbolic type of equation and possesses two families of characteristics (curves of slip) intersecting each other in the x, y-plane at constant angles. The equations mentioned may also be reduced to the so-called canonic form.

The problem of the pressure of a loose soil on a retaining wall was investigated by Th. von Kármán for the case of a vertical retaining wall. The angle of friction between the wall and the soil is equal to the angle of internal friction of the soil. The author (19) has developed a general method of solving the basic problems of limiting equilibria in soils.

The particular feature of these problems is the presence of angular points on the contour and the discontinuity of the boundary stresses at certain points, which prevents the direct application of the Christianovich method.

This obstacle may be avoided by introducing solutions having particular points, each of which has a corresponding range of characteristics in the plane of the characteristics. The problem of limiting equilibrium of a soil may now be reduced to various combinations of boundary-value problems (the Cauchy, the Riemann, and the so-called mixed boundary-value problem) for a canonic system of equations, to which Koetter's equation may be reduced. A number of problems of the theory of a soil[7] will be examined, including the retaining wall, the stability of slopes and grounds under foundations, and the pressure of the ground between parallel walls.

As an illustration let us consider the Prandtl-Reissner generalized problem of a soil with a horizontal boundary which is taken as the x-axis. Determine the minimum normal stresses q along the negative x-axis so that the soil is in a limiting equilibrium under the action of the stresses $\sigma_y = p(x)$ and $\tau_{xy} = t(x)$, which are given along the positive x-axis. Fig. 5 represents the distribution of the characteristics (lines of slip) and the distribution of stresses along the negative x-axis. The determination of the net of characteristics and of the state of stress in the domains OAB, OBC, and OBD raises the Cauchy, Riemann, and mixed problems, respectively, for the canonic system of equations in the auxiliary plane of the characteristics. The solution in the domain OBC has the singular point O. The sought load q_0 at the point O can be expressed in closed form (for $k = 0$)

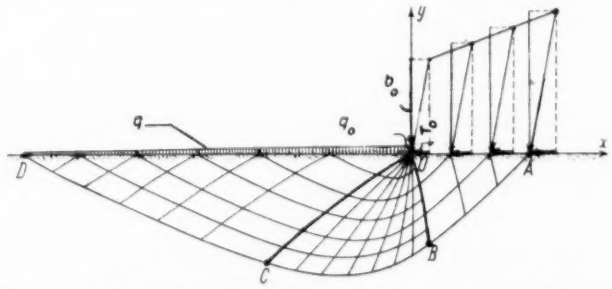

FIG. 5 SLIP PLANES AND STRESSES IN A SOIL SUBJECTED TO NORMAL AND SHEARING LOADS

$$q_0 = p_0 \frac{1 - \sin\rho}{\cos^2\mu[1 + \cos\rho \cdot \sqrt{\operatorname{tg}^2\rho - \operatorname{tg}^2\mu}]} e^{\left\{-\left[\pi+\mu+\arcsin\frac{\sin\mu}{\sin\rho}\right]\operatorname{tg}\rho\right\}}$$

where

$$\operatorname{tg}\mu = t_0/p_0, \quad p_0 = p(0), \quad t_0 = t(0)$$

The problem of the stability of the slope may be taken as another illustration of the foregoing. Let the normal pressure along the positive x-axis be given; find the form of the surface slope for a state of limiting equilibrium of a soil.

Fig. 6 shows the distribution of the characteristics and the form of the curve[8] bounding the slope. The state of stress in the domain OAB is given in closed form; where the characteristics (lines of slip) are two families of parallel straight lines. The determination of the net of characteristics and of the state of stress in the domains OBC and OBD raises the Riemann and mixed problems, respectively, for the canonic system of equations in the auxiliary plane of the characteristics. The solution in the domain OBC has the singular point O. Incidentally, the slope of the curve at the point O may be given in finite form.

For the case of a soil with ideal cohesion $\rho = 0$, the foregoing problem may be solved in finite form. The slope profile is given by the formula

$$x = \frac{2k}{\gamma} \ln \frac{\cos\left(\frac{p}{2k} - 1 - \frac{\gamma}{2k}\,y\right)}{\cos\left(\frac{p}{2k} - 1\right)} \ldots\ldots\ldots [4]$$

[6] In Equation [2], the European notation "ctg" ρ is used which is equivalent to "ctn" ρ in American usage. In succeeding equations, "tg" is equivalent to "tan;" arcsin $\{-\}$ is the same as $\sin^{-1}\{-\}$, etc.

[7] Of course it is supposed that the volume forces (weight of soil) are taken into consideration.

[8] For this problem, the line of repose appears to be similar to a straight line, but usually it has sufficiently large curvature.

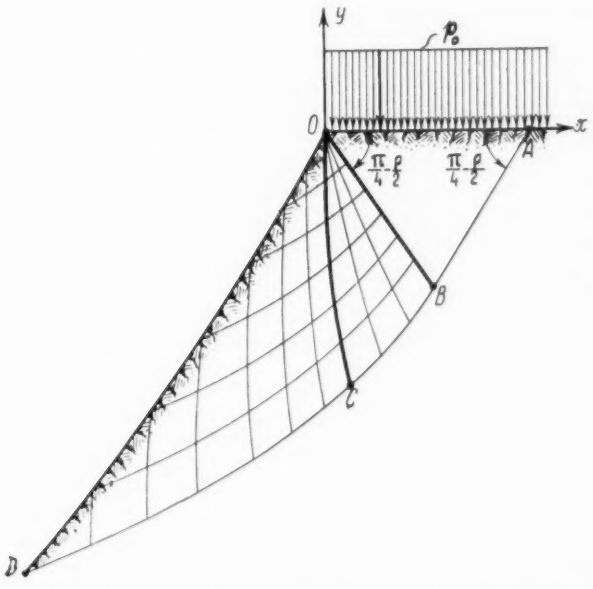

FIG. 6 SLIP PLANES IN A SLOPING SOIL SUBJECTED TO NORMAL LOADS ON PLATEAU

where γ is the weight per unit of volume.

A new problem (19) has been submitted for a limiting equilibrium of an anisotropic stratified medium, whose angle of internal friction $\bar{\rho}$ and coefficient of cohesion $\bar{k}$ over the horizontal planes $y = \text{const}$ are less than the angle of internal friction ρ and the coefficient of cohesion k over other planes

$$\bar{\rho} < \rho, \quad \bar{k} < k$$

The conditions of limiting equilibrium of a stratified soil may be expressed by the following equations

$$(\sigma_x - \sigma_y)^2 + 4\,\tau_{xy}^2 = \sin^2\rho\,(\sigma_x + \sigma_y + 2\,k\,\operatorname{ctg}\rho)^2 \ldots [5]$$

when

$$|\tau_{xy}| \leqq \sigma_y \operatorname{tg}\bar{\rho} + \bar{k}$$

and

$$|\tau_{xy}| = \sigma_y \operatorname{tg}\bar{\rho} + \bar{k} \ldots\ldots\ldots\ldots\ldots [6]$$

when

$$(\sigma_x - \sigma_y)^2 + 4\,\tau_{xy}^2 \leqq \sin^2\rho\,(\sigma_x + \sigma_y + 2k\,\operatorname{ctg}\rho)^2$$

Equation [5] coincides with the condition of the limiting equilibrium for an isotropic medium, while Equation [6] is valid for an isotropic stratified medium.

Employing these equations, various problems of the limiting equilibrium of a stratified medium may be solved.

In considering, for example, the Prandtl generalized problem, three zones must be distinguished in the soil. In these zones the limiting equilibrium is described by Equations [5] and [6]. The boundary between these zones is sought and must be determined in the process of the solution of the problem. For the sake of brevity, we shall limit ourselves to presenting the finite formula for the value q_0 at the point

$$0 \text{ (when } k = \bar{k} = 0,\ t = 0)$$

$$q_0 = p_0 \frac{(1 - \sin\rho)\,[\cos\bar{\rho} - \sqrt{\sin^2\rho - \sin^2\bar{\rho}}]}{(1 + \sin\rho)\,[\cos\bar{\rho} + \sqrt{\sin^2\rho - \sin^2\bar{\rho}}]}\, e^{\left\{-2\operatorname{tg}\rho\,\arcsin\frac{\sin\bar{\rho}}{\sin\rho}\right\}}$$

$p_0 - q_0$ is the value of the discontinuous drop of the normal boundary stresses at the point 0.

The comparison of this formula with the corresponding formula for the isotropic medium $\bar{\rho} = \rho$ shows that the magnitude q_0 for the stratified medium is larger than the corresponding magnitude for the isotropic medium, which is also obvious from physical considerations.

Further applications of methods developed in the theory of soils to plastic states of plane strain make it possible to consider a number of problems raised by H. Hencky and L. Prandtl.

As an illustration, we shall give a simple finite formula which occurs in the problem of driving a rough-surfaced circular punch of radius a into a plastic body (the maximum force of friction being constant and equal to τ). The value of the force P is related to the angle γ by the formulas, Fig. 7

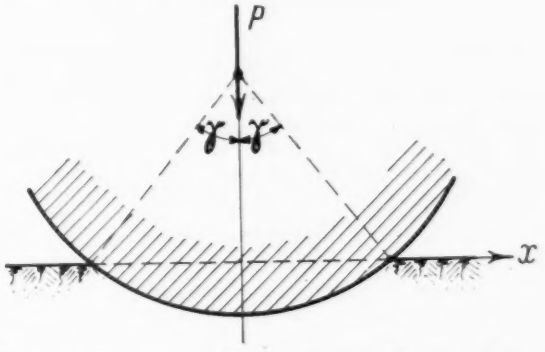

FIG. 7 INDENTATION OF PLASTIC BODY BY CIRCULAR PUNCH

for $2\gamma \leq \arcsin t$

$$\frac{P}{ka} = 2\,(\pi + 2)\sin\gamma$$

for $2\gamma \geq \arcsin t$

$$\frac{P}{ka} = 2\,(\pi + 2)\sin\gamma_* + 2\,(\sin\gamma - \sin\gamma_*)\,(\pi + 1 + \arcsin t + \sqrt{1 - t^2}) - 4\,(\gamma\sin\gamma - \gamma_*\sin\gamma_* + \cos\gamma - \cos\gamma_*) + 2t\,(\cos\gamma_* - \cos\gamma)$$

where

$$2\,\gamma_* = \arcsin t, \quad t = \frac{\tau}{k}$$

More complex problems may also be solved, for example, compression of a plastic strip of finite length between two rough-surfaced parallel plates.[9]

The important problem of the rolling of metals was raised by Th. von Kármán and further investigated by A. Nadai. The problem was further developed in Russia by C. Shevchenko, who considered this problem as a plane problem of the theory of plasticity. He found the distribution of the stresses throughout the thickness of the strip.

A few words may be said in conclusion concerning the axially symmetric problem investigated by A. Ishlinsky. It is known that the axially symmetric problem becomes statically determinable after assuming that not a condition of plasticity is considered according to Saint Venant or Mises, but a "completely plastic" body is postulated, according to Haar and von Kármán, in which the two principal shearing stresses in every point are equal to the constant of plasticity.

[9] Prandtl solved the same problem for strips of infinite length.

This problem was first considered by Hencky. A detailed investigation of the equations was carried out by A. Ishlinsky (10), who solved the problem of driving a ball into a plastic body (Brinell hardness test). The ratio between σ_s and H_B has the order

$$\frac{\sigma_s}{H_B} \approx 0.38$$

(σ_s = yield stress for compression, H_B = Brinell hardness.)

Experimental results obtained in driving steel balls into zinc and lead gave

$$\frac{\sigma_s}{H_B} \approx 0.34 - 0.36$$

Plastic States of Plane Stress

The starting point for the theory of the plastic states of plane stress may be either the Saint Venant or the Mises theory of plasticity. We shall consider both of these theories, investigated by the author (22, 23).

The Saint Venant condition of plasticity assumes that the maximum shearing stress is constant

$$|\tau|_{max} = \frac{1}{2}\sigma_s$$

For a state of plane stress ($\sigma_3 = 0$) this condition is presented in two forms, depending on the signs of the two principal stresses σ_1, σ_2 which are not equal to zero.

If σ_1 and σ_2 have different signs, i.e., $\sigma_1\sigma_2 \leqq 0$, the maximum shearing stress acts in planes parallel to the z-axis, and

$$|\tau|_{max} = \frac{1}{2}|\sigma_1 - \sigma_2|$$

If σ_1 and σ_2 have the same signs, i.e., $\sigma_1\sigma_2 > 0$, the maximum shearing stress acts in planes inclined to the z-axis at angles $\pi/4$ and

$$|\tau|_{max} = \frac{1}{2}|\sigma_1|, \quad (|\sigma_1| > |\sigma_2|)$$

In terms of the components of stress σ_x, σ_y, τ_{xy}, these conditions of plasticity may be presented in the form of the following equations

$$(\sigma_x - \sigma_y)^2 + 4\tau_{xy}^2 = 4k^2 \quad \ldots\ldots [7]$$

for

$$\sigma_x\sigma_y \leq \tau_{xy}^2$$

and

$$\sigma_x\sigma_y - \tau_{xy}^2 = \sigma_s(|\sigma_x + \sigma_y| - \sigma_s) \quad \ldots\ldots [8]$$

for

$$\sigma_x\sigma_y \geq \tau_{xy}^2$$

where

$$k = \sigma_s/2$$

The first of these equations coincides with the condition of plasticity for the state of plane strain (strain $\epsilon_z = 0$), while the second occurs only for a state of plane stress ($\sigma_3 = 0$).

The Huber-Mises condition of plasticity substitutes for the two conditions Equations [7] and [8], one equation

$$\sigma_x^2 + \sigma_y^2 - \sigma_x\sigma_y + 3\tau_{xy}^2 = \sigma_s^2 \quad \ldots\ldots [9]$$

The equations of equilibrium

$$\frac{\partial\sigma_x}{\partial x} + \frac{\partial\tau_{xy}}{\partial y} = 0, \qquad \frac{\partial\tau_{xy}}{\partial x} + \frac{\partial\sigma_y}{\partial y} = 0 \quad \ldots\ldots [10]$$

must also be satisfied.

We note that the system of Equations [7] and [10], if the constant is taken equal to $k = \sigma_s/\sqrt{3}$, coincides with the system of equations describing the plastic state of plane strain, according to the Mises theory. Consequently, a case of plane stress of Saint Venant is identical with a case of plane strain of Mises, provided that

$$\sigma_x\sigma_y < \tau_{xy}^2 \text{ and } k = \sigma_s/\sqrt{3}$$

The system of Equations [8] and [10] may be integrated in finite form. The integrals contain two arbitrary functions. The characteristics are a family of straight lines in the x, y-plane.

The system of Equations [9] and [10] may belong either to the hyperbolic or to the elliptic type, depending upon the character of the state of stress.[10]

When these equations are of the hyperbolic type, they have two families of characteristics intersecting at variable angles. Equations [9] and [10], in the domain where they are hyperbolic, may be reduced to a system of two linear equations, canonic equations (if both families of characteristics are curvilinear), or permit of integrals with an arbitrary function (if one of the families of characteristics consists of straight lines).

Our first illustration (23) is the problem of a plate with an aperture, along whose contour distributed stresses are applied, the plate being stretched by distributed forces at infinity. This problem may be solved either according to the Saint Venant or the Mises theory of plasticity.

In the particular case of a circular hole of radius a with an axially symmetric distribution of stresses, the solution of the problem can be obtained in finite form.

As an illustration, Fig. 8 shows the pattern of the characteristic curves, constructed according to the theory of Saint Venant for an inner pressure ($\sigma_r < 0$). The plastic ring domains $a \leq r < c$ and $c < r < \infty$ are zones in which the systems of Equations [7],

[10] Roughly speaking, Equations [9] and [10], in the domain where they are hyperbolic, correspond to Equations [7] and [10], and in the domain where they are elliptic to Equations [8] and [10].

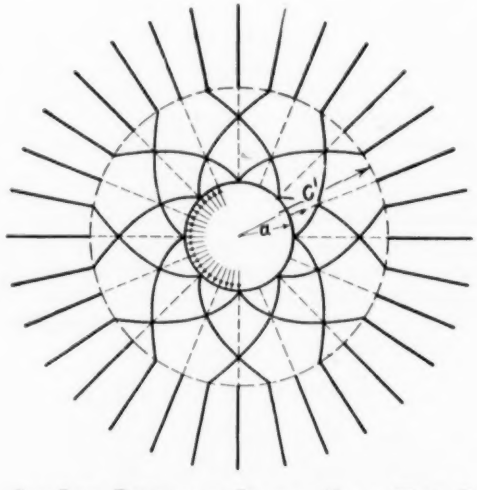

Fig. 8 Slip-Line Pattern in Infinite Plate With Circular Hole
(Saint Venant theory of plasticity.)

[10], and [8], [10] hold, respectively. The boundary between these zones is a circle of radius c.

Fig. 9 shows the form of the characteristic curves constructed according to the Mises theory,[11] also for the same value of the

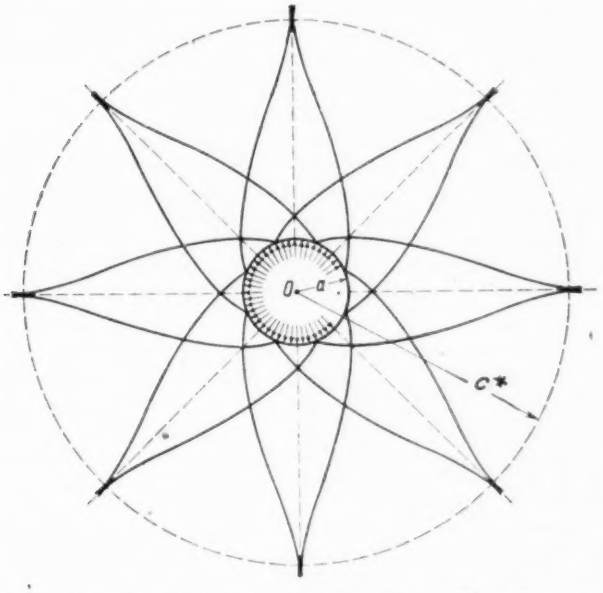

FIG. 9 SLIP-LINE PATTERN IN INFINITE PLATE WITH CIRCULAR HOLE
(Mises theory of plasticity.)

pressure, $\sigma_r < 0$. The plastic ring domains $a \leq r < c^*$ and $c^* < r < \infty$ are hyperbolic and elliptic zones for the system, Equations [8] and [10], respectively. The boundary between these zones is a circle of radius c^*.

Fig. 10 shows the case where internal pressure is absent $\sigma_r = 0$. The solid lines show the distribution of stresses according to the

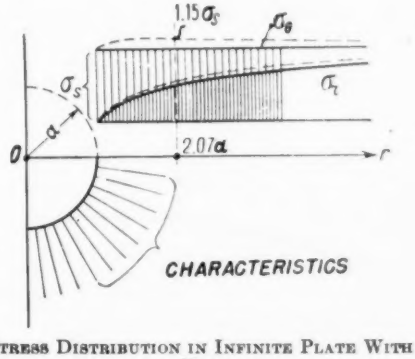

FIG. 10 STRESS DISTRIBUTION IN INFINITE PLATE WITH CIRCULAR HOLE

theory of Saint Venant, while the broken lines show the distribution of stresses according to the theory of Mises.

The states mentioned require uniformly distributed stresses of equal intensity in all directions

$$\sigma_r = \sigma_\theta = \sigma_s$$

at infinity.

In the general case of an arbitrary noncircular aperture, the problem may also be solved.

[11] The solution of this problem according to the Mises theory of plasticity belongs to A. Nadai.

Fig. 11 illustrates two regions of the characteristics outside an elliptic aperture, along the contour of which a uniformly distributed normal pressure is applied $\sigma_n < 0$, $\tau_{ln} = 0$, the calculation being made according to the theory of plasticity of Saint Venant.

(Saint Venant theory of plasticity.)

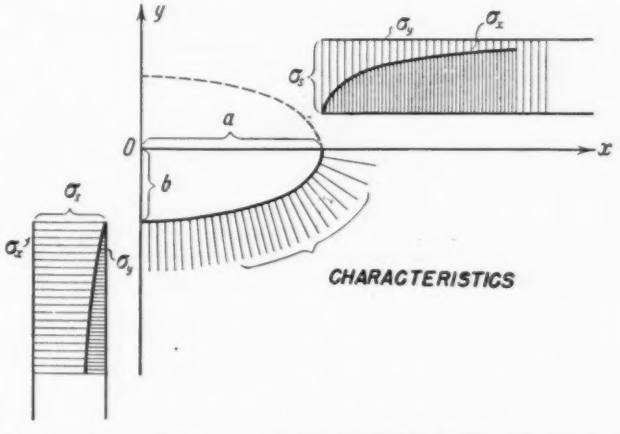

FIG. 12 STRESS DISTRIBUTION IN INFINITE PLATE WITH ELLIPTICAL HOLE

It will readily be seen that near the elliptic aperture the state of stress is described by Equations [7] and [10]; while at a distance from it, it is defined by Equations [8] and [10]. The net of the characteristics and the stress components near the aperture, where the characteristics are two families of curves, were determined by the Christianovich method. The net of the characteristics and the stress components at a distance from the aperture, where the former ones consist of straight lines, may be determined by defining the arbitrary function of the corresponding integrals (the solution may be given in finite form). The conditions of continuity of all the components of stress make it possible to determine the boundary curve between the two zones.

Fig. 12 illustrates the case of absence of internal pressure $\sigma_n = \tau_{ln} = 0$. The characteristics are normal to the contour, and the problem may be solved in finite form. The following formulas for the stresses along the x-axis and y-axis are given as illustrations:

Along the x-axis

$$\sigma_x = \sigma_s\left(1 + \frac{b^2}{a^2 - b^2 - a\,|x|}\right), \quad \sigma_y = \sigma_s, \quad \tau_{xy} = 0$$

and along the y-axis

$$\sigma_x = \sigma_s, \quad \sigma_y = \sigma_s\left(1 - \frac{a^2}{a^2 - b^2 + b\,|y|}\right), \quad \tau_{xy} = 0$$

where a and b are the semiaxes of the elliptical contour.

The foregoing distribution of stress requires the uniform stresses

$$\sigma_x = \sigma_y = \sigma_s, \quad \tau_{xy} = 0$$

at infinity.

As a second illustration (23), we may mention the problem of the distribution of stresses in a strip of material drawn through a fixed rigid die; the angle between the inclined sides of the die is equal to 2γ. The maximum force of friction between the die and the plastic strip is assumed to be constant and equal to τ. It is assumed that at the narrow end of the die cross section, $x = 0$

$$\sigma_x = p = \text{const}, \quad \tau_{xy} = 0, \quad \sigma_y < \sigma_x$$

Incidentally, any other assumption might have been made as to the distribution of stresses σ_x over the cross section $x = 0$. This would have significance only at the narrow butt end of the die. Therefore, in solving the problem according to the Saint Venant theory, the interesting closed solution for a wedge suggested by A. Nadai may also be employed.

Figs. 13 and 14 show the pattern of the characteristics in the plastic strip and the distribution of the pressures along the contact line, which are determined according to the theories of Saint Venant and Mises. The net of characteristics and stress components in the domains ABC, $CDEF$, ... where one of the families of characteristics is composed of straight lines, may be determined by defining the arbitrary functions of the corre-

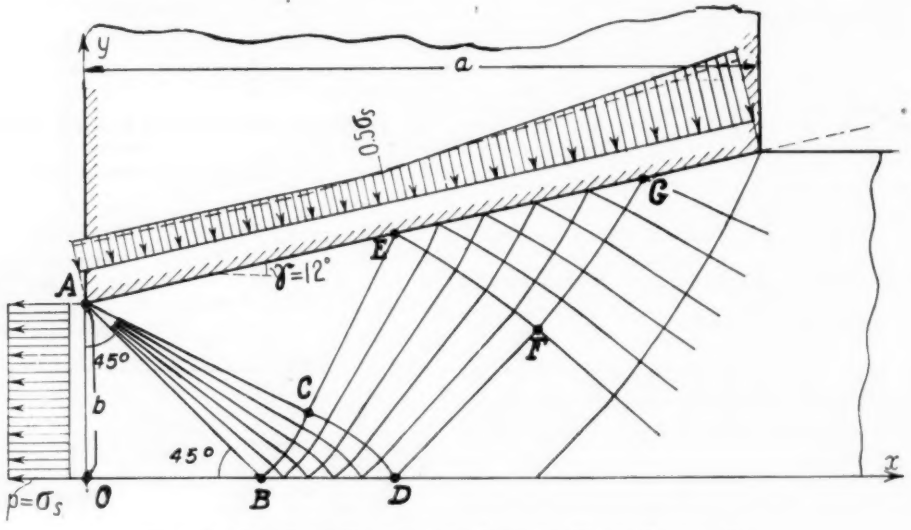

FIG. 13 SLIP-LINE PATTERN FOR STRIP IN WEDGE-SHAPED DIE
(Saint Venant theory of plasticity.)

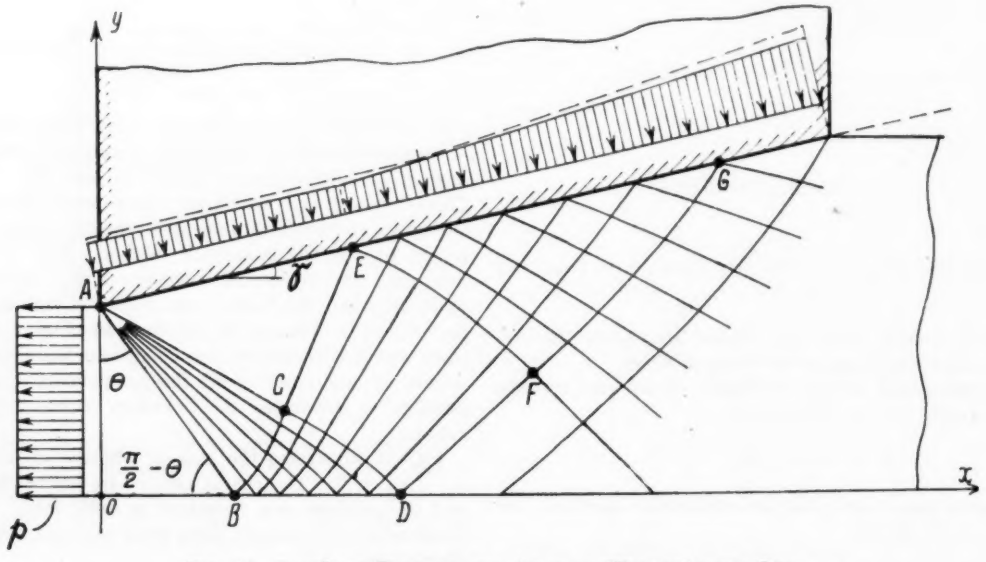

FIG. 14 SLIP-LINE PATTERN FOR STRIP IN WEDGE-SHAPED DIE
(Mises theory of plasticity.)

sponding integrals for the equations of plasticity (the solution is obtained in closed form). The net of characteristics and stress components in the domains *BCD*, *EFG*, ... where both families of the characteristics are curvilinear may be determined by solving the mixed boundary problems for the corresponding canonic equations (the calculation being made according to the approximate method of Massot). The drawing stresses p over the cross section O–A may be found from the conditions of equilibrium

$$pb = -\text{tg}\ \gamma \int_0^a \sigma_n\, dx + \tau a$$

where a is the length of the die, $2b$ is the thickness of the strip after drawing, γ the angle of inclination of the die, σ_n the normal stress, and τ = const the friction along the contact surface.

It is interesting to note that the net of the characteristic curves in the Saint Venant theory does not depend on the parameter p, while the net of the characteristics according to the Mises theory does depend on p.

The problem of drawing, according to the Saint Venant theory for a state of plane stress (if we will take $k = \sigma_s/\sqrt{3}$), may be treated as the same problem, according to the Mises theory for a state of plane strain. Therefore, comparison of the results may offer a conception of the differences resulting in the investigation of an infinitely wide and of a very thin strip.

The difference between the pressures along the contact lines can be seen from a comparison of the solid and the broken pressure lines in Figs. 13 and 14.

The solution of the problem of the elastico-plastic torsion of a cylindrical bar of an oval cross section, bounded by the contour

$$x = [a + b\,(\cos 2\alpha + 2)]\sin\alpha, \quad y = -[a + b\,(\cos 2\alpha - 2)]\cos\alpha, \qquad \text{for } b/a \leq 1/3$$

(where α is the slope of the contour toward the x-axis; this contour approaches an ellipse with semiaxes $a + b$ and $a - b$) was the subject of a previous investigation by the author (18).

The state of stress in the bar is described by the equation of equilibrium

$$\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} = 0$$

and by the equation

$$\frac{\partial \tau_{yz}}{\partial x} - \frac{\partial \tau_{xz}}{\partial y} = 2G\theta$$

in the elastic zone, where θ is the angle of twist per unit of length; and by the condition of plasticity

$$\tau_{xz}^2 + \tau_{yz}^2 = k^2$$

in the plastic zone. The components of stress and displacement are continuous on the boundary between the elastic and plastic zones.

The solution of this problem was obtained in finite form. The formula for the torque M, depending on the angle of twisting, is

$$|M| = \frac{2\pi}{3} ka^3 \left[1 - \frac{1}{8\Theta^3} - \frac{9}{2}\beta^2 - \frac{1}{2\Theta}\left(\frac{1}{4\Theta^2} - 2\beta^2\right)\sqrt{1 + 16\,\beta^2\Theta^2}\right]$$

The formula holds for

$$\Theta \geq \frac{1 - \beta}{(1 + \beta)(1 - 3\beta)}$$

where

$$\Theta = \frac{Ga}{k}|\theta|, \quad \beta = b/a$$

The well-known formula for a circular cylindrical bar follows from this formula as a particular case, if $\beta = 0$.

Fig. 15 shows one quarter of the oval cross section. The contour of this oval, shown by the solid line, differs but little from the ellipse, shown by the broken line. The distorted surface of the initially plane cross section after twisting is represented in the figure by means of contour lines. The co-ordinates of these curves may be calculated from finite formulas for given axial displacements.

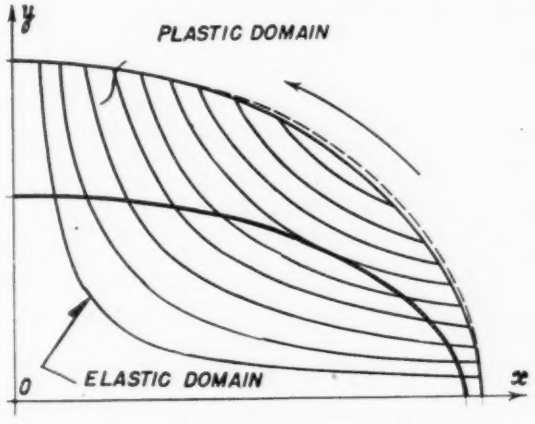

FIG. 15 TORSION OF ELLIPTICAL BAR

Using complex variables, I. Galin has solved the problem of the elastico-plastic torsion of a cylindrical bar having a polygonal cross section. As an example, the calculation was carried out in detail for a bar of square cross section.

The shapes of the plastic zones which were obtained by this calculation were closely similar to those which were observed by the sand-heap torsion analogy of A. Nadai.

A Velocity-Modified Temperature for the Plastic Flow of Metals

By C. W. MACGREGOR[1] and J. C. FISHER,[2] CAMBRIDGE, MASS.

Based on the work of Eyring and others relating to the creep problem, a velocity-modified temperature is developed for representing by means of a single variable the combined effects of strain rate and temperature on the stress reaction in a tension specimen. Available data are analyzed, indicating that the velocity-modified temperature is equally applicable to the tension test conducted at both slow and rapid rates and to the creep test. The data also indicate that the stress reaction, corresponding to tests at very slow and very rapid rates of deformation, may be found from tension tests at moderate strain rates and appropriately raised or lowered temperatures.

THE effects of different testing temperatures and true strain rates on the stress-strain properties of various metals tested in tension have been reported in an earlier paper (1).[3] Most of the previous investigations referred to therein were devoted to a study of the influence of temperature and speed of testing on the ordinary stress-strain properties as contrasted to the true stress-strain values. In addition an over-all rate of strain between the heads of the testing machine or over a standard gage length was usually employed where rates of strain were measured. Since the gage length changes as the specimen deforms and the rate of strain varies widely along the axis of the test bar when necking occurs, the more commonly used definition of strain rate obtained by dividing the rate of head motion by the initial gage length of the specimen entails certain errors.

This difficulty is overcome by using the true stress-strain approach (1, 2) in which the true strain is $\epsilon = q' = \log_e (A_0/A)$, where A_0 is the original area and A the instantaneous area of the cross section of the specimen. The value of ϵ is the actual strain at the smallest diameter of the specimen where it is deforming most rapidly. The time derivative of the true strain, $\frac{d\epsilon}{dt}$, then defines the true strain rate. This value can be maintained constant during any one test by varying the rate of head motion.

The experiments referred to (1) showed that in the temperature range $-70\ \text{C} \leq T \leq 665\ \text{C}$ and for true strain rates $5 \times 10^{-5}\ \text{sec}^{-1} \leq \dot{\epsilon} \leq 500 \times 10^{-5}\ \text{sec}^{-1}$, the true stress in a tension specimen of S.A.E. 1020 steel depends only on the true strain ϵ and a velocity-modified temperature $T_m = T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)$, where T is the absolute testing temperature, $\dot{\epsilon}$ is the constant true strain rate of the test, $\dot{\epsilon}_0$ is taken as $100 \times 10^{-5}\ \text{sec}^{-1}$, and k is a constant. The same was found to be true for S.A.E. 1045 steel and brass over smaller temperature ranges. Expressed symbolically then $S = f(\epsilon, T_m)$. In this manner the stress becomes a function of only two variables instead of a function of the three variables ϵ, $\dot{\epsilon}$, and T.

The principal objects of the present paper are to discuss the velocity-modified-temperature concept in greater detail and to show further evidence of its possible utility over a much wider range of strain rates extending from those found in slow creep tests to those present in rapid tension tests. In order to accomplish this, pertinent creep and rapid tension-test data available in the literature have been analyzed from the velocity-modified-temperature point of view.

The Velocity-Modified Temperature

Based on an absolute reaction-rate approach similar to that used in the problem of viscosity, Eyring (3) has developed a theory for the velocity of plastic flow as a function of temperature and stress. From the same standpoint, an expression for the velocity of secondary creep has been developed by Kauzmann (4) and has been discussed by Dushman, Dunbar, and Huthsteiner (5). At moderate stresses this expression is of the form

$$\frac{\dot{\epsilon}}{\dot{\epsilon}_0} = A \frac{T}{T_0} e^{-\frac{f^*(S)}{T}} \quad \text{.....[1]}$$

where $\dot{\epsilon}$ is the secondary creep rate, T is the absolute temperature, $f^*(S)$ is a function of the applied stress, and $\dot{\epsilon}_0$, A, and T_0 are constants.

Taking natural logarithms of both sides of Equation [1] and rearranging, the equation may be written as

$$T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0} \frac{T_0}{T}\right) = f_0(S) \quad \text{.....[2]}$$

where $k = 1/\log_e A$ and $f_0(S) = f^*(S)/\log_e A$. Equation [2] indicates that the quantity $T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0} \frac{T_0}{T}\right)$ is a function of the applied stress. Conversely, the stress is a function of

$$T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0} \frac{T_0}{T}\right)$$

or

$$S = f\left[T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0} \frac{T_0}{T}\right)\right] \quad \text{.....[3]}$$

The range of temperatures encountered in investigations of secondary creep is usually small, and the ratio T_{max}/T_{min} is often less than 1.3. In contrast to this, the range of creep rates is large, and the ratio $\dot{\epsilon}_{max}/\dot{\epsilon}_{min}$ is generally between 100 and 1000. When the range of temperatures is small, T_0 can be chosen so that $T_0/T \cong 1$. Making this approximation, Equation [3] reduces to

$$S = f\left[T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)\right] \quad \text{.....[4]}$$

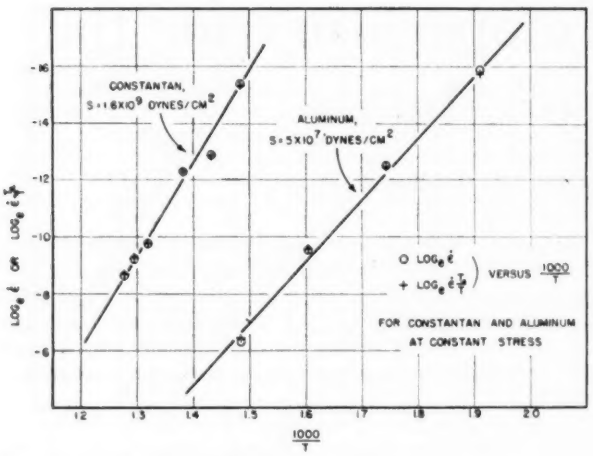

FIG. 1 $\text{LOG}_e\ \dot{\epsilon}$ AND $\text{LOG}_e\ \frac{\dot{\epsilon}T_0}{T}$ VERSUS $1000/T$ FOR THE SECONDARY CREEP OF CONSTANTAN AND ALUMINUM AT CONSTANT STRESS
(Data from Dushman, Dunbar, and Huthsteiner, ref. 5.)

Equation [4] can be derived also from the relationship

$$\frac{\dot{\epsilon}}{\dot{\epsilon}_0} = Ae^{-\frac{f^*(S)}{T}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

which is an approximation to Equation [1], in a manner similar to the derivation of Equation [3] from Equation [1].

Fig. 1 shows $\log_e\left(\frac{\dot{\epsilon}T_0}{T}\right)$ plotted versus $1000/T$ for the secondary creep of aluminum and constantan at constant stress from the data of Dushman, Dunbar, and Huthsteiner (5). Here T_0 has the value $\sqrt{T_{max}T_{min}}$. Fig. 1 also includes a plot of $\log_e \dot{\epsilon}$ versus $1000/T$ for the same experimental data. These curves are representative of those which may be obtained from the results of other carefully controlled measurements of the secondary creep rate. Since all of the curves in Fig. 1 are linear within the experimental error, and since both methods of plotting give points which are very nearly coincident, it may be concluded that Equations [1] and [5] are both satisfactory for a discussion of the creep data available at the present time. For this reason the simpler functional relationships contained in Equations [4] and [5] will be employed henceforth in this analysis, although it must be kept in mind that for an analysis of future work of a high degree of precision it may be desirable to use the relationships given in Equations [1] and [3], and for very low stresses an expression still more general than Equation [1] may be required (4).

The form of the relationship in Equation [4] can be found by considering a series of tests made at the constant strain rate $\dot{\epsilon}_0$. Equation [4] then reduces to

$$S = f(T) \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

and a plot of S versus testing temperature gives the functional form of f for the value of $\dot{\epsilon}_0$ chosen. Equation [4] states that the stress corresponding to a test at an arbitrary strain rate $\dot{\epsilon}$ and an arbitrary temperature T will be the same as for a test at the strain rate $\dot{\epsilon}_0$ and temperature $T\left(1 - k\log_e\frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)$. The quantity $T\left(1 - k\log_e\frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)$ is then the value of the temperature abscissa at which the stress value corresponding to a test at the strain rate $\dot{\epsilon}$ and temperature T must be plotted in order to coincide with the stress versus temperature curve for tests at the constant rate $\dot{\epsilon}_0$.

In practice a series of tests is conducted at a number of values of $\dot{\epsilon}$. The curve of S versus T_m for these tests should be identical with the curve of S versus T for tests at the particular rate $\dot{\epsilon}_0$, although it may have happened that none of the tests actually proceeded at the rate $\dot{\epsilon}_0$.

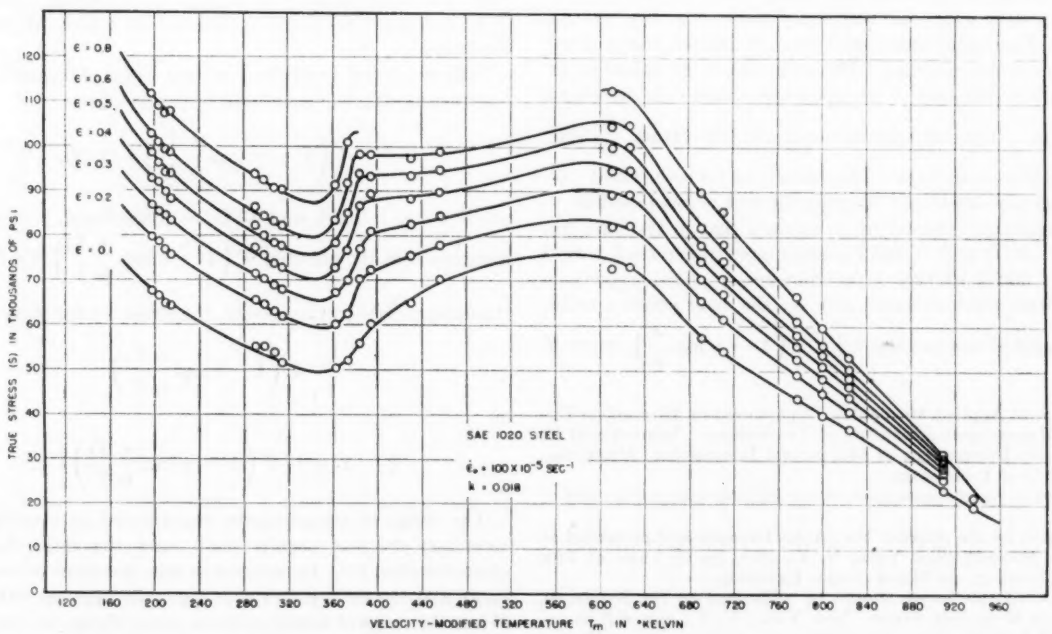

FIG. 2 STRESS VERSUS VELOCITY-MODIFIED TEMPERATURE AT CONSTANT STRAIN VALUES FOR CONSTANT TRUE-STRAIN-RATE TENSION TESTS OF S.A.E. 1020 STEEL

(Temperature and velocity values follow: At —70 C, 25 C, and 100 C, $\dot{\epsilon} = 5\times, 20\times, 100\times$, and 500×10^{-4} sec^{-1}; at 170 C, $\dot{\epsilon} = 20\times$ and 500×10^{-4} sec^{-1}; at 320 C, $\dot{\epsilon} = 5\times$ and 20×10^{-4} sec^{-1}; at 440 C and 665 C, $\dot{\epsilon} = 100 \times$ and 500×10^{-4} sec^{-1}; at 525 C, $\dot{\epsilon} = 20\times, 100\times$, and 500×10^{-4} sec^{-1}. After MacGregor and Fisher, ref. 1.)

The quantity $T\left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)$ has been called the velocity-modified temperature and has been designated (1) by the symbol T_m. With this notation, Equation [4] takes the form

$$S = f(T_m) \quad [7]$$

According to Equation [7], it should be possible for a given choice of $\dot{\epsilon}_0$ to select a value of k so that when stress is plotted versus T_m, a smooth curve will result.

It was suggested (1) that the functional relationship between stress and velocity-modified temperature might hold for tension tests at arbitrary temperatures and true strain rates as well as for secondary creep. Tension tests conducted at constant true strain rates showed that at a given strain the stress reaction in the specimen depended on the velocity-modified temperature, or in general

$$S = f(T_m, \epsilon) \quad [8]$$

From a series of true stress-strain tension tests conducted at constant true strain rates over a considerable range of temperatures, the stress reactions corresponding to a number of strain values were determined for several materials (1). Figs. 2 and 3 show the stress reactions for S.A.E. 1020 steel and for S.A.E. 1045 steel plotted as functions of the velocity-modified temperature for different strain values. Smooth curves were obtained for S as a function of T_m at constant strain as predicted by Equation [8]. Each closely grouped set of points in these figures corresponds to tests conducted at a given temperature.

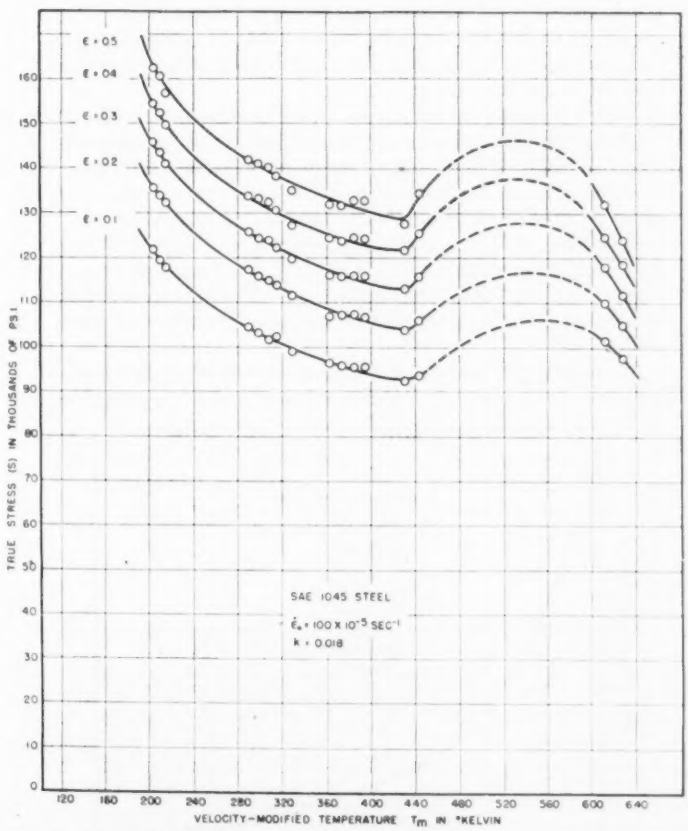

FIG. 3 STRESS VERSUS VELOCITY-MODIFIED TEMPERATURE AT CONSTANT STRAIN VALUES FOR CONSTANT TRUE-STRAIN-RATE TENSION TESTS OF S.A.E. 1045 STEEL

(Temperature and velocity values follow: At —70 C, $\dot{\epsilon}$ = 5×, 20 ×, and 100 × 10^{-5} sec^{-1}; at 25 C and 100 C, $\dot{\epsilon}$ = 5×, 20×, 100×, and 500 × 10^{-5} sec^{-1}; at 65 C, $\dot{\epsilon}$ = 500 × 10^{-5} sec^{-1}; at 170 C, $\dot{\epsilon}$ = 100× and 500 × 10^{-5} sec^{-1}; at 320 C, $\dot{\epsilon}$ = 5× and 20 × 10^{-5} sec^{-1}. After MacGregor and Fisher, ref. 1.)

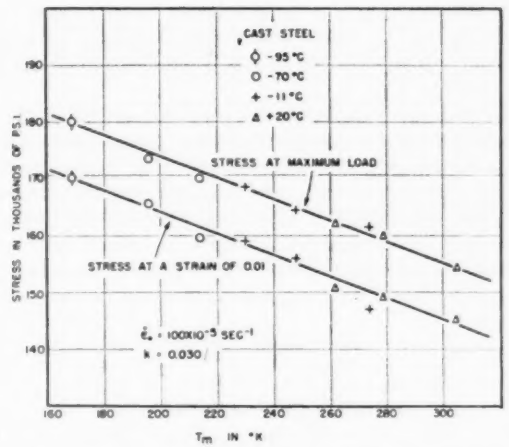

FIG. 4 STRESS AT MAXIMUM LOAD AND STRESS AT A STRAIN OF 0.01 VERSUS VELOCITY-MODIFIED TEMPERATURE FOR TENSION TESTS OF A CAST STEEL

(Temperature and velocity ranges follow: —95 C ≤ T ≤ 20 C and 1.7 × 10^{-4} sec^{-1} ≤ $\dot{\epsilon}$ ≤ 6.0 × 10^{-2} sec^{-1}. Data from Zener and Hollomon, ref. 6.)

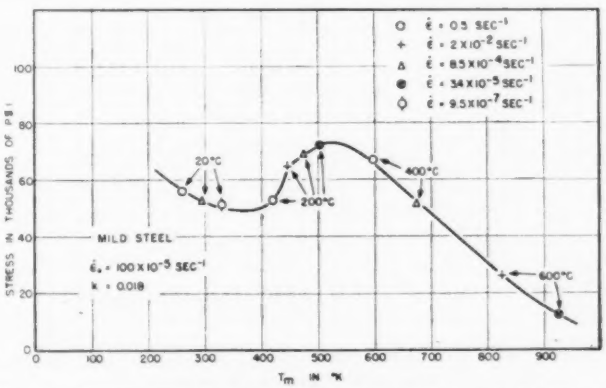

FIG. 5 STRESS AT A STRAIN OF 0.1 VERSUS VELOCITY-MODIFIED TEMPERATURE FOR TENSION TESTS OF MILD STEEL

(Temperature and velocity ranges follow: 20 C ≤ T ≤ 600 C and 9.5 × 10^{-7} sec^{-1} ≤ $\dot{\epsilon}$ ≤ 0.5 sec^{-1}. Data from Manjoine, ref. 7.)

For increasing temperatures, the stress reaction in the specimen is found farther to the right along the curve. In each group of points corresponding to tests at a given temperature the stress reaction is found farther to the right along the curve for decreasing strain rates.

As an illustration, for the group of points in Fig. 2 for the S.A.E. 1020 steel plotted near 300 K, the point lying to the left corresponds to a true strain rate of 500 × 10^{-5} sec^{-1} and the point lying to the right in this group corresponds to 5 × 10^{-5} sec^{-1}, while all the points in the group were for the testing temperature of 25 C.

Further examples of the application of the velocity-modified temperature T_m to tension-test data are given in Figs. 4 and 5. Fig. 4 shows the stress at the maximum load and at a strain of 0.01 plotted as a function of T_m from data given by Zener and Hollomon (6) for a cast steel. In Fig. 4 the over-all strain rates over a fixed gage length were of about the same order of magnitude as the true strain rates of Figs. 2 and 3, while the temperature range —95 C ≤ T ≤ 20 C was smaller. The stress at a strain of 0.1 for a mild steel is plotted versus the velocity-modified temperature T_m in Fig. 5, from data reported by Manjoine (7). The temperature range was slightly smaller than for Figs. 2 and

3, but the strain rates covered a larger range from 9.5×10^{-7} sec^{-1} to 0.5 sec^{-1}. Figs. 4 and 5 show essentially the same general utility of the velocity-modified temperature as do Figs. 2 and 3.

The qualitative similarity between the effects of increasing temperature and decreasing velocity has previously been pointed out by Carpenter and Robertson (8). The present results indicate that the use of the velocity-modified-temperature concept makes this relationship a quantitative one for the tension test. Points may be obtained on the curve of stress versus velocity-modified temperature to the left of a given point either by increasing the speed or by decreasing the temperature; and points may be obtained to the right of a given point by decreasing the speed or increasing the temperature.

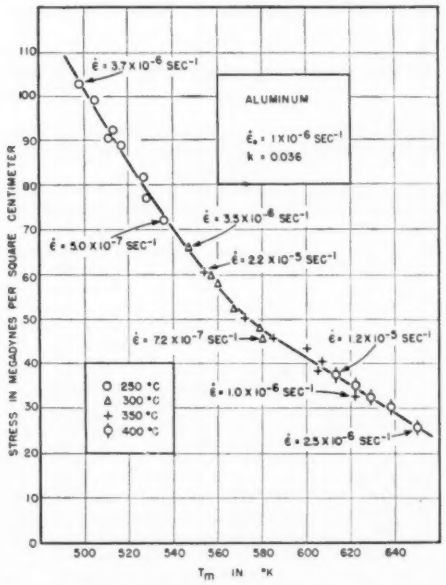

FIG. 6 STRESS VERSUS VELOCITY-MODIFIED TEMPERATURE FOR SECONDARY CREEP OF ALUMINUM

(Temperature and velocity ranges follow: 250 C $\leq T \leq$ 400 C and 5.0×10^{-7} $sec^{-1} \leq \dot{\epsilon} \leq 2.2 \times 10^{-5}$ sec^{-1}. Data from Dushman, Dunbar, and Huthsteiner, ref. 5.)

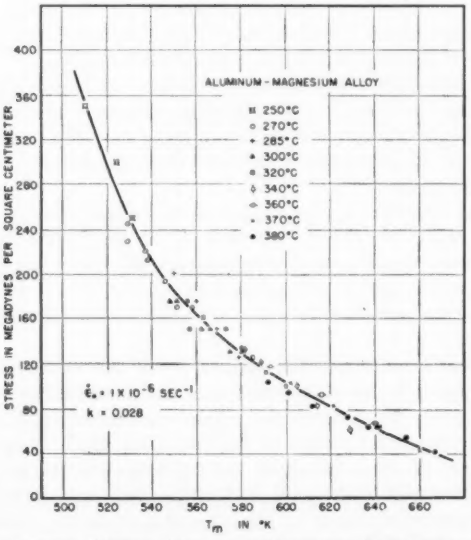

FIG. 7 STRESS VERSUS VELOCITY-MODIFIED TEMPERATURE FOR SECONDARY CREEP OF AN ALUMINUM-MAGNESIUM ALLOY

(Temperature and velocity ranges follow: 250 C $\leq T \leq$ 380 C and 2.7×10^{-7} $sec^{-1} \leq \dot{\epsilon} \leq 2.9 \times 10^{-5}$ sec^{-1}. Data from Dushman, Dunbar, and Huthsteiner, ref. 5.)

APPLICATION OF VELOCITY-MODIFIED TEMPERATURE TO CREEP TESTS

Since the velocity-modified temperature T_m appeared to be quite useful in connection with slow and rapid tension tests, its application to the creep problem was investigated.

Figs. 6 and 7 are based on creep data reported by Dushman, Dunbar, and Huthsteiner (5) for aluminum and an aluminum-magnesium alloy. In Fig 6 the stress is plotted as a function of the velocity-modified temperature T_m for the secondary creep of aluminum in the temperature range 250 C $\leq T \leq$ 400 C and for strain rates 5.0×10^{-7} $sec^{-1} \leq \dot{\epsilon} \leq 2.2 \times 10^{-5}$ sec^{-1}. Fig. 7 shows the stress reaction versus T_m for the secondary creep of an aluminum-magnesium alloy in the temperature range 250 C $\leq T \leq$ 380 C and for strain rates 2.7×10^{-7} $sec^{-1} \leq \dot{\epsilon} \leq 2.9 \times 10^{-5}$ sec^{-1}. It will be noted that groups of points representing tests at different temperatures frequently overlap in these figures.

Referring to Fig. 6, it can be seen that an increase in strain rate causes the same effect on the stress reaction as does a decrease in temperature. For example, the point corresponding to a test at $\dot{\epsilon} = 3.7 \times 10^{-6}$ sec^{-1}, $T = 250$ C lies to the left of the point corresponding to $\dot{\epsilon} = 3.5 \times 10^{-6}$ sec^{-1}, $T = 300$ C. The latter point, in turn, lies to the left of the one corresponding to $\dot{\epsilon} = 2.5 \times 10^{-6}$ sec^{-1}, $T = 400$ C. In general, points corresponding to equal values of $\dot{\epsilon}$ are ordered with temperatures increasing to the right. Similarly, the point corresponding to a test at $\dot{\epsilon} = 3.7 \times 10^{-6}$ sec^{-1}, $T = 250$ C lies to the left of the point corresponding to $\dot{\epsilon} = 5.0 \times 10^{-7}$ sec^{-1}, $T = 250$ C. In general, points corresponding to equal values of T are ordered with velocity increasing to the left.

More specifically, consider the point at the stress value 61 megadynes/cm² obtained by a test carried out at the temperature $T = 623$ K = 350 C and the strain rate $\dot{\epsilon} = 2.2 \times 10^{-5}$ sec^{-1}. It is evident from Fig. 6 that this same stress value could have been obtained with various combinations of strain rate and temperature, such as a test at a strain rate $\dot{\epsilon} = \dot{\epsilon}_0 = 1 \times 10^{-6}$ sec^{-1} and a temperature $T = 554$ K = 281 C, or a test at a strain rate of 2.5×10^{-6} sec^{-1} and a temperature $T = 573$ K = 300 C, since all of these temperature-velocity pairs give the same value of T_m.

Although Fig. 6 has been discussed in greater detail, essentially the same conclusions may be drawn from Fig. 7 for the creep of

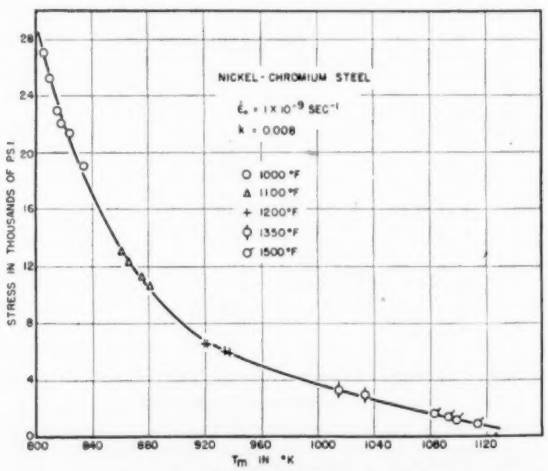

FIG. 8 STRESS VERSUS VELOCITY-MODIFIED TEMPERATURE FOR SECONDARY CREEP OF A NICKEL-CHROMIUM STEEL—STEEL B

(Temperature and velocity ranges follow: 538 C $\leq T \leq$ 816 C and 2.8×10^{-11} $sec^{-1} \leq \dot{\epsilon} \leq 2.1 \times 10^{-9}$ sec^{-1}. Data from Norton, ref. 9.)

an aluminum-magnesium alloy, and from Fig. 8, for a nickel-chromium steel. The latter was plotted from creep data reported by Norton (9).

In many creep tests the secondary creep rate is not determined and the test is not conducted at a constant true strain rate. The most common tests are those conducted at constant load (10). These usually do not extend beyond the region of primary creep, an initial period of relatively rapid and decreasing strain rate. Although such data are not as useful in checking the velocity-modified-temperature concept; in order to apply Equation [7], formulated for tests at constant true strain rates, to tests of this sort it is assumed that the value of $\dot{\epsilon}$ may be taken as the average strain rate, $\frac{\epsilon}{t}$, where ϵ is the strain value in question and t is the time required to reach that strain. Determining $\dot{\epsilon}$ in this way, Equation [7] should be *approximately* satisfied by the results of primary creep tests.

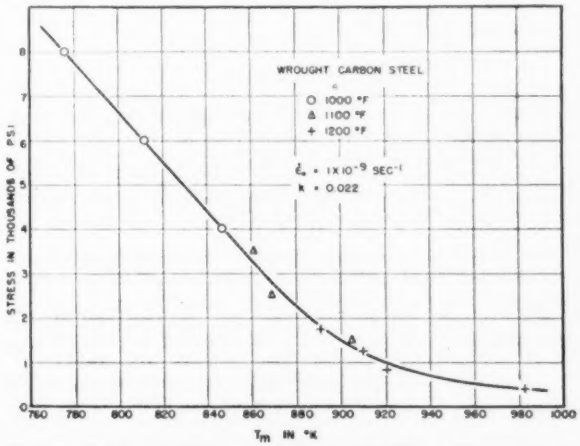

FIG. 9 STRESS AT PLASTIC STRAIN OF 0.001 AS FUNCTION OF VELOCITY-MODIFIED TEMPERATURE FOR PRIMARY CREEP OF A WROUGHT CARBON STEEL

(Temperature and velocity ranges follow: 538 C $\leq T \leq$ 649 C and 5.0×10^{-11} sec^{-1} $\leq \dot{\epsilon} \leq 6.9 \times 10^{-9}$ sec^{-1}. Data from "Creep Data" book, ref. 10.4)

Fig. 9 shows stress plotted as a function of T_m for the primary creep of low-carbon steel at a plastic strain of 0.001, according to data given in reference (10).[4] The temperature range was 538 C $\leq T \leq$ 649 C, and the strain rates were 5.0×10^{-11} sec^{-1} $\leq \dot{\epsilon} \leq 6.5 \times 10^{-9}$ sec^{-1}.

[4] Reference 10, pp. 20–21.

The velocity-modified-temperature concept can also be applied *approximately* to data such as that given by Tapsell and Johnson (11) for tests extending into the tertiary creep range, where the strain rate begins to increase with strain. Defining again $\dot{\epsilon}$ as the average value $\frac{\epsilon}{t}$, stress may be plotted versus T_m for a given strain. Such a curve is shown in Fig. 10 for a forged steel at a strain of 0.05. The temperature range here was 472 C

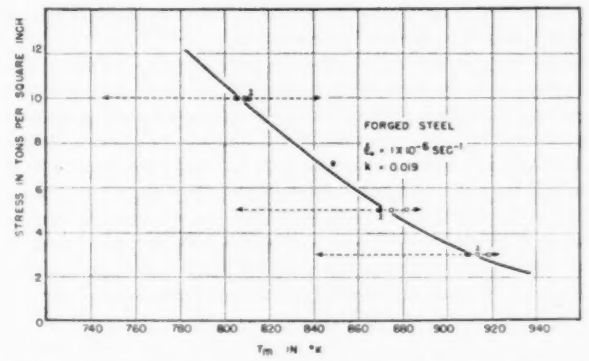

FIG. 10 STRESS AT A STRAIN OF 0.05 VERSUS VELOCITY-MODIFIED TEMPERATURE FOR TERTIARY CREEP OF A FORGED STEEL

(Temperature and velocity ranges follow: 472 C $\leq T \leq$ 650 C and 1.0×10^{-8} sec^{-1} $\leq \dot{\epsilon} \leq 7.7 \times 10^{-6}$ sec^{-1}. Dotted lines indicate temperature spread for points at each stress. Data from Tapsell and Johnson, ref. 11.)

$\leq T \leq$ 650 C, and the range of strain rates was 1.0×10^{-8} sec^{-1} $\leq \dot{\epsilon} \leq 7.7 \times 10^{-6}$ sec^{-1}. The dotted lines in Fig. 10 indicate the spread of testing temperatures for points at each stress.

A tension test of a low-carbon steel made at a constant true strain rate of $\dot{\epsilon} = 100 \times 10^{-5}$ sec^{-1} lasts approximately 20 min. If the stress reaction in creep tests or in high-speed tension tests for a given strain is plotted versus T_m for a value of $\dot{\epsilon}_0 = 100 \times 10^{-5}$ sec^{-1} the resulting curve may be used to determine the temperatures for which tension tests conducted at the constant true strain rate $\dot{\epsilon} = \dot{\epsilon}_0$ will give the same stress reactions as observed in the creep or high-speed tests.

In Fig. 11 the data of Manjoine (7), Tapsell and Johnson (11), MacGregor and Fisher (1) and the "Creep Data" book (10) are plotted with stress as a function of T_m for $\dot{\epsilon}_0 = 100 \times 10^{-5}$ sec^{-1}. The data from these various sources are for different low-carbon steels and at different values of strain, as listed in Fig. 11. In spite of this, Fig. 11 indicates that tension tests conducted at the constant true strain rate $\dot{\epsilon} = 100 \times 10^{-5}$ sec^{-1} may be used to ob-

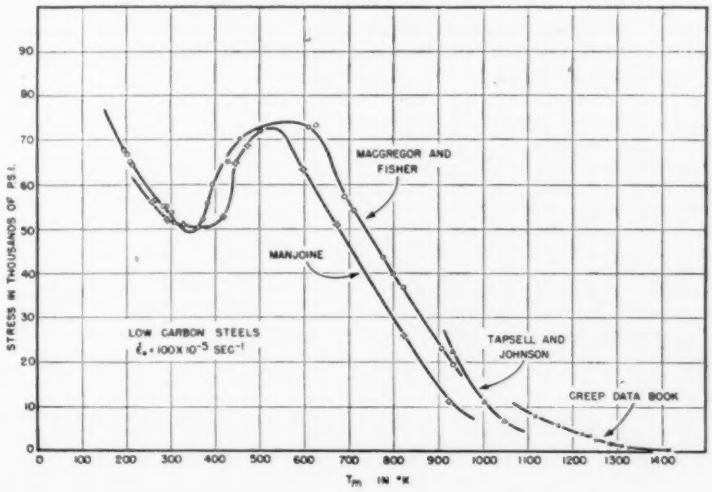

FIG. 11 STRESS VERSUS VELOCITY-MODIFIED TEMPERATURE FOR SEVERAL LOW-CARBON STEELS

(Strains, and temperature and velocity ranges follow:

1 Data from MacGregor and Fisher, ref. 1
Strain = 0.1, —70 C $\leq T \leq$ 665 C, 5×10^{-8} sec^{-1} $\leq \dot{\epsilon} \leq 500 \times 10^{-5}$ sec^{-1}

2 Data from Manjoine, ref. 7
Strain = 0.1, 20 C $\leq T \leq$ 600 C, 9.5×10^{-7} sec^{-1} $\leq \dot{\epsilon} \leq 0.5$ sec^{-1}

3 Data from Tapsell and Johnson, ref. 11
Strain = 0.05, 472 C $\leq T \leq$ 650 C, 1.0×10^{-8} sec^{-1} $\leq \dot{\epsilon} \leq 7.7 \times 10^{-6}$ sec^{-1}

4 Data from "Creep Data" book, ref. 10
Plastic strain = 0.001, 538 C $\leq T \leq$ 649 C, 5.0×10^{-11} sec^{-1} $\leq \dot{\epsilon} \leq 6.9 \times 10^{-9}$ sec^{-1})

tain essentially the same stress reactions as were obtained in the creep tests reported in the "Creep Data" book (10),[4] if the tests are made at temperatures from 1120 K (847 C) to 1420 K (1147 C), assuming of course that the velocity-modified-temperature concept holds for the range of velocities in question. Similarly, to obtain the same stress reactions as were reported in the creep tests of Tapsell and Johnson, tension tests at temperatures from 935 K (662 C) to 1050 K (777 C) and at a strain rate of $\dot{\epsilon} = 100 \times 10^{-6}$ sec^{-1} may be used. In order for this to be true the stress reaction must of course be measured at the proper strain for all cases where it depends on strain as well as on T_m.

An obvious inference from the foregoing discussion is that the true stress-strain tension test, conducted at constant true strain rates, may have some application in the development of a rational short-time creep test, when use is made of the velocity-modified-temperature concept. Although there are definite indications of the possibility of developing a short-time creep test in this manner, no final conclusions regarding such an application can be reached at this time owing to the fact that so few experimental data of the necessary type are available. An experimental program now being undertaken by the authors may serve to throw further light on the problem.

Conclusions

The following conclusions may be drawn:

1 The expression for the velocity of secondary creep at moderate stresses derived from Eyring's theory for the velocity of plastic flow,

$$\frac{\dot{\epsilon}}{\dot{\epsilon}_0} = A \frac{T}{T_0} e^{-\frac{f^*(S)}{T}}$$

and its approximation

$$\frac{\dot{\epsilon}}{\dot{\epsilon}_0} = A e^{-\frac{f^*(S)}{T}}$$

are consistent with the results of secondary-creep measurements, within the experimental error of the data reviewed.

2 The stress reaction in a specimen undergoing secondary creep is a function of the velocity-modified temperature

$$T_m = T \left(1 - k \log_e \frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)$$

where T is the absolute testing temperature, $\dot{\epsilon}$ is the true strain rate, and $\dot{\epsilon}_0$ and k are constants.

3 For large ranges of temperatures and velocities with extreme limits of $-95\ \text{C} \leq T \leq 665\ \text{C}$ and $9.5 \times 10^{-7}\ \text{sec}^{-1} \leq \dot{\epsilon} \leq 0.5\ \text{sec}^{-1}$ the stress reaction in a tension specimen being tested at a constant true strain rate has been shown to depend on the velocity-modified temperature and the strain.

4 The stress reaction in a specimen undergoing primary or tertiary creep is an *approximate* function of the velocity-modified temperature and the strain when the value of $\dot{\epsilon}$ is taken to be $\frac{\epsilon}{t}$.

5 By use of the velocity-modified temperature, there are definite indications that the stress reaction corresponding to tests at very slow and very rapid rates of deformation may be found from tension tests at moderate strain rates and appropriately raised or lowered temperatures.

6 Further experimentation employing constant true-strain-rate tests is necessary in order to determine the full range of applicability of the concept of velocity-modified temperature, and to discover any refinements in the relationship

$$\frac{\dot{\epsilon}}{\dot{\epsilon}_0} = A e^{-\frac{f^*(S)}{T}}$$

that may prove to be required.

Design of Crankpins for Locomotives

By O. J. HORGER[1] and W. I. CANTLEY[2]

This progress report presents the results of a fatigue investigation made on full-size 9½-in-diam crankpins by the Association of American Railroads. The primary object of this study was to develop an improved crankpin-and-wheel assembly which will alleviate crankpin fatigue failures occurring in the wheel-fit portion in service. A total of 50 full-size crankpin-and-wheel assemblies were tested, using four different types of pins. All pins were of plain-carbon steel, normalized and tempered, having a carbon content of 0.52 per cent and manganese of 0.80 per cent. Large double-ended cantilever-type fatigue machines subjected the crankpin-and-wheel assemblies to rotating-bending stresses. The fatigue resistance of the conventional assembly, against the crankpin breaking off in the wheel fit, may be expressed as 100 per cent. The other three types of pins gave values of 136, 146, and over 200 per cent (Table 7). Even with this greatly improved breaking-off strength, shallow fatigue cracks were found to initiate in the wheel-fit portion of all four types of pins at bending stresses much below what was required to propagate the cracks to complete fracture.

Introduction

THE Association of American Railroads (A.A.R.) has been conducting a program of research covering the fatigue-testing of full-size 9½-in-diam crankpins since July, 1942. Two progress reports[3] have been issued to members of A.A.R. presenting the results of this investigation up to April, 1944. The present paper advances these findings and also notes that this investigation is still in progress.

It is well known that a press fit is a source of extremely high stress concentration. Crankpins either in laboratory test or in service operation may completely break off inside the wheel fit at bending stresses which are only a fraction of the fatigue strength of the same material without a press fit.[4,5,6] For this reason mileage limits are usually established as a means of preventing service failures of crankpins.

While crankpins seldom actually break off inside of the wheel fit within the service mileage established, it is not uncommon to find fatigue cracks in the wheel-fit portion of the pin in various stages of crack propagation. Such service failures have been the subject of earlier study and two reports have been issued by A.A.R.[7] The initiation and development of these fatigue cracks have been found from laboratory tests to occur at very much lower bending stresses than that required to break off the pin. This condition is generally too little understood and appreciated.[8] These laboratory tests permit a study of this fatigue-crack initiation and propagation so that means of improving conditions may be determined.

It is realized that laboratory-test conditions cannot parallel service operation. The fatigue-strength values given in this report, however, permit a relative rating of various types of crankpins as to their fatigue resistance or life expectancy. It would be expected that this same order of rating would be reflected from service operation, but the percentage difference between the various types obtained in service would not necessarily be the same as that obtained in laboratory tests.

Crankpins in service may also develop fatigue failure at one of the journal fillets, but the present investigation was confined to a study of failures in the wheel-fit portion.

Crankpin Forgings

The steel in the crankpin forgings was made by the acid-open-hearth process. It was poured into big-end-up hot-top ingots of the round corrugated type. The ingot weight was about 8000 lb and had a mean diameter of approximately 23 in., while the ingot proper was 59 in. long. The hot top was approximately 16 in. diam × 19 in. long. A pipe-eliminator compound was used on the top of the steel in the hot top when pouring was completed to aid in reduction of the depth of pipe.

The ingots were heated to a forging temperature of approximately 2050 F, and forged under a steam-hydraulic press to blooms approximately 12 in. sq. The final blooming temperature was generally between 1600 and 1700 F. The blooms were allowed to cool to atmospheric temperature and surface defects were removed by chipping or scarfing. The blooms were then reheated to a forging temperature of 2050 F for approximately 1 hr per in. of thickness, and the pin forgings were made under a steam-hydraulic press with the finishing temperature approximately 1600 F. About ⅝ in. stock on each diameter was allowed in the rough forging over the rough-machined diameters. The forgings

[7] "Failures and Performance of Main Crank Pins on Steam Locomotives," first progress report, May, 1938; final report, May, 1940, Office of Mechanical Engineer, Association of American Railroads, Chicago, Ill. This latter report presented service data on 43,468 steam locomotives for a period of 9 months during which time 1695 main crankpins were removed and 151 or 9 per cent were found defective. Of these defective pins, 83 were removed from freight locomotives of which 41 per cent showed failure inside the wheel fit, and 32 per cent failed flush with the wheel-hub face (which is interpreted as also being in the wheel fit, but failure occurred at the end of the fit, rather than in the journal fillet). The remaining 68 pins were found defective from passenger locomotives, of which 54 per cent showed failure inside the wheel fit, and 18 per cent failed flush with the hub face.

were normalized and tempered in accordance with A.A.R. Specification M-104-37, Class A.[9]

The crankpins tested were taken from two different heats of steel as indicated in Table 3, there being 38 pins from one heat and 12 from another heat. Ladle analysis and physical properties[10] are given in Table 1. Additional chemical analysis was made from turnings taken from the outer diameter of the wheel seat of each crankpin at the time it was prepared for fatigue-testing. The values obtained were in substantial agreement with the ladle analysis given in Table 1, but residual alloys present were found to be 0.03 to 0.10 per cent Cr, 0.16 to 0.21 per cent Ni, and nil to 0.03 per cent Mo. Also additional physical properties, given in Table 2, were determined from the wheel seat of most of the crankpins following the fatigue test.[11]

Design and Properties of Wheel Centers

The crankpins were mounted and tested in the two following different types of wheel centers or disk[12] both of which were purchased to A.A.R. Specification M-201-36, Grade B, for steel castings:[9] (1) Double-plate type of disk, Fig. 1; (2) spoke type of disk, Fig. 2.

To simulate the influence of the large mass of metal on the axle side of a wheel center, as the pin is applied on a locomotive, a solid counterweight was cast on the test disks as shown in Fig. 1.[13]

[9] Manual of Standard and Recommended Practice Association of American Railroads, Mechanical Division, Chicago, Ill.

[10] These properties were determined on longitudinal 0.505-in-diam specimens taken at midway radius from prolongations on the end of a forging from each furnace charge.

[11] These properties determined on Izod impact specimens of the three-notch type and 0.505-in-diam tensile specimens were machined from both longitudinal surface layers and at midway radius

[12] It was originally intended to use only the first type of disk, but a number of fatigue failures developed in these disks when the crankpins mounted in them were tested at 16,000 psi and above. For this reason, the spoke-type disk was generally used when testing pins at 16,000 psi and above, but not below 16,000 psi, with the exception of pin No. 6R tested at 10,500 psi. These spoke wheels were ones which were already cast for other test purposes and so were immediately available. The use of the two types of disks is not believed to influence the comparative value of the fatigue results on the four types of pins investigated.

[13] This counterweight was balanced by filling the diametrically opposite pockets of the disk with lead. This balancing was done before the disk was mounted on the crankpin and required accurate balancing in order to rotate at 1500 rpm in the test machine without vibration.

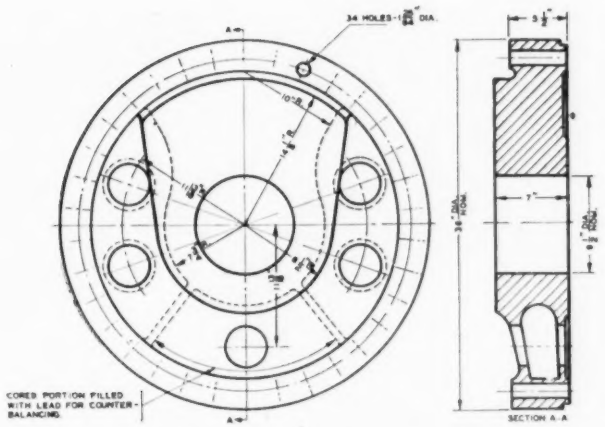

FIG. 1 DOUBLE-PLATE DISK REPRESENTING WHEEL CENTER

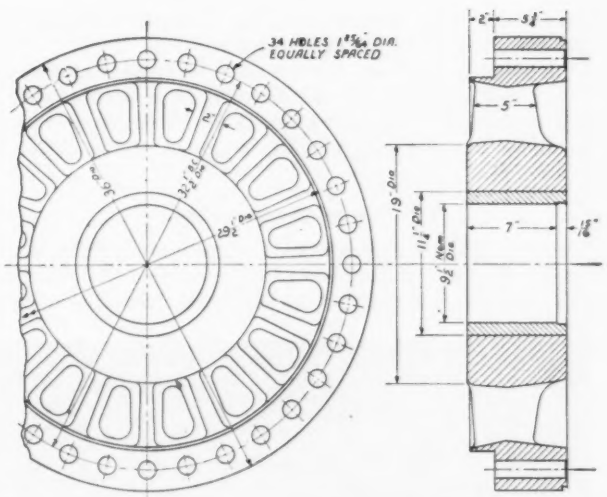

FIG. 2 SPOKE-TYPE WHEEL USED TO TEST CRANKPINS AT 16,000 PSI AND ABOVE

Chemical and physical properties of the double-plate-type disk are given in Table 1, as furnished by the foundry. Brinell-impact-meter readings made on the hub face of these wheels ranged between 149 and 164 Bhn, and these hardness readings agreed closely with those obtained on some of the same castings using the regular Brinell hardness tester. Table 1 also shows comparable data obtained from tensile and impact tests and chemical analysis on specimens from one of these disks which developed fatigue failure. The ductility characteristics found are much lower than those required by the specification. It is not unusual to find that specimens cut from actual castings give lower values than required by the specification, which is based on specimens taken from prolongations attached to the casting.

The spoke wheels available happened to have a nominal bore of $11^1/_4$ in.; therefore a cast-steel bushing to the same specification as the cast disks was press-fitted about 0.015 in. tight into the bore of these wheels. The bushing was then bored out to receive the crankpin, leaving a nominal $^7/_8$-in-thick wall section. Brinell-impact-meter readings made on these bushings usually gave 149 Bhn, although a few values of 137 Bhn were obtained.

CRANKPIN-AND-WHEEL ASSEMBLIES INVESTIGATED

Four different crankpin conditions were investigated,[14] consisting of two crankpin designs and two surface treatments, as indicated in Fig. 12. These may be described as follows:

Type 1 A straight cylindrical pin pressed into a wheel center having a straight cylindrical bore.

Type 2 Identical to type 1, except outer end of crankpin wheel seat was tapered 0.008 in. on diameter for a distance inside the wheel fit of $1^1/_4$ in.

Type 3 Identical to type 1, except wheel-fit portion of crankpin was cold-rolled.

Type 4 Identical to type 1 except wheel-seat portion of crankpin was flame-hardened.

All types of crankpins were prepared for test from 10 to $10^1/_8$-in-diam rough-turned forgings which were approximately $^1/_2$ in. to $^3/_4$ in. larger in diameter than the finished diameter at which they were tested. The pins were rough-turned in one cut to about $9^5/_8$ in. diam, and a second cut was taken about $^1/_{16}$ in. deep. Then finish cuts were taken about $^1/_{64}$ in. deep with the lathe operating at 45 rpm and a feed of $^1/_{64}$ in. per revolution. The finish cut was made with a broad-nosed tool having a contour radius of approximately 3 in. and produced a very good quality of turned finish.

Wheel bores for all designs of crankpins were bored with a straight cylindrical hole having a $^1/_{32}$-in. radius at each end of the bore. The finish cut in the wheel bore was made with a broad-nosed tool similar to that used on the crankpin, and the depth of

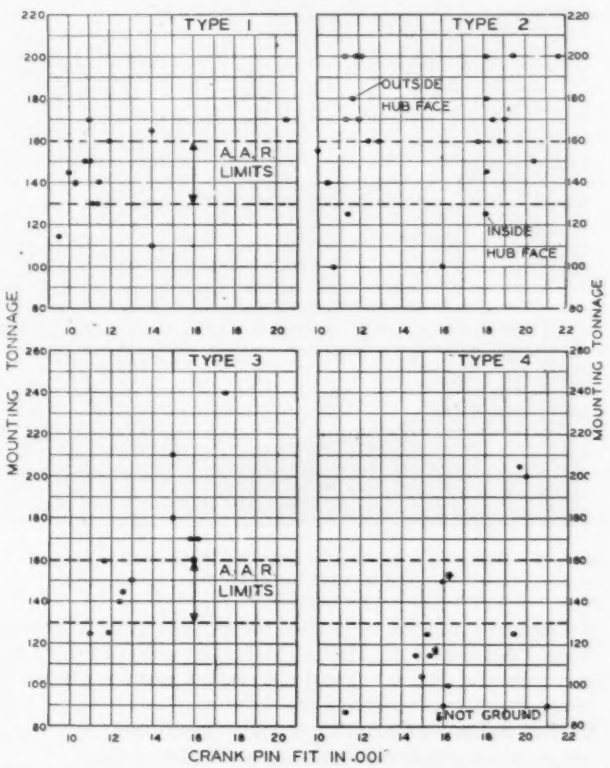

FIG. 3 COMPARISON CHART SHOWING MOUNTING TONNAGE VERSUS TOTAL FIT ON DIAMETER

[14] In all cases the design of pin was such that the wheel-seat diameter was the same as the diameter of the main side-rod journal. This shape was used because (*a*) this design already exists on some locomotives where the factors of cylinder stroke, wheel-hub sections, and journal-bearing pressure present certain design limitations, and (*b*) it would have less fatigue resistance than a pin in which the wheel seat was connected by an ample transition radius to a smaller diameter at the main side-rod journal portion. For these reasons, the least favorable design condition at the wheel seat was first investigated.

the cut was about 0.003 in. with the boring mill operating 15 rpm and a feed of $^1/_{32}$ in. per revolution.

All wheel centers were pressed onto the crankpins using the A.A.R. recommended lubricant[9] mixed in the proportions of 12 lb of white lead to 1 gal of boiled linseed oil. A summary of the fit allowance and mounting tonnage is plotted in Fig. 3, for all types of pins.

Type 3 Pins—Surface-Rolled

Type 3 pins were given a good smooth-turned finish at the fitted portion as just described and then surface-cold-rolled in a lathe, as shown in Fig. 4. The rolling device, illustrated in Fig. 5,

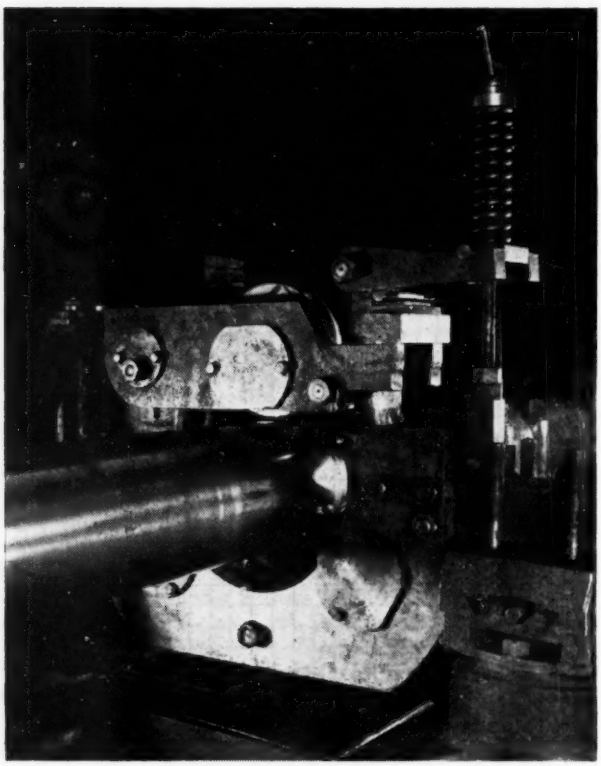

Fig. 4 Method of Surface-Rolling Wheel-Fit Portion of Crankpin in a Lathe

is equipped with three 10-in-diam rollers, the top roller having a contour radius of 5 in., and the two bottom rollers having a contour radius of $1^1/_2$ in. The $1^1/_2$-in-radius contour rollers give some penetration or thickness of cold-worked layer of metal, while the 5-in-radius contour roller tends to give the surface a good smooth finish suitable for mounting a press-fitted wheel.

The rolling procedure was to rotate the pin on lathe centers at 28 rpm and move the rolling device along the crankpin length with a feed of $^1/_{32}$ in. per revolution of the pin. The roller pressure was applied along the length of the crankpin wheel-seat surface, as shown in Fig. 6, where the inner and last 4-in. length of the crankpin fit was left about $^1/_{32}$ in. oversize. After the rolling operation was completed, this 4-in. length was remachined[15] to the

[15] This procedure permits the removal of any irregularities of surface finish which may be caused at the time the rolling pressure is being decreased. It also provides a pin length of 4 in. which has been turned and 3 in. of rolled surface for engagement in the wheel fit. As an alternative method, the pin is ground after rolling, removing not over 0.010 in. on the diameter, but this method was not tested in fatigue and it is not known if the fatigue resistance is decreased by removal of this rolled surface skin.

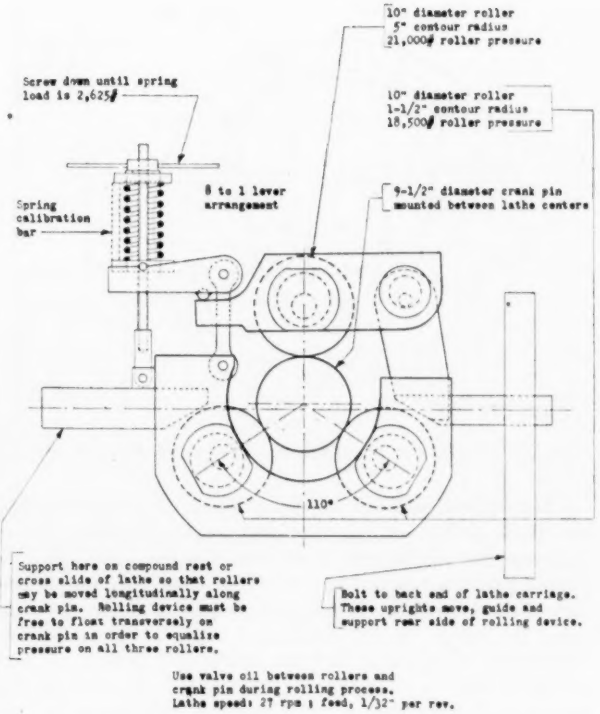

Fig. 5 Rolling Device for Preparing Wheel Seats of Type 3 Crankpins

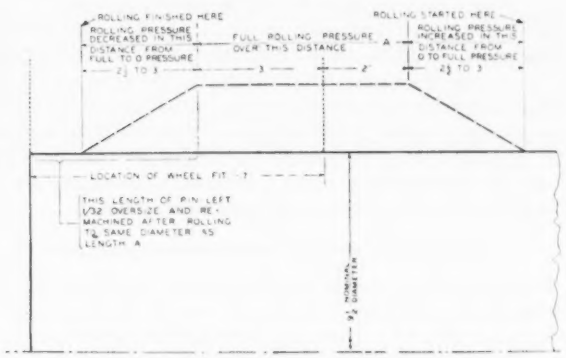

Fig. 6 Rolling Diagram for Crankpin Wheel Seats, Type 3

same diameter as the pin at the section where it was rolled at full pressure.

The reduction in pin diameter due to rolling varied between 0.0013 in. on some wheel seats to 0.0028 in. on others. A highly polished finish was obtained from rolling. Following the rolling and machining operation, the wheel was mounted on the crankpin, using the A.A.R. white lead and linseed oil mixture.

Type 4 Pins—Flame-Hardened

Crankpins were flame-hardened in a vertical position[16] while rotating at 260 rpm, as shown in Fig. 7. Before preparing fatigue specimens, four different case depths were investigated by flame-hardening $9^1/_2$-in. rounds. The speed of the lead screw was

[16] A circular gas head and water quench ring assembly surrounded the pin, which moved vertically along the axis of the pin by means of a motor-driven lead screw. A series of twenty flame heads, with seven tips (No. 56 drill size) per head, constituted the heating ring. A special water-quenching ring $10^1/_2$ in. diam was mounted directly below the heating head.

FIG. 7 METHOD OF FLAME-HARDENING WHEEL-FIT PORTION OF CRANKPINS

changed to give four different flame speeds which resulted in the hardness gradients shown in Fig. 8. Some softening may take place at the surface, but this soft layer is ground off before the wheel is mounted.

Two separate groups of crankpins were flame-hardened for fatigue tests. In the first group, eight crankpin wheel seats were flame-hardened so as to obtain a case depth of approximately 1/4 in., using a flame speed of 2 3/4 in. per min. The wheel seats of all pins were magnafluxed after flame-hardening and before grinding to determine if thermal cracks had developed on the surface during flame treatment. All wheel seats were found to be cracked. Considerable difficulty was encountered in grinding the wheel seats as these thermal cracks progressed deeper with the grinding. It was necessary to remove 0.071 to 0.108 in. stock from the diameter of each wheel seat to eliminate all traces of the thermal cracks.

It was believed that the thermal cracks found on the first group of pins could be eliminated by using a modified flame-hardening procedure,[17] so six additional crankpin wheel seats were flame-hardened. The flame speed was increased from 2 3/4 ipm used on the first group to 3 1/8 ipm on the second group of crankpins. The gas consumption was 0.25 cu ft per sq in. of pin surface which compares with 0.35 obtained on the first group. Both groups of pins were stress-relieved after hardening for 8 hr in an oil bath heated to 400 F. The surface hardness on the wheel fit ranged from 66 to 70 scleroscope on the first group of eight, as compared with 72 on the second group of six wheel seats. This hardness generally increased appreciably after the soft skin had been removed in the grinding operation.

This second group of pins were magnafluxed after flame-hardening, and all wheel seats were found to be cracked, but not as severely as those of the first group of flame-hardened pins. Four of these wheel seats were ground before fitting to wheels and the other two were not ground before mounting the wheels.[18] On this second group, it was necessary to remove only 0.038 to 0.040

[17] The thermal cracks which developed in the first group of crankpins were tentatively attributed to the cold quenching water used, so that the quench water was heated to approximately 85 F, for the second group. It was also believed that a case of less depth would require less surface heating and reduce the tendency to develop thermal cracks.

[18] The wheel seats on both ends of crankpin No. 4 were not cracked in the region of the outside hub face, but only in the region of the inside hub face. Crankpin No. 4 was therefore selected to be used for test where the wheel seat was not ground.

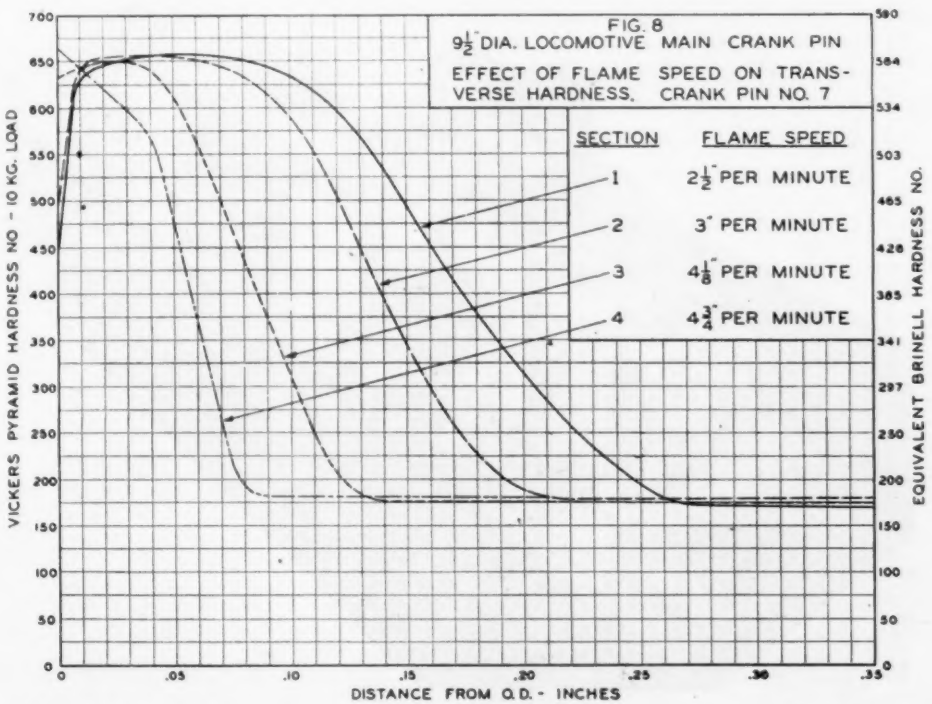

FIG. 8 EFFECT OF FLAME SPEED ON TRANSVERSE HARDNESS OF 9 1/2-IN-DIAM LOCOMOTIVE MAIN CRANKPIN, NO. 7

in. stock on the diameter. Magnaflux examination after grinding indicated that all quench cracks had been removed from the critical section of the four wheel seats.[19]

Method of Testing

A typical wheel-and-crankpin assembly ready for fatigue test is shown in Fig. 9. The machine in which these pins were tested is illustrated in Fig. 10. The crankpin is tested as a rotating cantilever beam,[20] as shown diagrammatically in Fig. 11. The wheel mounted on the crankpin is bolted at the rim to a flanged head located on either end of the main spindle of the testing machine. A constant spring load is applied on the end of the crankpin opposite the end on which the wheel is mounted. After one wheel seat is tested on the long crankpin[21] the pin is

[19] There was still some indication of thermal cracks at the inside and unstressed end of the wheel fit, but inasmuch as they were well away from the test section they were allowed to remain. A thermal crack found in the region of the test section of wheel seat No. 8R was outside the wheel fit and on this account was not removed. After the completion of the fatigue test on this pin, the depth of the crack had not increased, as determined from a micrographic study.

[20] See reference 3, First Progress Report, p. 26. The A.A.R. recommended design practice is 16,000 psi allowable stress for main crankpins but crankpins on locomotives are not subjected to a complete stress reversal. It is recognized that these laboratory tests impose a complete stress reversal and give a much lower endurance limit than would be obtained if the pins were subjected to the stress range of actual service operation which varies from about zero to a maximum stress value. Abnormal stresses from locomotive operation are also discussed. This divergence between road operation and laboratory testing should not influence the value of comparative data presented here. Also see "The Design of Railway Axles and Crankpins," by R. Eksergian, Trans. A.S.M.E., vol. 60, 1938, p. 153.

[21] See reference 3, First Progress Report, p. 5, for reasons that crankpins for test purposes were longer than those used in service. This length influences direct shearing stresses but they do not usually exceed 2000 psi. Such stresses are small compared with the bending and press-fit stresses in the pin and should have little or no influence of practical importance on the value of these comparative tests.

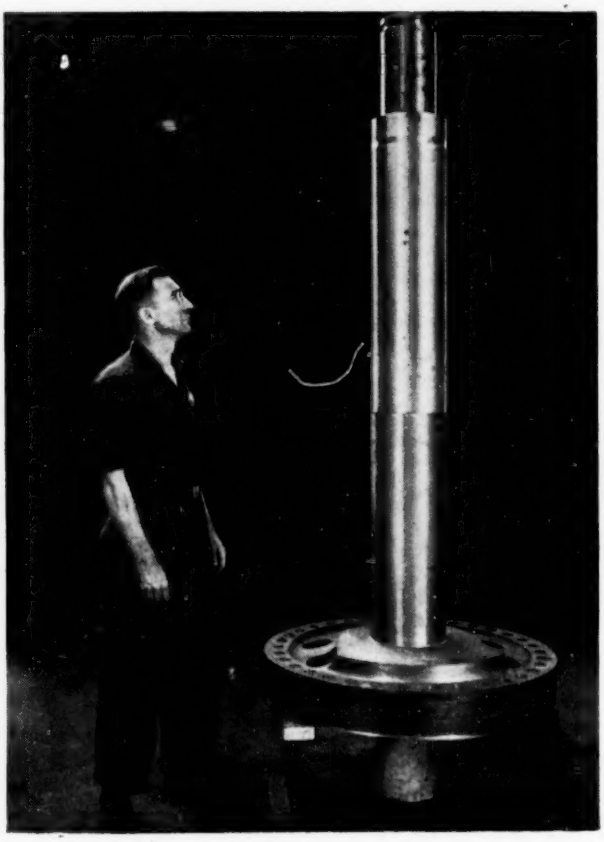

Fig. 9 Crankpin Assembly Ready for Fatigue Test

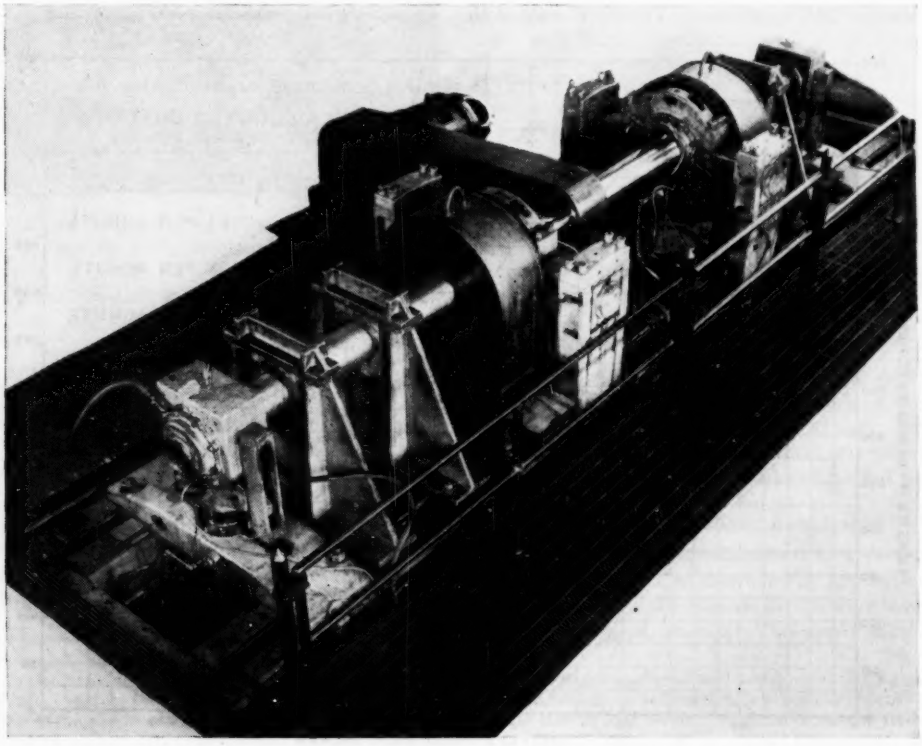

Fig. 10 Double-Ended Cantilever Beam Fatigue Machine With 9 1/2-In-Diam Crankpins in Test

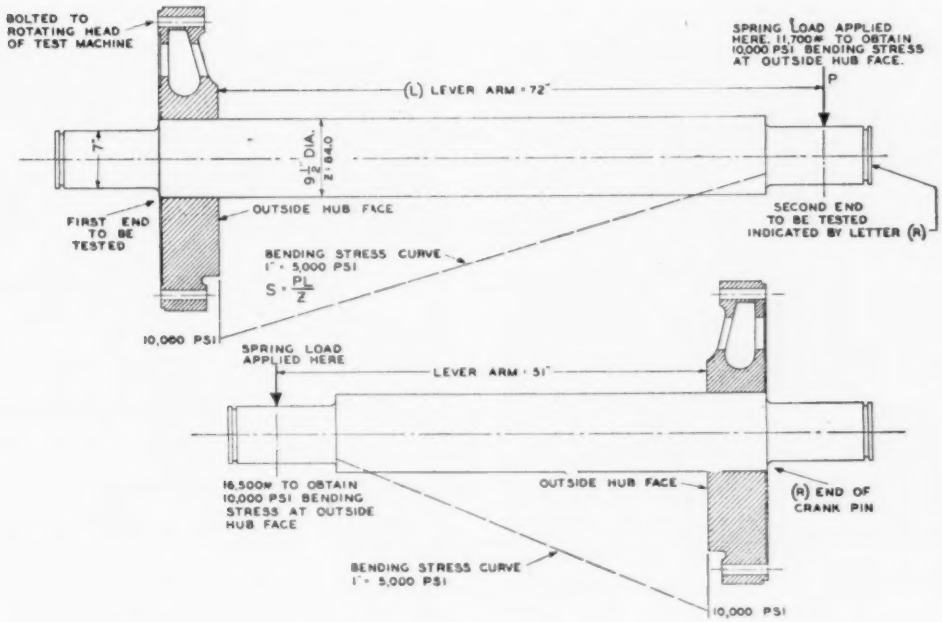

FIG. 11 CRANKPIN TEST ASSEMBLY

reversed, and a wheel is mounted on the opposite end for a second fatigue test in accordance with Fig. 11. Crankpin bending-stress values given in this report are nominal stresses in the pin at the outside hub face of the wheel, calculated on the basis of the elementary beam formulas, given in Fig. 11.

All crankpins were tested at 1500 rpm for a duration of about 85,000,000 revolutions, which is equivalent to 300,000 miles (not necessarily locomotive miles) on 72-in. wheels, unless the pin failed before that time. The wheels were then pressed off and the wheel fit magnafluxed, and photomicrographs made through any fatigue cracks which were detected.

RESULTS OF FATIGUE TEST

Type 1 Crankpins. Fatigue tests were completed on fifteen type 1 crankpins at stress levels from 5000 through 22,000 psi, and the test results are given in the comparison Table 3, and S-N diagram, Fig. 12. It will be noted that nine of these crankpins broke off in the wheel fit, and the lowest stress at which breaking-off occurred was 12,000 psi, after running an equivalent of 160,500 miles (45,000,000 revolutions). Tests made at the lowest stress level of 5000 psi developed fatigue cracks 0.0045 in. deep in the wheel fit after an equivalent of 309,000 miles (86,700,000 revolutions).

A typical fatigue fracture for any type of pin is illustrated in Fig. 13, showing how the crankpin breaks off a short distance inside the wheel fit.

On the basis of these tests, the safe allowable bending stress to prevent breaking off of type 1 pin inside the wheel fit is 11,000 psi and to prevent fatigue cracks initiating is some value less than 5000 psi.

Type 2 Crankpins. Fatigue tests were completed on twelve type 2 crankpins at stress levels from 5000 through 19,000 psi. The results are given in Table 3 and shown in S-N curves, Fig. 12, in comparison with tests made on the other types. Only two type 2 crankpins broke off in the wheel fit; these occurred at 16,000 and 19,000 psi bending stress after 20,800 and 14,850 equivalent miles (5,840,000 and 4,160,000 revolutions), respectively. Tests made at the lowest stress level of 5000 psi developed fatigue cracks 0.003 in. deep in the wheel fit after an equivalent 321,000 miles (90,000,000 revolutions).

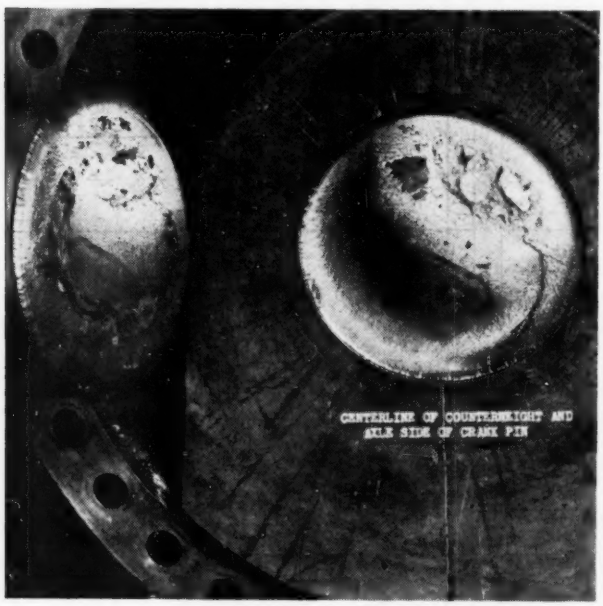

FIG. 13 TYPICAL FATIGUE FRACTURE IN WHEEL-FIT PORTION OF CRANKPIN, TYPES 1 AND 2
(Note that failure initiated toward axle side of pin.)

3 crankpins at stress levels from 7000 through 22,000 psi. The results and S-N curve are summarized in comparison with other types of crankpins in Table 3 and Fig. 12. None of these crankpins broke off during the entire test so that the endurance limit is greater than 22,000 psi. Eight of these pins completed their test run of 300,000 equivalent miles (85,000,000 revolutions), and two pin tests were discontinued at 12,400 and 81,600 equivalent miles (3,470,000 and 22,900,000 revolutions), because the wheels in which they were mounted developed fatigue failure. While no pins broke off even at stresses as high as 22,000 psi, nine of these ten pins exhibited fatigue cracks in the wheel-fit portion, as determined by magnaflux and micrographic examination made after the fatigue test. A typical failure of this kind is illustrated in Fig. 14, indicating a band of numerous fatigue cracks having a maximum depth of 0.085 in. after 307,000 equivalent miles (86,200,000 revolutions) at 19,000 psi.

Type 4 Crankpins. Results obtained from fatigue tests on thirteen flame-hardened pins are shown in Table 4, as well as in Table 3 and S-N curve in Fig. 12, where the results are compared with those from the other three types of crankpins. A fatigue fracture, illustrated in Fig. 15, developed late in life after 245,000 equivalent miles (68,700,000 revolutions). After opening up the crack, it was found to be 5½ in. deep. On the basis of these data, type 4 pin, ground after flame-hardening, has an allowable fatigue strength of 16,000 to 18,000 psi against breaking off in the wheel fit.

DISCUSSION OF FATIGUE TESTS

Propagation of Fatigue Cracks. Even after running any of the four types of crankpins at bending stresses below the endurance-limit value, at which they broke off in the wheel fit, it was found that fatigue cracks were present. These cracks were found in the pin, just inside the wheel fit, after a fatigue test of 300,000 equivalent miles (85,000,000 revolutions). In each case the maximum depth of the fatigue cracks in every pin was measured as given in Table 3. A straight-line relationship appears to exist between this crack depth and the bending stress when these values are plotted logarithmically as was done in Fig. 16.

In the case of type 1 pin, for example, the slope portion of the curve, Fig. 16, shows a linear relationship up to a stress of 12,000 psi, at which stress the pin breaks off. The upper portion of the curve being a horizontal line indicates that at 12,000 psi the

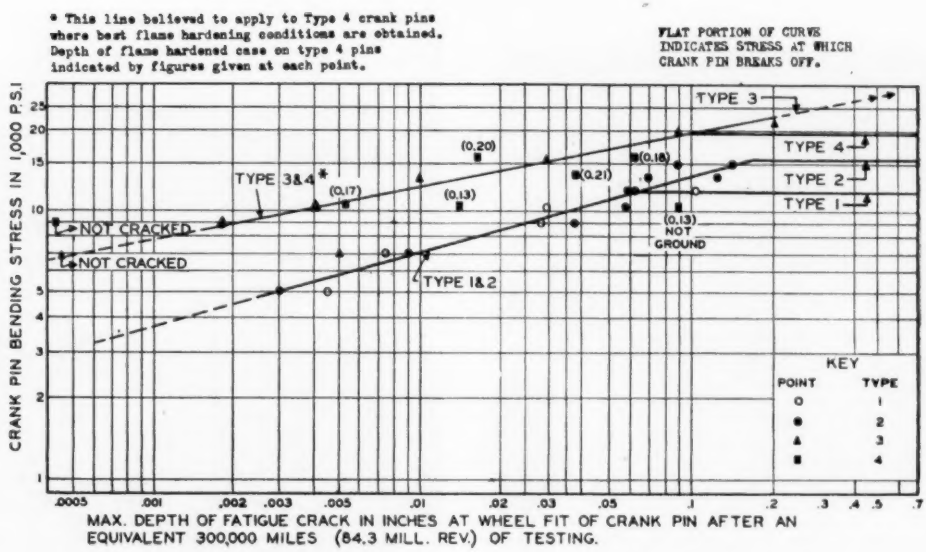

FIG. 16 COMPARATIVE PROPAGATION OF FATIGUE CRACKS IN CRANKPIN WHEEL SEATS

fatigue crack becomes infinitely deep, meaning that the pin will break off as found in these tests.

The slope portion of a similar curve drawn for type 2 pins, Fig. 16, coincides with that drawn for type 1 crankpins, except that the upper end of the slope extends toward a higher stress of 16,000 psi before the pin breaks off, whereas type 1 pin breaks off at 12,000 psi. This graphical analysis indicates that the fatigue cracks tend to initiate and propagate in both types 1 and 2 crankpins in the same manner up to 12,000 psi.[22]

All points showing crack depth for rolled pins, Fig. 16, fall close to the line drawn except for one point at 7000 psi. Two crankpins were tested at a stress of 7000 for 300,000 equivalent miles (85,000,000 revolutions); one pin was found not cracked, while the other had a maximum crack depth of 0.005 in. Even at 22,000 psi, the fatigue crack was only 0.205 in. deep after an equivalent 300,000 miles. At 16,000 psi both types 1 and 2 pins broke off after 17,820 to 27,600 equivalent miles, whereas type 3 pin at the same stress was only cracked 0.016 in. deep after over 10 times the mileage, or 300,000 equivalent miles.

The graphic relationship between crack depth and bending stress, Fig. 16, indicates considerable scatter for type 4 flame-hardened pins. It is believed, however, that the curves for types 3 and 4 pins would be about the same up to 19,000 psi, assuming best flame-hardening conditions.

A further graphical comparison may be drawn between the ratio of the crack depth of types 1 and 2 pins with type 3, as shown in Fig. 17. Here the full-line ratio curves are calculated from the curves in Fig. 16, and these ratios are shown on the lower horizontal scale; the broken line and the upper horizontal-crack-depth scale in Fig. 17 are merely repeated from Fig. 16. These studies, Figs. 16, 17, indicate that the fatigue-crack depth and its propagation for the rolled pin (type 3) were only a fraction of what was found on the unrolled pins (types 1 and 2). Therefore type 3 pin offers a means of increasing greatly the factor of safety over types 1 and 2 against breaking off in service and/or

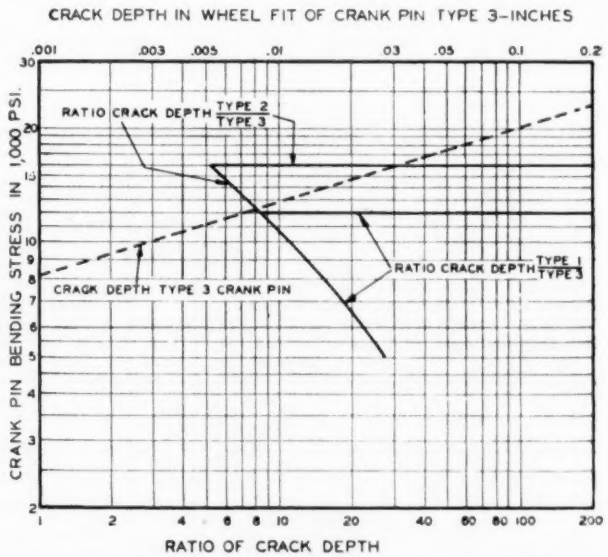

FIG. 17 RATIO OF FATIGUE-CRACK DEPTH IN TYPES 1 AND 2 CRANKPINS TO THAT IN TYPE 3

(Flat horizontal portion of ratio curves indicates infinite crack depth at bending stress at which crankpin breaks off in the wheel fit.)

increasing present safe mileage limits already established on types 1 and 2 pins.

The question often arises as to how deep below the surface the rolling penetrates, and this was investigated on a typical rolled pin No. 27. Photomicrographs were made to detect changes in structure in the longitudinal plane of the rolled portion of the wheel fit, as shown in Fig. 18. It is apparent that the structure at the surface is little, if any, changed from that $^{5}/_{8}$ in. below the surface. This does not mean that changes have not taken place, as X-ray examinations made on similar cold-worked pieces have indicated structural displacements in the cold-worked layer. A hardness survey in Fig. 19 was also made in a longitudinal plane through the surface and core layers. The Vickers hardness is increased from 180 at the surface before rolling to about 230 after rolling and drops off in a linear manner to a penetration of about

[22] An interesting speculation may be made by extrapolating the lower portion of the sloped line as shown by the dotted lines. It indicates that at even 3000 psi fatigue cracks 0.0005 in. deep would develop. Conclusions based on such extrapolation are dangerous, but the curve does help explain the practical findings in service, in that fatigue cracks initiate at very low bending stresses.

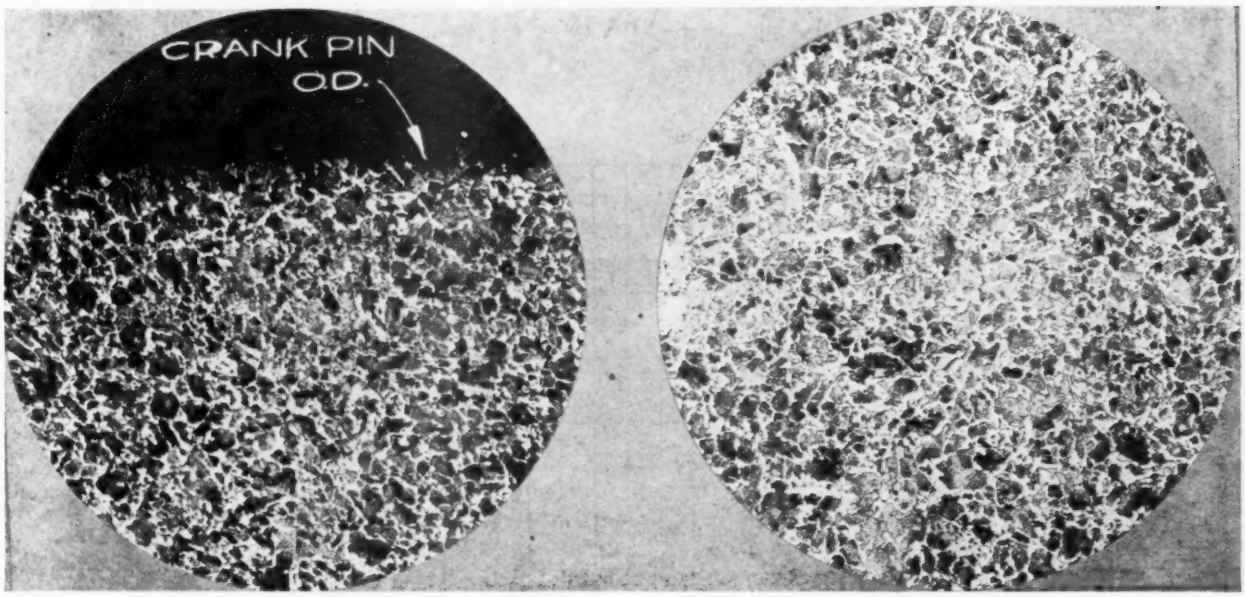

FIG. 18 PHOTOMICROGRAPH OF SURFACE AND CORE LAYERS OF CRANKPIN AFTER SURFACE-ROLLING; ×90

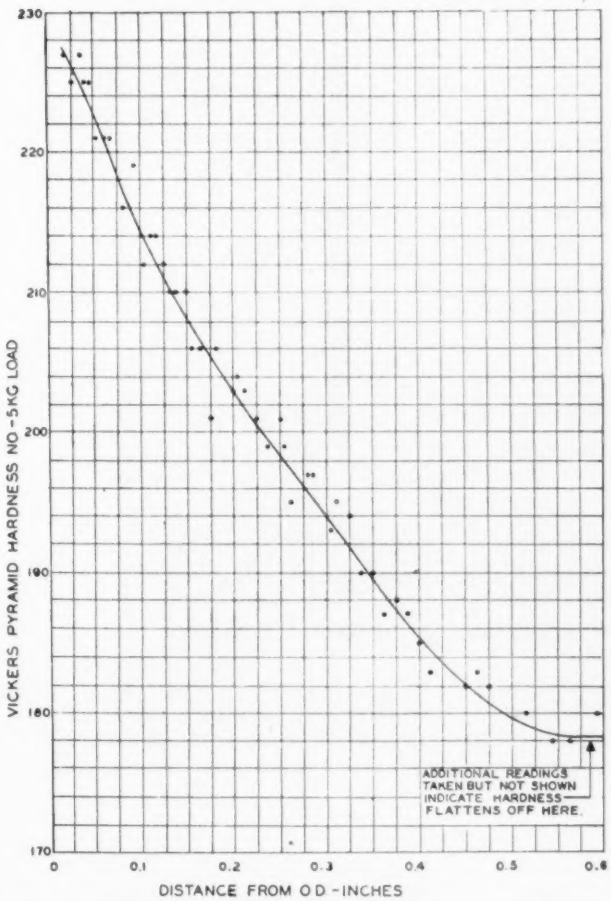

FIG. 19 HARDNESS GRADIENT OF SURFACE LAYER OF ROLLED CRANKPIN

$^{9}/_{16}$ in. below the surface to the original hardness of about 180.[23]

It is interesting to note from Table 4 and Fig. 16, that the crack depths on the rolled pins (type 3) ranged from 0.005 in. deep at 7000-psi stress to 0.205 in. deep at 22,000 psi. This cold-worked layer $^{1}/_{2}$ in. deep certainly offers much increased resistance to the fatigue crack propagating through this layer than the pins with the unrolled surface.

Flame-Hardened Pins of Type 4. There are not sufficient data in Tables 3 and 4 from tests on flame-hardened pins to draw general conclusions as to the influence on fatigue strength of the factors of case depth and whether the pins should or should not be ground after flame-hardening. The trend of the results, however, does show that the deeper case depths lead to a higher endurance-limit value as well as less depth of fatigue crack after 300,000 equivalent miles (85,000,000 revolutions) than the shallow case. If the pin is not ground after flame-hardening and before mounting the wheel, then the fatigue resistance seems to be lower than if the wheel seat is ground.

Photomicrographs and hardness surveys made on pins after the fatigue test are shown in Fig. 20, for a flame speed of $3^{1}/_{8}$ ipm, and in Fig. 21, of $2^{3}/_{4}$ ipm.

A number of pins were found to have thermal cracks after fatigue-testing which were not detected by magnaflux[24] before testing. None of the thermal cracks found showed any evidence of having propagated during the fatigue test.[25] Fig. 22 shows a photomicrograph through a thermal crack found in a highly stressed region of pin No. 23 after test. Some of the pins which broke off in the fatigue test (Table 4) may have fractured through

[23] Similar micrographic and hardness studies were made on rolled sections cut transverse to the axis of the pin but the findings were in close agreement with those just given made on the horizontal planes.

[24] Both wet and dry methods were used as discussed in reference (3), first report, p. 20, and second report p. 28. High surface residual compressive stresses from flame-hardening may press sides of crack together and make detection difficult with 3000-ampere a-c unit used here.

[25] Such thermal cracks are opened up during the fatigue testing and were detected by magnaflux and also by etch examinations of longitudinal slices through wheel fit of pin. Thermal cracks follow the grain boundaries while fatigue cracks pass through the grains.

(Unetched on left and nital-etched on right where crack follows original grain boundaries.)

a thermal crack, but there was no means for determining whether this was the case. The mere presence of thermal cracks introduces some doubt as to whether the fatigue values obtained are influenced by thermal cracks. Despite these thermal cracks, the flame-hardened pins still gave improved fatigue resistance over type 1 not flame-hardened.

While the flame-hardened pins indicated greater fatigue resistance than exhibited by types 1 and 2, the fatigue values were not as high as would be expected[26] on the basis of earlier fatigue tests of press-fitted members presented in Table 5. Very high surface residual stresses established in the surface after flame-hardening[27] are believed to be associated with the favorable increase in fatigue resistance indicated, although it is not possible to separate or appraise the influence of the case structure.

ROLLED PINS OF TYPE 3

A review of the literature with respect to the fatigue resistance of press-fitted assemblies is shown in Table 6, in comparison with the data obtained on crankpins. In all cases the fatigue characteristics are improved by surface rolling. Presence of surface residual compressive stress and/or strain-hardening is responsible for this improvement.

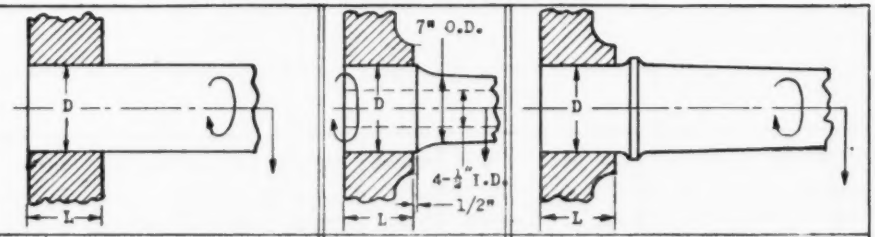
LOSS OF WHEEL FIT

The loss of wheel fit due to changes in wheel bore and crankpin developed during the fatigue test is given in Fig. 23. In some cases all of the original wheel fit near the outside hub face was lost during the test due to bellmouthing of the wheel bore and rubbing corrosion;[28] this is particularly noticeable at the high crankpin stresses. In general about one third of this loss of fit takes place on the crankpin and two thirds on the wheel center.

CONCLUSIONS

A summary of results from all fatigue tests made on the four types of crankpins is shown in Table 7. From these data a percentage rating may be assigned to each type of crankpin as to its fatigue strength against breaking off (not cracking) in the wheel-fit portion as follows:

	Per cent
Type 1	100
Type 2	136
Type 3	Over 200
Type 4	146 to 164



[26] Some explanation for this divergence may be (*a*) case depth or relative depth of case to diameter of axle; (*b*) excessive removal of stock ground off the crankpins may leave low residual compressive stresses on surface; (*c*) size effect, and (*d*) presence of thermal cracks on crankpins. All members in Table 5 except $9^1/_2$-in. pins were flame-hardened by spinning method when entire length of hardened area was heated and quenched at one time and no thermal cracks were detected. Disadvantages of this method are large gas demand and quenching large areas. Crankpins were done by progressive spinning method so that a relatively short length of wheel fit was heated and quenched at one time. This latter method was used on axle wheel seats 8 in. diam without thermal cracking, but axles were preheated to 200 F before hardening.

[27] "Correlation of Residual Stresses in the Fatigue Strength of Axles," by O. J. Horger and H. R. Neifert, JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 64, 1942, p. A-85.

[28] The presence of rubbing corrosion found on all 50 pins tested was accompanied by fatigue cracks with exception of one pin (Type 3, No. 30R, at 7000 psi). Some fundamental work was reported on such corrosion, "Investigation of the Fretting Corrosion of Closely Fitted Surfaces," by G. A. Tomlinson, P. L. Thorpe, and H. J. Gough, Journal and Proceedings of The Institution of Mechanical Engineers, vol. 141, 1939, pp. 223–249.

ACKNOWLEDGMENTS

Appreciation is extended to the railroad members of the Association of American Railroads, Crankpin Committee, who guided this research; K. Cartwright, Chief Mechanical Engineer, New York, New Haven & Hartford Railroad; E. L. Bachman, General Superintendent Motive Power, Pennsylvania Railroad; J. B. Blackburn, Mechanical Engineer, Chesapeake & Ohio Railroad; G. W. Bohannon, Assistant Chief Mechanical Officer, Chicago & North Western Railroad; also H. R. Neifert, Supervisory Research Engineer, and F. M. Dieringer, Engineer, both of The Timken Roller Bearing Company, who carried out the actual testing.

No difficulty was experienced with the preparation of types 1, 2, and 3 crankpins. Some difficulty was experienced with thermal cracks developing in the flame-hardening of type 4 pins. Caution should be exercised in the application of flame-hardening as the procedure followed here was too critical, and fatigue values much lower than those given here could be obtained, depending on the degree to which thermal cracks are produced in flame-hardening and removed by grinding.

This project is being continued and fatigue tests are now being made on quenched and tempered crankpins as well as on pins of various designs.

On Dimensional Analysis and the Presentation of Data in Fluid-Flow Problems

By E. R. VAN DRIEST,[1] CAMBRIDGE, MASS.

The method and application of dimensional analysis are discussed, making use of the fundamental concept of function. The π theorem is restated and proved in general form.

Pipe friction, drag of spheres, and flow through Venturi meters are examples used to illustrate the rearrangement of dimensionless products of a relationship to obtain the most convenient form for presentation of data.

Introduction

THROUGH a comprehensive paper published in 1914, E. Buckingham[2] formally introduced dimensional analysis to the scientific world. It was in this paper that the famous theorem, commonly known as the Buckingham π theorem, was first explicitly stated. Although a concise form of proof of the theorem was given, it has not been readily understandable to the student of fluid mechanics. Furthermore, the young scientist has difficulty in understanding the process of rearrangement of the dimensionless products of a relationship to obtain the most convenient form for presentation of the data. In an attempt to clarify this situation, the present paper was written.

Purpose of Dimensional Analysis

The principal purpose of dimensional analysis from the engineering point of view is the arrangement of the variables of a physical relation so that, without destroying the generality of the relationship, it may be more easily determined experimentally. The method is particularly valuable when the number of variables is so great (usually four or more) that the data cannot be plotted conveniently using a co-ordinate axis for each variable. By dimensional analysis it is possible to arrange the variables into a lesser number of dimensionless groups which can be represented on co-ordinate axes.

Two or three variables can be plotted as (*a*) and (*b*) of Fig. 1, while four variables would require repetitions of (*b*), five would require repetitions of graphs for four, etc. The advantage of reducing the number of quantities to be plotted is obvious, not only because of the simplicity of presentation of the data, but also because of the possibility of determining an analytical formula for the general function.

Function Concept and Grouping of Variables

The variable Q_1 is said to be a function of the variables $Q_2, Q_3, Q_4, \ldots Q_n$, if for some values of $Q_2, Q_3, Q_4, \ldots Q_n$ there correspond values of Q_1. This idea is written symbolically as

$$Q_1 = f(Q_2, Q_3, Q_4, \ldots Q_n) \quad [1]$$

It is absolutely essential to note that this concept is written in symbolic form because it does not have to be expressible by an analytical formula; indeed a graph is sufficient to indicate the relationship.

Once such a function is established or assumed, then a function will still exist even after the variables are intermultiplied in any manner whatsoever. For example, taking

$$z = f(x, y)$$

the following functions will exist

$$z = f_1(xy, y), \quad xz = f_2(x, x^2y)$$

or

$$x^a y^b z = f_3(xy^c z^d, x^e y z^g), \text{ etc.}$$

The principle of dimensional homogeneity will now be introduced. The principle states that each and every term of a correct physical equation must have the same dimensions. Hence if Equation [1] is a correct physical relation, and the left-hand side is made dimensionless in any manner, the right-hand side must also become dimensionless, which means that each variable of the right-hand side is combinable with other variables of the equation to form a dimensionless product. Thus by the foregoing process of intermultiplication, Equation [1] can be written in the nondimensional form as symbolized by

$$\pi_1 = \phi(\pi_2, \pi_3, \pi_4, \ldots \pi_n) \quad [2]$$

If in any assumed physical relation any Q is not combinable with any other Q's to form a dimensioness product, then that Q cannot appear in the original function. In such cases the corresponding π in Equation [2] would be zero. This dimensionless grouping is therefore a method of eliminating, early, those variables which cannot appear in an assumed function. Further, if any π's of Equation [2] are necessarily the same to satisfy the condition of dimensional homogeneity, then that is the way in which the Q's forming those π's must appear in the function. An example of this latter case occurs when two length variables appear in a function along with other variables that do not contain the length dimension; to satisfy the condition of dimensional homogeneity, the two length variables would have to appear as a ratio. Such early grouping of the variables is another advantage of the use of the principle of dimensional homogeneity.

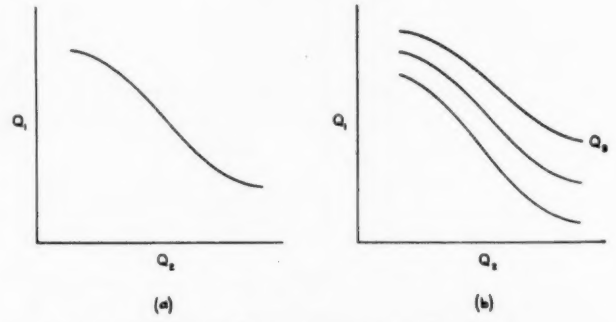

FIG. 1 GRAPHICAL REPRESENTATION OF FUNCTIONS

[2] "On Physically Similar Systems: Illustrations of the Use of Dimensional Equations," by E. Buckingham, *Physical Review*, second series, vol. 4, 1914, pp. 345–377.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of authors and not of the Society.

While the two cases of the preceding paragraph show some results of the use of dimensional analysis, yet the greatest advantage of the method lies in the fact that through its use it is not necessary to write out n π's, one for each variable of the original function, but only i π's, where $i < n$, unless the Q's are all dimensionless, whereupon $i = n$. Equation [2] then becomes

$$\pi_1 = \phi(\pi_2, \pi_3, \pi_4, \ldots \pi_i) \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Such a result has obviously great value since by reducing the number of π's in Equation [2], the function may be plotted on a reduced number of co-ordinates.

The π Theorem

The number of dimensionless groups that are necessary to represent Equation [2] completely is of course the number of independent π's that can form, by proper combination, any other possible π's. It will be seen that this number depends upon the number of variables involved and the greatest number of variables which will not form a dimensionless product.

Theorem. The number of independent dimensionless products is $i = n - k$, where k is the greatest number of Q's that will not combine to form a dimensionless product, or, in other words, where k is the number of Q's whose units can be used to measure all the variables. The number k cannot exceed m, the number of fundamental dimensions used to measure the variables in the mass, length, time, etc., system.

The number k cannot exceed m because any greater number of Q's than m always will form a dimensionless product. To prove this, first write an expression for any π using more than m Q's, say, $(m + 1)$ Q's; thus

$$Q_1^{x_1} Q_2^{x_2} \ldots Q_m^{x_m} Q_{m+1}^{x_{m+1}} = \pi \ldots\ldots\ldots\ldots [4]$$

If the dimensions of Q are given by, say

$$p_1^{a_1} p_2^{a_2} \ldots p_m^{a_m} = [Q]$$

where $p_1, p_2, \ldots p_m$ are the fundamental dimensions measuring Q, then the dimensional equation for Equation [4] will be

$$(p_1^{a_1} p_2^{a_2} \ldots p_m^{a_m})^{x_1} (p_1^{b_1} p_2^{b_2} \ldots p_m^{b_m})^{x_2} \ldots (p_1^{\alpha_1} p_2^{\alpha_2} \ldots p_m^{\alpha_m})^{x_m} (p_1^{\beta_1} p_2^{\beta_2} \ldots p_m^{\beta_m})^{x_{m+1}} = [\pi] = 1 \ldots [5]$$

Equating the exponents to zero in order to eliminate each p results in m equations as follows

$$\left.\begin{array}{ll} p_1: & a_1x_1 + b_1x_2 + \ldots + \alpha_1x_m + \beta_1x_{m+1} = 0 \\ p_2: & a_2x_1 + b_2x_2 + \ldots + \alpha_2x_m + \beta_2x_{m+1} = 0 \\ \ldots\ldots & \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ p_m: & a_mx_1 + b_mx_2 + \ldots + \alpha_mx_m + \beta_mx_{m+1} = 0 \end{array}\right\} \ldots [6]$$

Since the set of m homogeneous Equations [6] has $(m + 1)$ unknowns, it will yield solutions of x other than zero; it follows that any greater number of Q's than m will always form a dimensionless product.

Proceeding with the proof of the theorem, assume that the number k has been determined. Then, in order to form a π containing $(k + 1)$ Q's, there must exist a sufficient number of independent π's to eliminate, upon combination, the $n - (k + 1) = n - k - 1$ remaining Q's; furthermore, to form a π containing less than $(k + 1)$ Q's, it will still be necessary to eliminate only $(n - k - 1)$ Q's because the extra Q's to be eliminated can be chosen to be noncombinable with the Q's forming the particular π and hence will automatically disappear. The elimination process is shown as follows: The grouping of i independent π's to form a certain π will appear algebraically thus

$$\pi_1^{x_1} \pi_2^{x_2} \ldots \pi_i^{x_i} = \pi$$

whence

$$(Q_1^{a_1} Q_2^{a_2} \ldots Q_{n-k-1}^{a_{n-k-1}} \ldots Q_n^{a_n})^{x_1} (Q_1^{b_1} Q_2^{b_2} \ldots Q_{n-k-1}^{b_{n-k-1}} \ldots Q_n^{b_n})^{x_2} \ldots (Q_1^{\alpha_1} Q_2^{\alpha_2} \ldots Q_{n-k-1}^{\alpha_{n-k-1}} \ldots Q_n^{\alpha_n})^{x_i} = \pi \ldots [7]$$

where the exponents are, of course, different from those of Equation [5]. In order to eliminate a Q, the exponents of that Q must be made to vanish. Hence when $(n - k - 1)$ Q's are to disappear, there will result $(n - k - 1)$ equations as follows, if, say, the first $(n - k - 1)$ Q's are to be eliminated

$$\left.\begin{array}{ll} Q_1: & a_1x_1 + b_1x_2 + \ldots + \alpha_1x_i = 0 \\ Q_2: & a_2x_1 + b_2x_2 + \ldots + \alpha_2x_i = 0 \\ \ldots\ldots & \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ Q_{n-k-1}: & a_{n-k-1}x_1 + b_{n-k-1}x_2 + \ldots + \alpha_{n-k-1}x_i = 0 \end{array}\right\} \ldots [8]$$

Now, since Equations [8] are homogeneous in the variables x_1, x_2, $\ldots x_i$, solutions other than $x_1 = x_2 = \ldots = x_i = 0$ will exist provided there are more unknowns than equations. Hence a sufficient condition that any π can be formed by i independent π's is that $i = n - k$. It is to be noted that this elimination process is precisely the same as that by which fundamental dimensions were caused to vanish in the formation of a π from a set of Q's.

In order to complete the proof of the theorem it must also be shown that $i = n - k$ is a necessary condition that any π can be formed, or in other words, that s independent π's, where $s < n - k$, can never represent all the possible π's. To demonstrate this, observe that $n - k$ independent π's can always be found by merely taking any set of k Q's, noncombinable among themselves, and combining them with each of the remaining Q's in turn. Since this set of $n - k$ independent π's can represent all the other possible π's by the foregoing reasoning, it can of course form one of the s π's. This new one of the s π's can then be substituted for one of the $(n - k)$ π's that definitely contributed to the formation of the new π, thus creating a new set of $n - k$ independent π's. Using this new set of $(n - k)$ π's, another of the s π's, other than that one already obtained belonging to the s set, can be formed and substituted for one of the new set. After all of the s π's are constructed and substituted in succession, it is seen that there are still $n - k$ independent π's, including the s π's. Hence, since the remaining $(n - k - s)$ π's are independent of the s π's, a lesser number of independent π's than $n - k$ can never represent all possible dimensionless products.

Although it is seen that any $i = n - k$ independent π's will represent all possible dimensionless groups that can be formed by the variables of a function, the simplest procedure to follow in selecting $n - k$ independent π's is to take a certain set of k Q's that will not form a dimensionless product and combine them with each of the remaining Q's in turn.

The π theorem is therefore proved in general without any assumption as to the form of the original function or the use of any complex mathematics. It is to be noted that in the foregoing statement of the theorem, $n - m$ is not necessarily the number of independent π's required to specify a function, since more may be needed depending upon the problem at hand. The procedure, however, is to see if any m Q's can be found which will not form a dimensionless product, and if all sets of m Q's will form such a product, then to continue down until the greatest number is found.

As an example, consider the propeller problem where the thrust T is assumed to be a function of the axial velocity V, the diameter D, the rotational speed N, the density of the fluid ρ, and the viscosity of the fluid μ. In symbolic form

$$T = f(V, D, N, \rho, \mu) \ldots\ldots\ldots\ldots\ldots [9]$$

The number of fundamental dimensions m involved is three, viz.,

mass, length, and time, and three variables can be found which will not form a dimensionless quantity; hence $n - k = n - m = 6 - 3 = 3$ independent π's will be necessary to represent the function. They may be chosen at random as

$$\frac{T}{\rho V^2 D^2}, \quad \frac{\rho V^2}{N\mu}, \text{ and } \frac{T}{\rho N^2 D^4}$$

to represent Equation [9] by

$$\frac{T}{\rho V^2 D^2} = \phi\left(\frac{\rho V^2}{N\mu}, \frac{T}{\rho N^2 D^4}\right)$$

or, systematically, by taking three of the variables, say, ρ, D, V, that will not form a π, and combining them with each of the remaining variables giving

$$\frac{T}{\rho V^2 D^2}, \quad \frac{VD\rho}{\mu}, \text{ and } \frac{V}{ND}$$

to represent Equation [9] by

$$\frac{T}{\rho V^2 D^2} = \psi\left(\frac{VD\rho}{\mu}, \frac{V}{ND}\right)$$

It will be of interest to note the number of possible dimensionless groups that can be formed by the n variables. The combinations of n variables taken $k + 1$ at a time are given by

$$\frac{n!}{(k+1)!(n-k-1)!}$$

which gives for the propeller example, $\frac{6!}{4!.2!} = 15$. Written out, these are

$$\frac{T}{\rho V^2 D^2}, \frac{T\rho}{\mu^2}, \frac{T}{\rho N^2 D^4}, \frac{T\rho}{\mu^2}, \frac{TN^2}{\rho V^4}, \frac{T\rho}{\mu^2}, \frac{T}{VD\mu}, \frac{V}{ND}, \frac{T}{\mu N D^2}, \frac{TN}{\mu V^2},$$
$$\frac{VD\rho}{\mu}, \frac{V}{ND}, \frac{ND^2\rho}{\mu}, \frac{\rho V^2}{N\mu}, \frac{V}{ND}$$

The products $\frac{T\rho}{\mu^2}$ and $\frac{V}{ND}$ appear more than once so that there are eleven different π's available from the six variables. This example shows clearly how the problem of almost hopeless plotting of one variable in terms of five variables can be readily reduced to that of the plotting of one variable quantity against but two.

As another illustration, consider the case of a fluid flowing through an orifice, and assume that the velocity V depends only on the difference in pressure Δp, and the density of the fluid ρ, or

$$V = f(\Delta p, \rho) \quad \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

Now, although the number of fundamental dimensions is three, viz., mass, length, and time, the greatest number of variables which will not form a dimensionless product is 2. Therefore, there will be $3 - 2 = 1$ independent π to yield

$$\phi\left(\frac{\rho V^2}{\Delta p}\right) = 0.$$

and $\frac{\rho V^2}{\Delta p}$ will be a constant. This is a very simple case where k is less than m; it shows the generality of the π theorem as stated.

Another example of where k is less than m can be found by adding a compressibility term to the variables of Equation [10]. Accordingly

$$V = f_1(\Delta p, \rho, E)$$

where E is the modulus of compressibility of the fluid. Since $k = 2$, there will appear 2 independent π's thus

$$\frac{V}{\sqrt{\frac{\Delta p}{\rho}}} = \phi_1\left(\frac{V}{\sqrt{\frac{E}{\rho}}}\right)$$

The Physical Interpretation of Dimensionless Products

Sometimes it is helpful to attach a physical interpretation[3] to the dimensionless products of a function. The heat-transfer problem lends itself readily to such a treatment and therefore will be used as an example.

Considering the transfer of heat q to or from a liquid of mean cross-sectional temperature θ_m flowing in a smooth pipe with wall at temperature θ_w, the film coefficient $h = \frac{q}{\theta_w - \theta_m}$ is found to be a function of the diameter D, the mean velocity V the density ρ, the viscosity μ, the specific heat c, and the thermal conductivity k, or

$$h = f(D, V, \rho, \mu, c, k)$$

There are four fundamental dimensions which describe these quantities, viz., mass, length, time, and temperature, and four quantities are available which will not form a dimensionless product. Hence, $7 - 4 = 3$ independent π's exist and a set can be found easily by choosing D, μ, ρ, and k as basic. There follows

$$\frac{hD}{k} = \phi\left(\frac{VD\rho}{\mu}, \frac{c\mu}{k}\right)$$

In this equation, $\frac{hD}{k}$ is called the Nusselt number, $\frac{VD\rho}{\mu}$ the Reynolds number, and $\frac{c\mu}{k}$ the Prandtl number.

Now the rate of heat transfer by molecular action is given by

$$q_m = k\frac{d\theta}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

where θ is the mean temperature at a point. Furthermore, the heat transfer by turbulent action can be written similarly

$$q_t = k'\frac{d\theta}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

where k' can be called the turbulence coefficient of thermal conductivity. Division of Equation [12] by Equation [11] gives

$$\frac{q_t}{q_m} = \frac{k'}{k} \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

But q_t can be placed equal to the product of a local heat-transfer coefficient h_L and the differential temperature $d\theta$, thus

$$q_t = h_L d\theta$$

so that

$$k' = h_L dy$$

and Equation [13] becomes

$$\frac{q_t}{q_m} = \frac{h_L dy}{k}$$

a local Nusselt number which is a function of the over-all Nusselt number $\frac{hD}{k}$. It is therefore seen that the Nusselt number is a

[3] "The Analogy Between Fluid Friction and Heat Transfer," by Th. von Kármán, Trans. A.S.M.E., vol. 61, 1939, pp. 705–710.

dimensionless quantity which can be thought of as the ratio of turbulent heat transfer to molecular heat transfer.

The Reynolds number can be interpreted in a similar way by first writing for the turbulent shear stress

$$\tau_t = \rho\epsilon \frac{dv}{dy} = \rho \sqrt{\overline{v_y'^2}}\, l \frac{dv}{dy} = \sqrt{\overline{v_y'^2}}\, l \frac{d(\rho v)}{dy} \quad \ldots\ldots [14]$$

where v is the mean velocity, v_y' the transverse-velocity fluctuation, l the mixing length at a point, and ϵ the turbulence-exchange coefficient. For molecular shear

$$\tau_m = \mu \frac{dv}{dy} = \frac{\mu}{\rho} \frac{d(\rho v)}{dy} \quad \ldots\ldots\ldots\ldots [15]$$

The ratio of Equations [14] and [15] is

$$\frac{\tau_t}{\tau_m} = \frac{\sqrt{\overline{v_y'^2}}\, l\rho}{\mu} = \frac{\epsilon}{\nu}$$

a local Reynolds number which is a function of the over-all Reynolds number $\frac{VD\rho}{\mu}$. The Reynolds number can therefore be thought of as a measure of the ratio of the turbulent momentum exchange and an effective molecular momentum exchange.

The Prandtl number can now be interpreted as connecting the momentum and heat transfer due to molecular action. For, again

$$\tau_m = \mu \frac{dv}{dy} = \frac{\mu}{\rho} \frac{d(\rho v)}{dy}$$

and

$$q_m = k \frac{d\theta}{dy} = \frac{k}{\rho c} \frac{d(\rho c\theta)}{dy}$$

from which, for the same gradient

$$\frac{\tau_m}{q_m} = \frac{c\mu}{k}$$

The Peclet number is the product of the Reynolds and Prandtl numbers, and hence can be thought of as connecting the turbulent momentum with the molecular heat exchange, thus

$$\text{Peclet number} = \frac{VD\rho}{\mu} \cdot \frac{c\mu}{k} = \frac{\rho c VD}{k}$$

$$= \frac{\tau_t}{\tau_m} \cdot \frac{\tau_m}{q_m} = \frac{\tau_t}{q_m}$$

The foregoing physical interpretations of the various dimensionless numbers involved in the heat-transfer problem may be represented diagrammatically by Fig. 2.

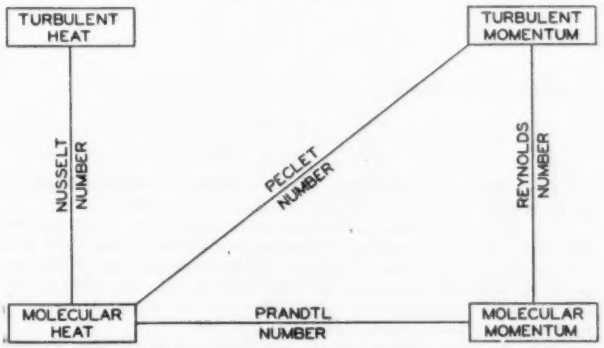

FIG. 2 PHYSICAL INTERPRETATION OF DIMENSIONLESS NUMBERS INVOLVED IN THE HEAT-TRANSFER PROBLEM

Since the heat-transfer problem is reducible from seven variables to three groups of variables, the type of graph shown by (*b*) in Fig. 1 is all that is necessary for presentation of the data.

Another interesting engineering problem is that of sediment transportation by a liquid flowing in an open channel. The solution of this problem has not met with as much success as the heat-transfer problem, probably because of the great number of variables involved. If the sediment grains are spherical and uniform in size, the channel bed saturated with sediment, and the channel wide relative to its depth, a concentration coefficient $h = \dfrac{\text{Mean concentration of sediment flowing}}{\text{Concentration of sediment at the bed}} = \dfrac{N_m}{N_b}$ may be assumed dependent upon the diameter of the sediment D, the fall velocity of the sediment η, the mean velocity of flow V, the depth of flow d, the density of the fluid ρ, and the viscosity of the fluid μ. Hence

$$h = f(D, \eta, V, d, \rho, \mu)$$

There are three fundamental dimensions, viz., mass, length, and time, and three variables can be found which will not form a dimensionless product; hence $7 - 3 = 4$ independent π's exist. Choosing d, V, and ρ as the common variables

$$\frac{N_m}{N_b} = \phi\left(\frac{\eta}{V}, \frac{Vd\rho}{\mu}, \frac{D}{d}\right) \quad \ldots\ldots\ldots\ldots [16]$$

To plot this function, a set of graphs such as (*b*) in Fig. 1, should be anticipated unless one of the terms of Equation [16] is found to have no effect upon the relation.

Introducing the shear at the bed τ_0, which is a function of D, V, d, ρ, and μ, there results furthermore

$$\frac{\tau_0}{\rho V^2} = f_1\left(\frac{\sqrt{\frac{\tau_0}{\rho}}\, d\rho}{\mu}, \frac{D}{d}\right)$$

and Equation [16] may be written in the form

$$\frac{N_m}{N_b} = \phi_1\left(\frac{\eta}{\sqrt{\frac{\tau_0}{\rho}}}, \frac{\sqrt{\frac{\tau_0}{\rho}}\, d\rho}{\mu}, \frac{D}{d}\right)$$

or, by combination of the last two terms

$$\frac{N_m}{N_b} = \phi_2\left(\frac{\eta}{\sqrt{\frac{\tau_0}{\rho}}}, \frac{\sqrt{\frac{\tau_0}{\rho}}\, D\rho}{\mu}, \frac{D}{d}\right) \quad \ldots\ldots\ldots [16a]$$

Interpreting physically the dimensionless products involved in Equation [16*a*], the term $\eta/\sqrt{\frac{\tau_0}{\rho}}$ is a measure of the suspension ability of the turbulent fluid since

$$\tau = \rho \overline{v_x' v_y'} \sim \rho \sqrt{\overline{v_x'^2}}\, \sqrt{\overline{v_y'^2}} \sim \rho \overline{v_y'^2}$$

so that

$$\frac{\eta}{\sqrt{\frac{\tau_0}{\rho}}} \sim \frac{\eta}{\sqrt{\overline{v_y'^2}}}$$

where v_x' and v_y' are the instantaneous velocity fluctuations at a point parallel and vertically perpendicular to the mean flow, respectively. The third term is a Reynolds number and may be interpreted as the ratio of the diameter of a particle of sediment

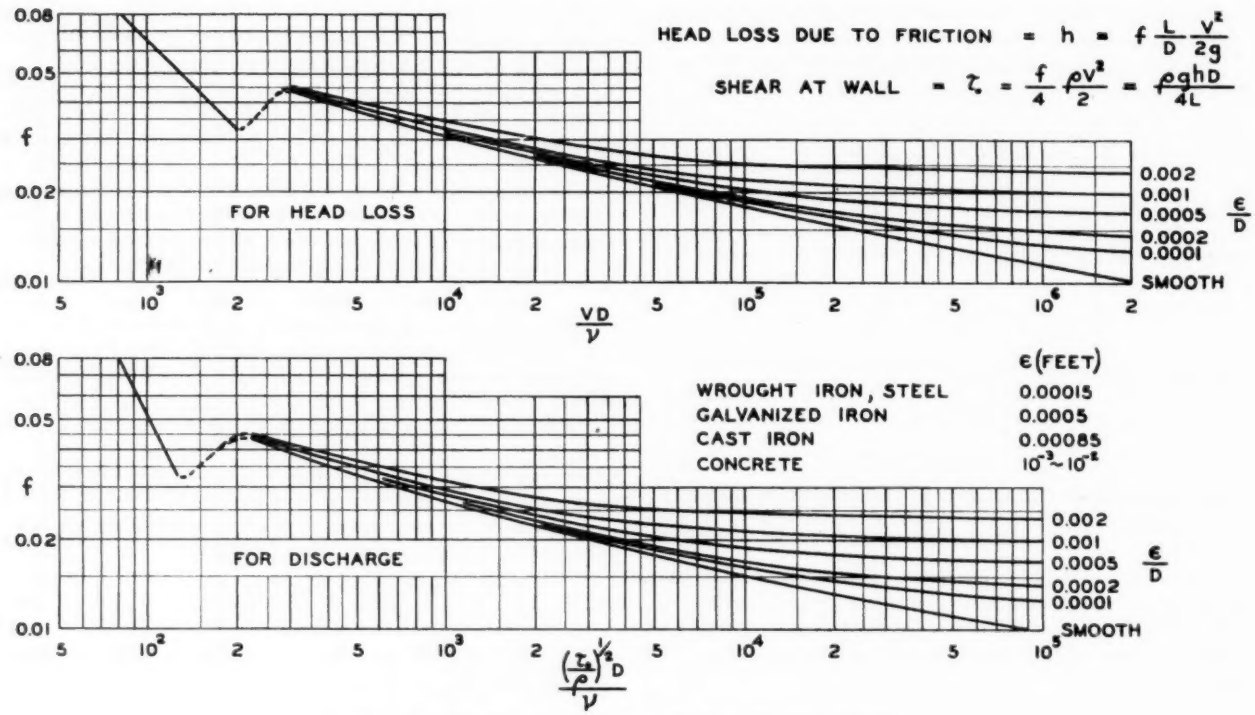

FIG. 3 FRICTION COEFFICIENTS FOR COMMERCIAL PIPES[4]

to the thickness of the laminar layer δ since $\delta \sim \frac{\nu}{\sqrt{\frac{\tau_0}{\rho}}}$; therefore this term may be thought of further as an indication of the exposure of the sand grains in the bed to the turbulent fluid outside the laminar boundary layer. At low flows, the Reynolds number will be influential, while at high flows, it will probably disappear from the function. The term D/d may be called the relative grain-size factor. Indeed, the corresponding terms of Equation [16] are expressions for the same physical pictures.

The element of arbitrariness in the procedures outlined is obvious, since other interpretations can often be given to the same dimensionless quantities.

PHYSICAL SIMILARITY

Another advantage of the method of dimensional analysis is that the method allows model studies to be made of physical problems so that information may be obtained without knowledge of the exact relationship of the variables involved.

With reference to Equation [3], viz.

$$\pi_1 = \phi(\pi_2, \pi_3, \pi_4, \ldots \pi_i)$$

it is seen that if ϕ is held constant, then π_1 will be constant and

$$(\pi_1)_m = (\pi_1)_p$$

where m and p refer to the model and prototype, respectively. Now the simplest way to fix the function ϕ is to fix the π's within ϕ; therefore, if certain information is desired before the construction of a large expensive structure, that information may be obtained by building a model and attempting to hold constant all the π's affecting the π in which one is interested. The word "attempting" is used because in most engineering problems such complete success is practically impossible.

When two systems are performing in such a manner that all the corresponding dimensionless products are equal, those systems are said to be physically similar. Such similarity may include thermal, dynamic, and geometric similarity as in the case of the heat-transfer problem previously cited.

PRESENTATION OF DATA

Once a relationship between several variables has been determined by the plotting of any set of independent dimensionless quantities involving the variables, the idea of function allows one to plot graphs corresponding to any other set of independent dimensionless products. As a result of such manipulation of functions, the solution of many problems by the method of successive approximations can be eliminated.[5,6,7,8] The first example to be considered will be that of pipe friction.

It has been found by experiment that in the flow of incompressible fluids through pipes, the shear τ_0 at the wall is a function of the mean cross-sectional velocity V, the diameter of the pipe D, the density of the fluid ρ, the viscosity of the fluid μ, and the absolute roughness ϵ, or

$$\tau_0 = \phi(V, D, \rho, \mu, \epsilon)$$

whence

$$\frac{\tau_0}{\rho V^2} = \psi\left(\frac{VD\rho}{\mu}, \frac{\epsilon}{D}\right)$$

In terms of the Darcy f

$$\frac{8\tau_0}{\rho V^2} = f\left(\frac{VD\rho}{\mu}, \frac{\epsilon}{D}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

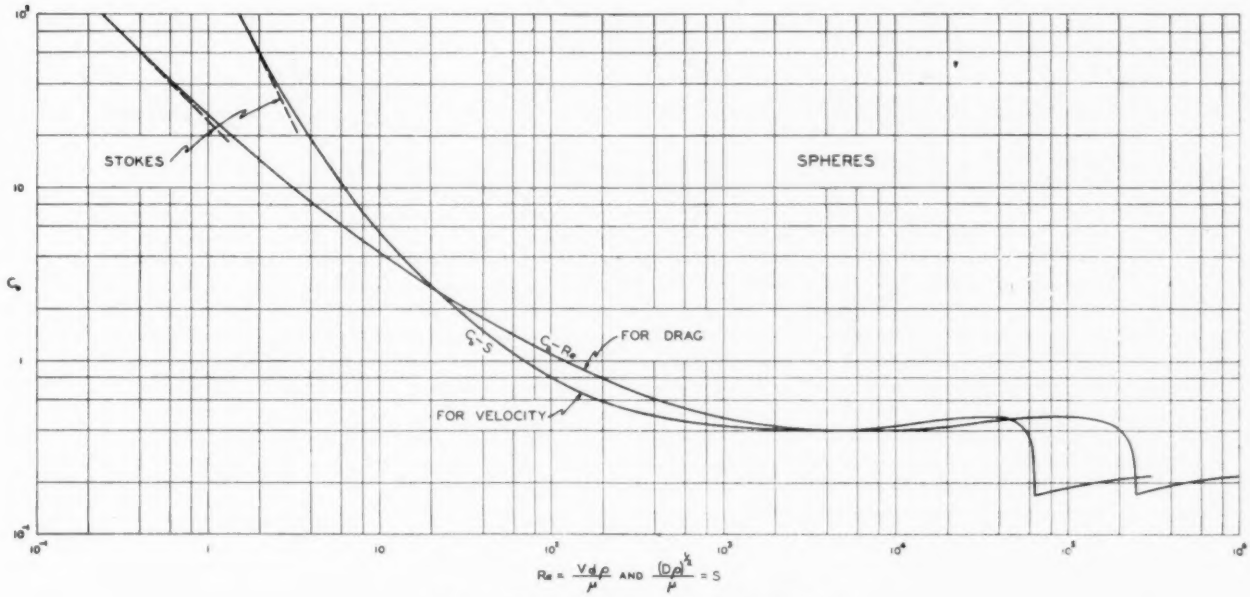

FIG. 4 DRAG COEFFICIENTS FOR SPHERES[9]

which is plotted[4] in Fig. 3 for a range of $\frac{\epsilon}{D}$, called the relative roughness.

The functional representation of Equation [17] by the graph allows direct determination of the wall friction or head loss, upon a knowledge of the discharge, diameter, and wall material of the pipe, but requires a solution by successive approximation when the discharge is desired. In order to obviate the latter rather laborious method, it is only necessary to rewrite Equation [17] thus

$$\frac{8\tau_0}{\rho V^2} = f\left(Re, \frac{\epsilon}{D}\right) = f_1\left(Re \cdot f^{1/2}, \frac{\epsilon}{D}\right)$$

$$= f_1\left[\frac{VD}{\nu} \cdot \frac{\left(\frac{\tau_0}{\rho}\right)^{1/2}(8)^{1/2}}{V}, \frac{\epsilon}{D}\right]$$

$$= f_2\left[\frac{\left(\frac{\tau_0}{\rho}\right)^{1/2} D}{\nu}, \frac{\epsilon}{D}\right]$$

which can readily be plotted (see Fig. 3) from the f — Re diagram by the relation

$$\frac{\left(\frac{\tau_0}{\rho}\right)^{1/2} D}{\nu} = Re \cdot \left(\frac{f}{8}\right)^{1/2}$$

Therefore, knowing the wall friction, diameter, and roughness of a pipe, the discharge can be determined directly.

A second example which illustrates the application of the concept of function is the problem of drag of a sphere moving in an incompressible fluid. Here it is found that the total drag D is related to the speed V, the diameter d, and the density and viscosity of the fluid. Hence

$$D = \phi(V, d, \rho, \mu)$$

or

$$\frac{D}{\rho/2AV^2} = C_D\left(\frac{Vd\rho}{\mu}\right) = C_D\,(Re) \ldots\ldots\ldots [18]$$

where C_D is called the drag coefficient and A is the projected area This equation is plotted[9] in Fig. 4.

The relationship given by Equation [18] and its graph is in the best form for the direct determination of the drag, knowing the speed of the sphere, but it is not in the best form for the calculation of the speed given the drag. Hence it is necessary to change the independent π's as follows

$$\frac{D}{\frac{\rho}{2}AV^2} = C_D(Re) = C_{D_1}(Re \cdot C_D^{1/2})$$

$$= C_{D_1}\left[\frac{Vd\rho}{\mu} \cdot \frac{D^{1/2}}{\left(\frac{\rho}{2}\right)^{1/2}\left(\frac{\pi}{4}\right)^{1/2} dV}\right]$$

$$= C_{D_1}\left[\frac{(D\rho)^{1/2}}{\mu} \cdot \left(\frac{8}{\pi}\right)^{1/2}\right]$$

$$= C_{D_2}\left[\frac{(D\rho)^{1/2}}{\mu}\right] \ldots\ldots\ldots\ldots\ldots\ldots [19]$$

where

$$\frac{(D\rho)^{1/2}}{\mu} = \left(\frac{\pi}{8}\right)^{1/2} \cdot Re \cdot C_D^{1/2}$$

Equation [19] which is plotted also in Fig. 4, is now in the proper form for direct determination of the speed once the drag is given.

A third illustration is that of the Venturi meter in which the velocity V_2 at the throat of diameter D_2 is given by

$$V_2 = C\left(\frac{V_2 D_2}{\nu}, \frac{D_2}{D_1}\right)\sqrt{\frac{2gh}{1 - (D_2/D_1)^4}} = CM\sqrt{2gh}$$

or

$$\frac{V_2}{M\sqrt{2gh}} = C\left(\frac{V_2 D_2}{\nu}, \frac{D_2}{D_1}\right) \ldots\ldots\ldots\ldots [20]$$

[9] Basic data adapted from "Das Widerstandsproblem," by F. Eisner, Proceedings Third International Congress Applied Mechanics, Stockholm, Sweden, 1931.

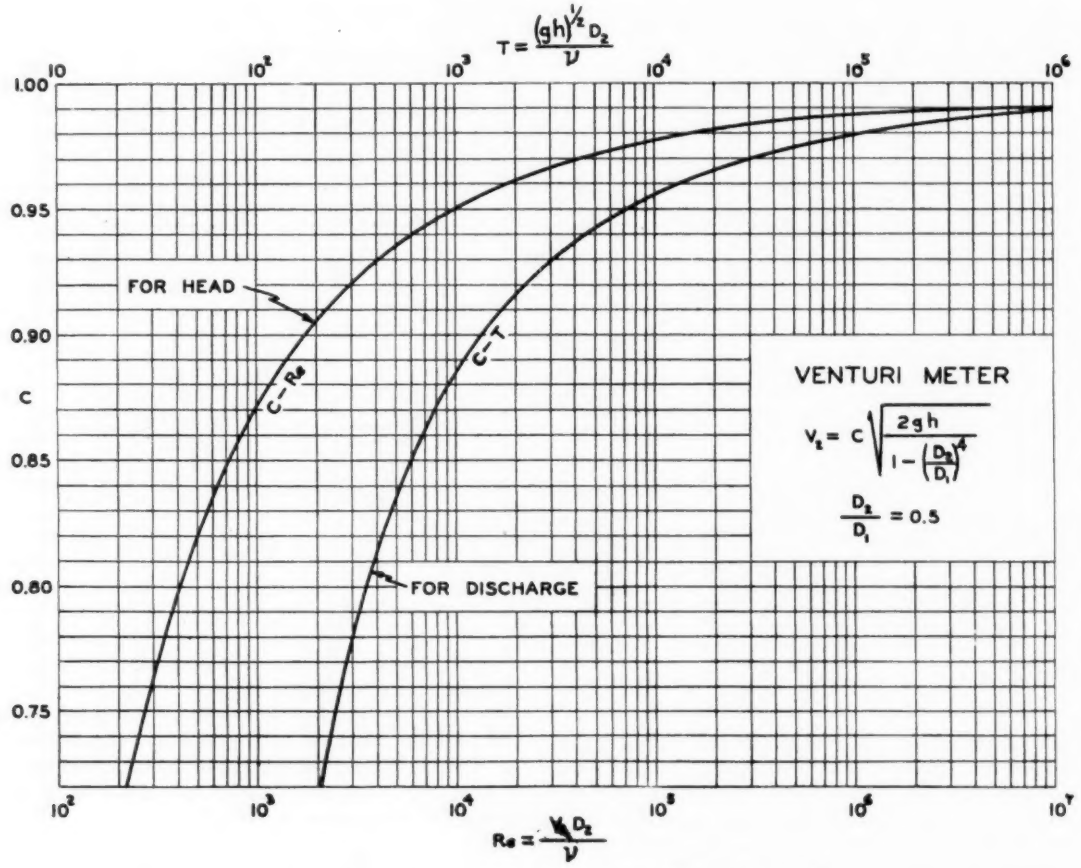

FIG. 5 VELOCITY COEFFICIENTS FOR A VENTURI METER[10]

where

$$M = \frac{1}{\sqrt{1 - (D_2/D_1)^4}}$$

and h is the difference in the static heads at the throat (2) and base (1).

Again, while Equation [20] is most useful for calculation of the head given the discharge, yet its graph requires the use of successive approximation to determine the discharge given the head. A simple manipulation can take care of this situation; thus

$$\frac{V_2}{M\sqrt{2gh}} = C\left(\frac{V_2 D_2}{\nu}, \frac{D_2}{D_1}\right) = C\left(Re, \frac{D_2}{D_1}\right)$$

$$= C_1\left(\frac{Re}{C}, \frac{D_2}{D_1}\right) = C_1\left(\frac{V_2 D_2}{\nu} \cdot \frac{\sqrt{2gh}M}{V_2}, \frac{D_2}{D_1}\right)$$

$$= C_1\left(\frac{\sqrt{2gh}\, D_2}{\nu} \cdot M, \frac{D_2}{D_1}\right)$$

$$= C_2\left[\frac{(gh)^{1/2} D_2}{\nu}, \frac{D_2}{D_1}\right] \quad \text{.....[21]}$$

where

$$\frac{(gh)^{1/2} D_2}{\nu} = \frac{Re}{C} \cdot \frac{1}{\sqrt{2}M}$$

Fig. 5 shows both Equations [20][10] and [21]. The discharge can now be found directly through the graph and Equation [21].

The rearrangement of the dimensionless products of a function may be useful also in finding the best mode of presentation of the data for a particular problem. For example, in the pipe-friction problem where

$$\frac{8\tau_0}{\rho V^2} = f\left(Re, \frac{\epsilon}{D}\right) \quad \text{.....[22]}$$

another function may have been found, viz.

$$\frac{8\tau_0}{\rho V^2} \cdot \frac{VD\rho}{\mu} = f_b\left(Re, \frac{\epsilon}{D}\right)$$

or

$$\frac{8\tau_0 D}{V\mu} = f_b\left(Re, \frac{\epsilon}{D}\right) \quad \text{.....[23]}$$

but Equation [23] involves a much larger variation than Equation [22] in the more common turbulent range of flow and therefore is not so well suited for presentation as Equation [22].

[10] Data adapted from "Fluid Meters, Their Theory and Application," Part 1, A.S.M.E., 1937, pp. 56 and 100.

A Uniform Method for Determining Angular Accelerations in Mechanisms

By L. R. KOENIG,[1] ST. LOUIS, MO.

The purpose of this paper is to disclose a more reliable and uniform method, applicable to mechanisms in general, for determining directly the angular accelerations of the constituent links. The method completely suffices where the determination of angular accelerations is the end in view. Although it is independent of normal, tangential, and total accelerations of points on the links, reliable determinations of such accelerations are considerably facilitated with the aid of the acquired angular accelerations. Angular-acceleration problems may be solved with increased assurance because; (*a*) only velocity-vector considerations are required in the necessary kinematic layouts; (*b*) full advantage may be taken of the process of inversion in simplifying velocity-vector layouts, which is not possible when acceleration vectors are employed; and (*c*) the method gives considerable insight into the effects of the various factors controlling the angular accelerations.

Nomenclature

The following nomenclature is used in this paper:

- ω = angular velocity, radians per sec
- α = angular acceleration, radians per sec per sec
- V = linear velocity of a point, superscripts being used to distinguish different vectors
- k = instantaneous line of three rotopoles[2] of three rigid systems moving relatively
- V^k = velocity along line k of a moving point on line k
- r = radial distance between the two rotopoles in a given rigid system and located on line k
- ϕ = tangent rolling circles respectively attached at a given instant to relatively moving rigid systems and reproducing their angular movements, as will be elucidated below.
- —— line segment; thus (a——a), or (ab——af)
- //////// reference system, body or link, generally fixed with respect to the earth, such as a machine frame, to be indexed F

Capital English letters from the first part of the alphabet symbolize rigid point systems, thus, A, B, C, F . . . etc. Such systems include as particular cases the rigid links, either moving or stationary, of mechanisms.

Pairs of lower-case English letters designate the rotopoles of the corresponding capital-lettered, rigid, point systems; thus a pair of coincident points a and b on links A and B, respectively, when they are at the rotopole for these links, are indexed ab.

It should be noted more carefully than is the ordinary practice that where two rotopoles are associated with one rigid system (for example, rotopoles ab and bf with system B) each rotopole is constituted by two coincident points, making four in all, of which only the two points having the common letter b are in the system B and determine a unique line segment b——b therein. Thus line segment b——b between rotopoles ab and bf is on system B. According to the notation adopted, points a and f in the foregoing case belong to relatively moving systems A and F on which are other line segments a——a and f——f, respectively. In the case of three relatively moving systems A, B, and F, rotopoles ab, bf, and af are collinear according to Aronhold's theorem,[3] and line segments a——a, b——b, and f——f are therefore necessarily coincident.

Subscripts used in connection with any symbol designate the entity to which the symbol applies, thus V_{ab} is the velocity of the rotopole ab; $V_{fc}{}^{k}$ is the velocity along line k of rotopole fc, etc.

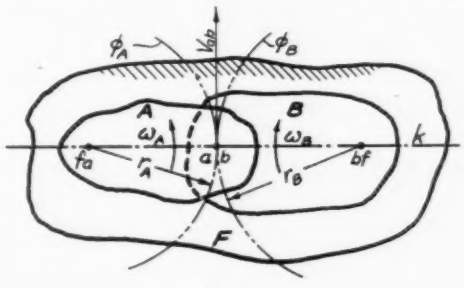

Fig. 1

Basic Considerations

Assume, Fig. 1, three rigid point systems (in a more limited sense bodies, or links) A, B, F, moving relatively, which have rotopoles fa, ab, and bf. These rotopoles necessarily lie upon a straight line k (Aronhold's theorem).[3] Let body F be stationary and without acceleration relative to the desired frame of reference, generally the earth. It follows that at any given instant a line k passing through points f——f is stationary and without acceleration relative to the frame of reference. To this line k are to be referred angular motions of the moving systems A and B.[4] Point ab is the common rotopole of the two relatively moving systems A and B, being coincident points a and b on bodies A and B, respectively, and has in each, relative to F, the same tangential velocity, thus

$$V_{ab} = \omega_A\,(a——a) = \omega_B\,(b——b) \quad \ldots\ldots\ldots\ldots [1]$$

[1] Assistant Professor of Mechanical Engineering, Washington University. Member, firm Haynes and Koenig, St. Louis, Mo. Mem. A.S.M.E.

[2] The term "rotopole" is considered to be preferable to the variety of formerly used equivalent English terms, such as instantaneous center, instant center, and centro. The term "rotopole" has been suggested and its advantages discussed by A. E. R. de Jonge in "A Brief Account of Modern Kinematics," Trans. A.S.M.E., vol. 65, 1943, pp. 663–675. It is employed throughout this paper.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until April 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of authors and not of the Society.

[3] Ascribed to Aronhold by A. E. R. de Jonge,[2] but heretofore often called Kennedy's theorem.

[4] It may be observed that successive lines k drawn through successive positions assumed by rotopoles fa and bf may, in time, be angularly related, but each is simply a new line upon which attention is being fixed at the instant and has no angular velocity or acceleration, the line k being determined always by a set of motionless points f——f in the motionless reference system F.

Circles ϕ_A and ϕ_B drawn in the systems A and B, respectively, centered at rotopoles fa and bf, respectively, and rolling tangentially at ab will, at the instant under consideration, reproduce the angular motions of systems A and B relative to the fixed line k in the fixed system F. These angular motions are the same as those that originally determined the rotopoles fa, ab, and bf.[5] Thus from Equation [1] and Fig. 1

$$\frac{\omega_A}{\omega_B} = \frac{(b\text{——}b)}{(a\text{——}a)} = \frac{r_B}{r_A} \quad [2]$$

Now, r_A and r_B are the radii of instantaneous circles ϕ_A and ϕ_B but, since rotopoles fa, ab, and bf may advance toward or away from one another on line k as successive positions of line k are assumed, these radii r_A and r_B, in many linkages, may change throughout finite time intervals, although this is not universally the case.[6] Thus at any given instant the following relations in Fig. 1 hold relatively to system F

$$\omega_A r_A = V_{ab} = \omega_B r_B \quad [3]$$

Differentiating Equation [3] with respect to time yields

$$\frac{d(\omega_A r_A)}{dt} = \frac{d(\omega_B r_B)}{dt} \quad [4]$$

Then

$$\omega_A \frac{dr_A}{dt} + r_A \frac{d\omega_A}{dt} = \omega_B \frac{dr_B}{dt} + r_B \frac{d\omega_B}{dt} \quad [5]$$

But since

$$\frac{d\omega_A}{dt} = \alpha_A \quad [6]$$

and

$$\frac{d\omega_B}{dt} = \alpha_B \quad [7]$$

Substituting Equations [6] and [7] in Equation [5] will yield

$$\omega_A \frac{dr_A}{dt} + r_A \alpha_A = \omega_B \frac{dr_B}{dt} + r_B \alpha_B \quad [8]$$

Hence

$$r_B \alpha_B = \omega_A \frac{dr_A}{dt} + r_A \alpha_A - \omega_B \frac{dr_B}{dt} \quad [9]$$

Transposing and simplifying

$$\alpha_B = \frac{1}{r_B}\left(\omega_A \frac{dr_A}{dt} - \omega_B \frac{dr_B}{dt} + \alpha_A r_A\right) \quad [10]$$

Also, since from Fig. 1 and Equation [2]

$$\frac{\omega_A}{\omega_B} = \frac{r_B}{r_A} \quad [11]$$

then

$$\omega_B = \frac{\omega_A r_A}{r_B} \quad [12]$$

and substituting Equation [12] in Equation [10] yields

$$\alpha_B = \frac{1}{r_B}\left(\omega_A \frac{dr_A}{dt} - \frac{\omega_A r_A}{r_B}\frac{dr_B}{dt} + \alpha_A r_A\right) \quad [13]$$

Equation [13] provides for the uniform procedure without acceleration vectors. It is general for any three relatively moving rigid systems, and thus also for any three rigid links in any mechanism. The left-hand term α_B of Equation [13] is the desired angular acceleration of a rigid point system B, which may be any link in any mechanism.

The factor ω_A in the bracket is the assigned or known angular velocity with respect to the frame of reference F of some link A, and α_A is its assigned or known angular acceleration. The frame of reference F is the fixed link or frame of the mechanism, if results relative to the earth are desired.

The first and second terms in the bracket, respectively, include the factors $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$ which are the rates of change in time of the radii of circles ϕ_A and ϕ_B. Thus $\frac{dr_A}{dt}$ may be evaluated by determining the instantaneous velocity difference along line k of rotopoles ab and fa; and likewise $\frac{dr_B}{dt}$ may be evaluated by determining the instantaneous velocity difference along line k of rotopoles ab and bf. These velocity differences are obtainable from well-known rotopole and velocity-vector layouts, as will be exemplified later. The lengths r_A and r_B may be obtained from the mechanism layout, wherein the determined positions of the rotopoles fa, ab, and bf determine these radii.

The ordinary rotopole and velocity-vector layout supplies all of the substitutions required in Equation [13] and provides all of the engineering accuracy required. Nevertheless, it will be clear that the layout may be treated algebraically in order to increase the accuracy of the substitution values to any extent worth while. In practice, the latter is very seldom necessary. The process of kinematic inversion may be used at will for simplifying velocity-vector solutions, because "relative" velocities between links are unaffected thereby; hence the correctness of values for $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$ is unaffected by inversion. This is an important advantage of the method over the prior use of "acceleration" vectors wherewith inversions may never be employed.

As to signs in Equation [13], any assumed independent angular velocity ω_A is indicated plus, whether clockwise or anticlockwise. Then α_A is positive for increase in angular velocity in that direction and negative for a decrease. A positive result for the dependent acceleration α_B indicates an acceleration which is in the direction of rotation of link B, in whatever direction that may be; and a negative result indicates a deceleration with respect to that same direction. The factor $\frac{dr_A}{dt}$ is evaluated positive when r_A is increasing, and $\frac{dr_B}{dt}$ is evaluated positive when r_B is increasing. Decreasing values make these factors negative and they must then be so indicated. Due care should be exercised to retain the negative sign between the first and second terms in addition to the proper signs to be applied to $\frac{dr_A}{dt}$ and

[5] It may be noted that in the case of free bodies, external forces determine the motions and hence the rotopoles; but in a closed, kinematically constrained chain of rigid links, it is only the characters of the pairs connecting the links that determine the relative motions, and which determine the rotopoles. All rotopoles in a kinematically constrained chain of links may always be located at any position assumed at a given instant.

[6] In some linkages these radii r_A and r_B do not change as, for example, in an ordinary gearset wherein ab is the fixed pitch point, fa and bf are the fixed gear centers, and the circles ϕ_A and ϕ_B centered on fa and bf, and tangent at ab, are the pitch circles. Such special cases, as will appear, also respond to the present treatment, and although trivial among the problems in hand, they help to illustrate the universality of the method.

$\frac{dr_B}{dt}$, operating algebraically with these signs in arriving at a solution.

Application of Method to Mechanisms

In any closed kinematically constrained linkage all of the rotopoles are determinable. This includes the three rotopoles of any selected three links. In application the method herein described amounts to determining from a scaled layout of the mechanism in the position desired the numerical substitutions required on the right-hand side of Equation [13]. In any linkage, no matter how complex, the process is only one of choosing as the three links for primary consideration a link A having a known independent angular velocity ω_A and independent angular acceleration α_A (for brevity to be called the independent link); F the reference link, generally the frame of the mechanism; and the link B of which the dependent angular acceleration α_B is desired (for brevity to be called the dependent link). Designate these three links accordingly and find their three rotopoles, thus also determining the instantaneously fixed line k. This is the same procedure often followed in linkage-velocity problems.

From this layout the relative velocities of the three rotopoles along line k will produce $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$. Substitute these along with the values of ω_A, α_A, r_A, and r_B and solve for the desired α_B in Equation [13]. Any additional rotopoles which will facilitate finding the velocities represented by $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$, or which will facilitate velocity determinations, may readily be found and employed in the usual way.

An example will now be worked out, showing how the entire problem of substituting in Equation [13] reduces to an ordinary linkage velocity and dimensional problem. The particular example has been selected to bring out several points of interest in the method.

Example. Consider the quadric link mechanism A, B, C, F, in the position shown in Fig. 2, wherein the independent driving link A in the actual machine is 1.65 in. long and the remaining links are in proportion, link F being the frame of reference with $\alpha_F = 0$. Let the independent angular velocity $\omega_A = 10$ radians per sec, and the independent angular acceleration $\alpha_A = 6$ radians per sec per sec. Required is the dependent angular acceleration of all links in radians per sec per sec. The solution for the link B will first be given.

Lay out the linkage to any scale in the desired position, Fig. 2, and determine in the usual manner the six rotopoles *ab*, *af*, *bf*, *ac*, *bc*, and *fc*.[7] It will be seen at once that factors $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$ (rates of change of r_A and r_B) are in this case the same, both being the velocity along line k of the intersection at rotopole *ab*, rotopoles *af* and *bf* being fixed. Rotopole *ab* is always at the intersection between the fixed line k, and the line (*ab*——*bc*) moving with link C. The velocity of this intersection may readily be found, since line (*ab*——*bc*) is at the instant rotating about rotopole *fc*. Thus to a convenient velocity scale let V_{ac}^1 be the tangential velocity of point $ac = 10 \times 1.65 = 16.5$ ips. Rotate V_{ac}^1 into the radius (*ab*——*fc*), thus obtaining V_{ac}^2. Draw the direct proportioning line ϑ, determining V_{ab}^1 which for the purpose is drawn parallel to V_{ac}^2. Vector V_{ab}^1 represents the instantaneous velocity of *ab*, considered as being on line (*ab*——*bc*) in link C, the velocity being relative to the fixed link F. Draw the vector V_{ab}^2 parallel to line (*ab*——*bc*), which represents the relative movement along line (*ab*——*bc*) of the intersection at *ab*. Thus V_{ab}^k, which equals $V_{ab}^1 + V_{ab}^2$, is the desired velocity of rotopole *ab* on line k, and evaluates $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$. To the same scale that V_{ac}^1 represents 16.5 ips, as just found, V_{ab}^k represents 54.30 ips $= \frac{dr_A}{dt} = \frac{dr_B}{dt}$. To full scale $r_A = 2.87$ in. and $r_B = 7.12$ in. Substituting in Equation [13] the values given for $\frac{dr_A}{dt}$, $\frac{dr_B}{dt}$, r_A, r_B and the assumed values of ω_A and α_A, we obtain

$$\alpha_B = \frac{1}{7.12}\left[(10 \times 54.30) - \left(\frac{10 \times 2.87}{7.12} \times 54.30\right) + (6 \times 2.87)\right]$$

$$= 47.90 \text{ radians per sec per sec}$$

angular acceleration of link B.

This first part of the example illustrates a case wherein both radii r_A and r_B change at the same rate. It also illustrates a ase wherein the line k, as well as being instantaneously fixed,

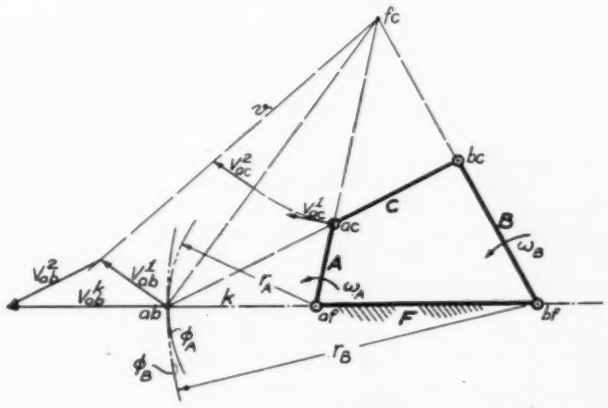

Fig. 2

is also permanent in all possible positions of the mechanism, no inversion being called for.

Next the angular acceleration of the connecting link will be obtained. In Fig. 3, for clarity of explanation, the identical mechanism in Fig. 2 has been redrawn and relettered. The scale has also been changed. If desired, Fig. 2 could have been used except that for the purpose of this paper it is preferred that the symbols of the drawing be changed to accord with those of Equation [13]. It is the object to find α_B, the angular acceleration of the connecting link now lettered B. The angular velocity and acceleration of crank A are the same as in Fig. 2. The rotopoles also are located the same as in Fig. 2, except that they have different symbols in view of the change of link symbols B and C. The rotopoles *af*, *ab*, and *bf* associated with the fixed link F, independent link A, and dependent link B produce a new instantaneously fixed line k between fixed points *f*——*f*.

Radius $r_A = 1.65$ in., full scale, and constant. Therefore in this case $\frac{dr_A}{dt} = 0$. Radius $r_B = 4.12$ in. The factor $\frac{dr_B}{dt}$ is determined by the velocity along moving line (*af*——*ab*) extended, of its intersection at *bf* with moving line (*cf*——*bc*) extended. Vector V_{ab}^1 is the same as was V_{ac}^1 in Fig. 2, namely, $10 \times 1.65 = 16.5$ ips. If the mechanism is inverted, releasing F and holding A, the problem of the movement on line k of the intersection at *bf* is simplified.

Thus the velocity V_p of point p on link F at radius r_A is set up inversely as shown, equal in length to V_{ab}^1. By the proportion line ϑ^1 vector V_{af} is determined on link C. Link C in the inver-

[7] Not all of the rotopoles are always required but all have been shown to facilitate discussion. The method of finding these is not discussed, being well known.

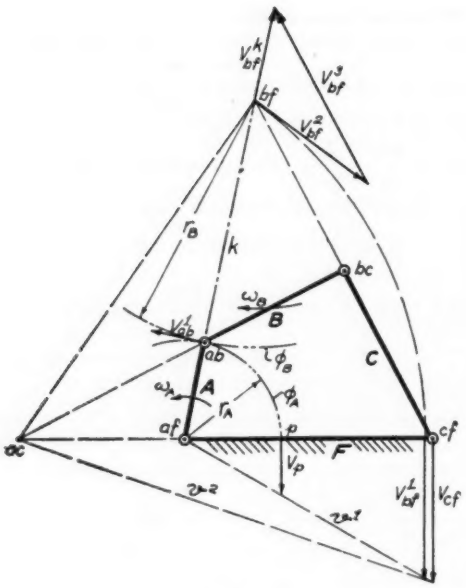

FIG. 3

sion swings about rotopole *ac*. Now *bf* is a point always on line (*cf*——*bc*), extended, and moves with *C*. Its motion with (*cf*——*bc*), extended, may be found by drawing the porportion line ϑ^2 from rotopole *ac* to the end of V_{cf}. Then vector V_{bf}^1 is determined at the radius of point *bf* from point *ac*. Hence, rotate V_{bf}^1, back to point *bf* to determine V_{bf}^2, which is located at 90 deg to (*ac*——*bf*). This vector V_{bf}^2 is, in the inversion, the velocity relative to the frame of a point on link *C* at the intersection *bf*. Vector V_{bf}^3, drawn parallel to line (*cf*——*bc*) represents the relative velocity of the intersection along line (*cf*——*bc*), extended. Remembering that line (*af*——*ab*), extended, is fixed in the inversion V_{bf}^2, + V_{bf}^3, = V_{bf}^k, = $\frac{dr_B}{dt}$. To the same scale that V_{ab}^1 = 16.5 ips, V_{bf}^k, = 28.25 ips = $\frac{dr_B}{dt}$.

Substituting in Equation [13] we obtain

$$\alpha_B = \frac{1}{4.12}\left[0 - \left(\frac{10 \times 1.65}{4.12} \times 28.25\right) + (6 \times 1.65)\right]$$

$$= -25.29 \text{ radians per sec per sec}$$

the negative sign denoting a deceleration.

This second part of the example illustrates a case wherein one radius r_A does not change; and also one wherein the inversion method may be used, although it is to be emphasized that the problem could have been solved without inversion, if preferred.

The advantages of the method increase when applied to more complex mechanisms but lack of space precludes further examples.

CONCLUSION

In regard to the insight into problems afforded by the method, the following points are of interest:

The first and second terms in the brackets in Equation [13] disappear when the independent variable ω_A becomes 0. The independent variable α_A in the third term is then exclusively the independent controlling acceleration factor in a given mechanism at a given position. Under such conditions, the mechanism is starting from rest from the position assumed. The third term disappears when α_A also becomes 0. The mechanism then has no motion and no acceleration in the assumed position.

On the other hand, the first and second terms in the bracket, if not zero, depend on the angular velocity ω_A of link *A*, whatever that may be at the instant. But even with $\omega_A > 0$ either or both of these two terms will disappear when, respectively, either or both factors $\frac{dr_A}{dt}$ or $\frac{dr_B}{dt}$ becomes 0, that is, when r_A or r_B remains constant. This constancy (or lack of it) is determined only by the character of the linkage. A gearset, referred to elsewhere in the paper,[6] is an obvious case in point. In that case these first and second terms both become 0 because r_A and r_B are constant, while the third term may or may not become 0, depending upon whether or not the driving gear is accelerating (note α_A in this third term within the brackets).

The foregoing and other deductions that may be drawn from Equation [13] provide a penetrating attack on all angular-acceleration problems in linkages.

It is interesting to note that if at a given position of a given mechanism operating at a certain instantaneous angular velocity of a link *A*, it would be desired to have zero angular acceleration of a certain link *B*, this could be solved simply by setting the right side of Equation [13] equal to 0 and solving for α_A, all other factors being known. Also, the equating could be done against values $\neq 0$ where the desired angular acceleration α_B of link *B* is to be $\neq 0$. Many other avenues of procedure are opened by the method.

It may be remarked that the angular accelerations obtained are useful in many investigations, for example, in determining turning moments necessary to accelerate the links. Also, once the angular acceleration of a link is known, in addition to its angular velocity and its center of acceleration, the normal, tangential, and total linear acceleration of any point on it is readily available. Thus the tangential acceleration of the point is simply the product of its angular acceleration and its radius from the acceleration center; its normal acceleration is the product of the square of its angular velocity and the same radius; and the total acceleration is the square root of the sum of the squares of the tangential and normal accelerations. Regarding the required factors of angular velocity and center of acceleration, the former is usually quite easy to find, and the latter, although not always easy to locate, is often obvious, for example, in cases of links pinned to the frame (see links *A* and *B* in Fig. 2).

Stresses in Rotating Disks at High Temperatures

By A. STANLEY THOMPSON,[1] LESTER, PA.

A general method was found by which the problem of the rotating disk with any arbitrary profile could be solved, including the effect of plastic flow and of variable temperature, and including the change with temperature of modulus of elasticity, coefficient of thermal expansion, and allowable stress. The solution requires for its application to a specific disk only the elementary arithmetic involved in completion of a tabular form sheet. Two applications of the method are made. For an arbitrary disk profile, an integral equation was found which converges rapidly to the radial stress distribution in a series of successive substitutions. For an arbitrary choice of radial stress, the necessary disk profile can be found in one calculation. Appendix 1 gives an example of the use of the method for the design of a partially plastic disk with a central hole.

Nomenclature

The following nomenclature is used in the paper:

- r, R = independent variables expressing radial distance, in.
- a = radius of bore in disk, in.
- b = radius to rim of disk, in.
- c = radius to junction of elastic and plastic portions of disk, in.
- h, h_R = thickness of disk at radius r, R, in.
- ω = angular speed of rotation, radians per sec
- ρ = mass density of disk material, lb sec^2 per in.^{4}
- σ_r, σ_R = radial stress at radius r, R, psi
- σ_t = tangential stress at radius r, psi
- σ_y = yield strength of disk material at radius r, psi
- E = modulus of elasticity, psi
- T = temperature at radius r, deg F
- α = coefficient of thermal expansion, in. per in. per deg F
- μ = Poisson's ratio
- u = radial deformation, in.
- ϵ_r = radial strain, in. per in.
- ϵ_t = tangential strain, in. per in.

$$S_r = (1 - \mu)\sigma_r + E\alpha T$$

$$f(r) = \int_a^r \frac{hE}{r^{2+\mu}}\,dr \qquad f(R) = \int_a^R \frac{hE}{r^{2+\mu}}\,dr$$

$$g(r, R) = \frac{h}{r} + (1 + \mu)\frac{r^\mu}{E}\{f(r) - f(R)\}$$

$$H_a = \frac{a^{1+\mu}}{E_a}\{\sigma_{t,a} - \sigma_{ra} + S_{ra}\}$$

$$k(r) = \int_a^r \frac{E}{r^{2+\mu}\sigma_r}\,dr \qquad k(R) = \int_a^R \frac{E}{r^{2+\mu}\sigma_r}\,dr$$

$$p(r) = \frac{1}{\sigma_r}\left(\frac{d\sigma_r}{dr} + \rho\omega^2 r\right)$$

$$q(r, R) = \frac{1}{r\sigma_r} + (1 + \mu)\frac{r^\mu}{E}\{k(r) - k(R)\}$$

General

It has been verified that the method described in this paper gives the usual solutions for the parallel-sided rotating plastic disk (1),[2] the parallel-sided rotating elastic disk, with or without a central hole (2), the parallel-sided stationary elastic disk with variable temperature (2), and the uniform-strength rotating elastic disk (3).

The limits to the accuracy attainable are lack of knowledge of material properties, the amount of tabular work done, and inaccuracies in assumptions stated.

Partial or total plasticity of the disk can be calculated. Allowance can be made for stress concentrations and concentrated masses. The equations written apply equally well to solid disks or to disks with holes.

Assumptions. In all calculations for the elastic state, Poisson's ratio has been assumed constant. The actual variation for five different steels is given by Everett and Miklowitz (4). The author of this paper knows of no data for high-temperature materials.

The disks involved are considered thin in the sense that stresses in the axial direction are neglected. Temperature is assumed to vary only linearly with axial distance, and the radial temperature distribution used is that at the axial middle plane of the disk.

For the plastic state, the maximum-shear theory was taken as the criterion for yielding. This is a matter of convenience since the more accurate octahedral-stress theory (5) becomes burdensome in this case. The maximum-shear theory is thought to give a sufficiently good approximation.

All variables involved are considered to be symmetrical about the axis of rotation of the disk.

The stress-strain curve assumed is that shown in Fig. 1 (6). It is assumed that there is no strain-hardening, which should be nearly true for high temperatures.

Mathematical Development

The development of the equations for the rotating disk is divided into three parts, as follows:

1 The equilibrium condition is expressed in a form in which it can be handled numerically.

2 The compatibility condition is written in terms of stresses, instead of strains as is usual, this expression being integrated to give a relationship for tangential stress in terms of radial stress.

3 The compatibility and equilibrium conditions are combined to eliminate σ_t, giving an expression for σ_r in terms of thickness. For the plastic condition, the maximum-shear theory is

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

used instead of the compatibility condition to determine tangential stress.

The Equilibrium Condition

The equilibrium equation for a thin rotating disk of variable thickness is (2)

$$\frac{1}{h}\frac{d(rh\sigma_r)}{dr} - \sigma_t + \rho\omega^2 r^2 = 0 \quad [1]$$

This equation can be expanded by differentiating the product

$$\frac{r}{dr}\sigma_r\frac{dh}{h} - (\sigma_t - \sigma_r) + \left(r\frac{d\sigma_r}{dr} + \rho\omega^2 r^2\right) = 0$$

Solving for thickness

$$\frac{dh}{h} = \left[-\frac{1}{\sigma_r}\left(\frac{d\sigma_r}{dr} + \rho\omega^2 r\right) + \frac{1}{r\sigma_r}(\sigma_t - \sigma_r)\right]dr \quad [2]$$

On integration between the limits $r = a$ and $r = R$, the expression for thickness of the disk becomes

$$\frac{h_R}{h_a} = e^{\varphi(R)} \quad [3]$$

where

$$\varphi(R) = \int_a^R \left[-p(r) + \frac{1}{r\sigma_r}(\sigma_t - \sigma_r)\right]dr$$

$$p(r) = \frac{1}{\sigma_r}\left(\frac{d\sigma_r}{dr} + \rho\omega^2 r\right)$$

For both the solid disk and for the disk with a central hole and no press fit, the denominator of the integrand of $\varphi(R)$ becomes zero where $r = a$. For a usable equation in the vicinity of $r = a$, $\varphi(R)$ must have a finite integrand at $r = a$. By use of Equation [1]

$$\lim_{r\to a}\left[-\frac{1}{\sigma_r}\left(\frac{d\sigma_r}{dr} + \rho\omega^2 r\right) + \frac{1}{r\sigma_r}(\sigma_t - \sigma_r)\right] = \lim_{r\to a}\frac{1}{h}\frac{dh}{dr}$$

This limit is finite for any reasonable disk shape, and Equation [3] is usable for either a solid disk or for a disk with a central hole.

Equation [1] may be solved for tangential stress

$$\sigma_t = \frac{1}{h}\frac{d(rh\sigma_r)}{dr} + \rho\omega^2 r^2 \quad [4a]$$

$$= \frac{r}{h}\frac{d(h\sigma_r)}{dr} + \sigma_r + \rho\omega^2 r^2 \quad [4b]$$

$$= r\frac{d\sigma_r}{dr} + \left(\frac{r}{h}\frac{dh}{dr} + 1\right)\sigma_r + \rho\omega^2 r^2 \quad [4c]$$

Equation [4] may be solved for radial stress

$$\sigma_R = \frac{1}{h_R R}\left[\int_a^R h(\sigma_t - \rho\omega^2 r^2)dr + ah_a\sigma_{ra}\right] \quad [5a]$$

$$= \frac{1}{h_R}\left[\int_a^R \left\{\frac{h}{r}(\sigma_t - \sigma_r) - \rho\omega^2 rh\right\}dr + h_a\sigma_{ra}\right] \quad [5b]$$

$$= \int_a^R \frac{1}{r}\left\{\sigma_t - \sigma_r\left(1 + \frac{r}{h}\frac{dh}{dr}\right)\right\}dr - \left[\frac{\rho\omega^2 r^2}{2}\right]_a^R + \sigma_{ra} \quad [5c]$$

As will be seen later, the form of Equation [5a] is useful for the plastic case, since σ_r does not appear on the right side. Equation [5b] is the most useful for finding the stress distribution in an arbitrary elastic disk, since the form of Equation [5a] causes it to converge very slowly for small values of R, and since Equation [5c] has a more complicated form, and a derivative under the integral sign.

Compatibility Condition for Elastic Disk

For a two-dimensional stress distribution symmetrical about an axis, the radial and tangential strains are related to the radial deformation by the expressions

$$\epsilon_r = \frac{du}{dr} \quad [6]$$

$$\epsilon_t = \frac{u}{r} \quad [7]$$

Eliminating u from Equations [6] and [7] gives the compatibility equation in terms of strains

$$\epsilon_r - \frac{d}{dr}(r\epsilon_t) = 0 \quad [8]$$

From Hooke's law for the elastic case

$$\epsilon_r = \frac{1}{E}(\sigma_r - \mu\sigma_t) + \alpha T \quad [9]$$

$$\epsilon_t = \frac{1}{E}(\sigma_t - \mu\sigma_r) + \alpha T \quad [10]$$

Combining Equations [8], [9], and [10] gives the compatibility equation in terms of stresses

$$\frac{\sigma_r - \mu\sigma_t + E\alpha T}{E} - \frac{d}{dr}\left\{\frac{r(\sigma_t - \mu\sigma_r + E\alpha T)}{E}\right\} = 0 \quad [11]$$

Equation [11] can be rewritten

$$-\mu\left\{\frac{\sigma_t - \sigma_r + S_r}{E}\right\} - \frac{d}{dr}\left\{\frac{r(\sigma_t - \sigma_r + S_r)}{E}\right\} + (1 + \mu)\frac{S_r}{E} = 0 \quad [12]$$

where

$$S_r = (1 - \mu)\sigma_r + E\alpha T$$

Multiplying through by r^μ

$$\frac{d}{dr}\left\{\frac{r^{1+\mu}(\sigma_t - \sigma_r + S_r)}{E}\right\} - \frac{(1 + \mu)r^\mu S_r}{E} = 0 \quad [13]$$

Integrating this expression from $r = a$ to $r = r$, and solving for σ_t

$$\sigma_t = \sigma_r - S_r + \frac{E}{r^{1+\mu}}\left[(1 + \mu)\int_a^r \frac{r^\mu S_r}{E}dr + H_a\right] \quad [14]$$

where

$$H_a = \frac{a^{1+\mu}}{E_a}\{\sigma_{ta} - \sigma_{ra} + S_{ra}\}$$

For the solid disk, $a = 0$, and it becomes necessary to evaluate the indeterminate quantity

$$\lim_{r\to 0}\frac{E}{r^{1+\mu}}\left[(1 + \mu)\int_0^r \frac{r^\mu S_r}{E}dr + H_a\right]$$

$$= \lim_{r\to 0}\frac{E}{r^\mu}\left[\frac{r^\mu}{E}S_r\right] = S_{r0}$$

This evaluation of the indeterminate quantity gives $\sigma_{r0} = \sigma_{t0}$ for the solid disk as would be expected.

Equations for Elastic Disk

Equations [3], [4], and [5] are expressions of the equilibrium condition for the rotating thin disk. Equation [14] is an expression of the compatibility condition in terms of stress. These equations can be combined to find the stress in an arbitrary disk profile, or to find the profile necessary for a required stress distribution.

Substitution of Equation [14] into Equation [5b] gives an integral equation for radial stress in terms of thickness.

$$\sigma_R = \frac{1}{h_R}\left[\int_a^R \left\{\frac{h}{r}\left(-S_r + \frac{E}{r^{1+\mu}}\left[(1+\mu)\int_a^r \frac{r^\mu S_r}{E}dr + H_a\right]\right) - \rho\omega^2 rh\right\} dr + h_a\sigma_{ra}\right] \quad [15]$$

Partial integration of the repeated integral in Equation [15] gives (Appendix 2)

$$(1+\mu)\int_a^R \frac{hEdr}{r^{2+\mu}}\int_a^r \frac{r^\mu S_r dr}{E} \quad [16]$$

$$= -(1+\mu)\int_a^R \left\{f(r) - f(R)\right\}\frac{r^\mu S_r}{E}dr$$

where

$$f(r) = \int_a^r \frac{hE}{r^{2+\mu}}dr \qquad f(R) = \int_a^R \frac{hE}{r^{2+\mu}}dr$$

Substitution of Equation [16] into Equation [15] gives

$$\sigma_R = \frac{1}{h_R}\left[-\int_a^R g(r,R)S_r dr - \int_a^R \rho\omega^2 rh dr + H_a f(R) + h_a\sigma_{ra}\right] \quad [17]$$

where

$$g(r,R) = \frac{h}{r} + (1+\mu)\frac{r^\mu}{E}\left\{f(r) - f(R)\right\}$$

Equation [17] is an integral equation for the radial stress in terms of an assumed thickness and known variables of temperature, modulus of elasticity, and thermal coefficient of expansion.

Substitution of Equation [14] into Equation [3] gives an expression for thickness in terms of radial stress in the disk.

$$\varphi(R) = \int_a^R\left[-p(r) + \frac{1}{r\sigma_r}\left(-S_r + \frac{E}{r^{1+\mu}}\left[(1+\mu)\int_a^r \frac{r^\mu S_r}{E}dr + H_a\right]\right)\right]dr \quad [18]$$

On performance of partial integration of the repeated integral (Appendix 2)

$$\varphi(R) = -\int_a^R\left[p(r) + \frac{S_r}{r\sigma_r} + (1+\mu)\left\{\int_a^r \frac{Edr}{r^{2+\mu}\sigma_r} - \int_a^R \frac{Edr}{r^{2+\mu}\sigma_r}\right\}\frac{r^\mu S_r}{E} - \frac{H_a E}{r^{2+\mu}\sigma_r}\right]dr \quad [19]$$

$$= -\int_a^R [p(r) + q(r,R)S_r]dr + H_a k(R) \quad [20]$$

where

$$k(r) = \int_a^r \frac{Edr}{r^{2+\mu}\sigma_r} \qquad k(R) = \int_a^R \frac{Edr}{r^{2+\mu}\sigma_r}$$

$$q(r,R) = \frac{1}{r\sigma_r} + (1+\mu)\frac{r^\mu}{E}\left\{k(r) - k(R)\right\}$$

Substitution of Equation [20] into Equation [3] gives for thickness

$$\frac{h_R}{h_a} = e^{-\int_a^R [p(r) + q(r,R)S_r]dr + H_a k(R)} \quad [21]$$

Evaluation for the solid disk of the terms in Equations [17] and [21] can be done by taking limits as the radius approaches zero. However, since the curves for both radial and tangential stress have stationary values at the center of the disk, the numerical work can be simplified by assuming that the disk has a region, $0 < r < a$ (where a is a small dimension compared with the radius to the rim of the disk), in which $\sigma_R = \sigma_r = \sigma_t = \sigma_{ra} = \sigma_{ta}$. The procedure for the solid disk, aside from the assumption of constant stress for $r < a$, is identical with that for the disk with a hole of radius a.

By solving Equation [17] for the tangential stress at the edge of a small hole of radius a, and at radius a on a solid disk, it can be found that the ratio of these stresses as $a \to 0$ is

$$\lim_{a\to 0}\frac{\sigma_{ta}}{\sigma_{ra}} = (1-\mu) + h_a E_a \lim_{a\to 0}\frac{a^{-(1+\mu)}}{\int_a^b \frac{hE}{r^{2+\mu}}dr} = (1-\mu) + \frac{(1+\mu)a^{-(2+\mu)}h_a E_a}{h_a E_a a^{-(2+\mu)}} = 2$$

This ratio is in agreement with theory.

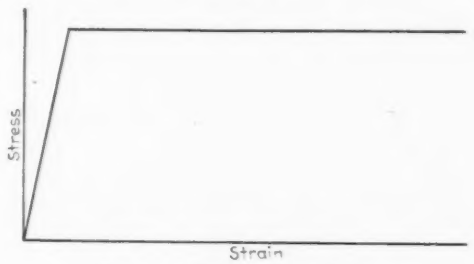

Fig. 1 Stress-Strain Curve

Equation for Plastic Disk

Over any portion of a disk in which the stresses are elastic, it is necessary to find a solution for the distribution of radial and tangential stresses satisfying both the equilibrium and compatibility conditions. It is reasonable to expect that this is true for the plastic case also. However, on the assumption of a stress-strain curve such as is shown in Fig. 1, where the modulus of elasticity is zero in the plastic range, the compatibility condition is satisfied automatically. This assumes that there is no strain-hardening, which seems reasonable for disks operating at high temperatures. Only the equilibrium condition need be fulfilled by the stress solution in the plastic region.

According to the maximum-shear theory, plastic flow occurs when the maximum shearing stress, determined as one half the difference in the maximum and minimum principal stresses, passes a certain value. In our case σ_t, σ_r, and σ_s are principal stresses, of which $\sigma_s = 0$ and σ_t is generally the maximum. We can write for the maximum shearing stress

$$\tau = \frac{\sigma_t - \sigma_s}{2} = \frac{\sigma_t}{2}$$

We can write for the tangential stress in the plastic portion of the

disk, assuming the yielding will occur when the maximum shearing stress is one half the tensile yield strength of the material

$$\sigma_t = \sigma_y \quad \ldots\ldots [22]$$

where σ_y is the yield stress of the disk material in tension.

From Equations [22] and [5a], the radial stress in the plastic range is

$$\sigma_R = \frac{1}{h_R R}\left[\int_a^R h(\sigma_y - \rho\omega^2 r^3)dr + a h_a \sigma_{ra}\right] \quad \ldots\ldots [23]$$

From Equations [22] and [23] it can be seen that, for a disk which is plastic in the center, σ_t will generally be larger than σ_r in the plastic region, and hence will be the largest principal stress. The only effect of variable temperature on the stress in the plastic region will be to change the yield point. At the outside of the disk where $\sigma_t < 0$, the criterion for yielding becomes

$$\tau = \frac{\sigma_r - \sigma_t}{2}$$

Substitution of Equation [22] into Equation [3] gives an expression for the thickness form necessary to maintain a given radial stress in a disk operating under conditions of plastic flow

$$\left.\begin{aligned} \varphi(R) &= \int_a^R \left[-p(r) + \frac{1}{r\sigma_r}(\sigma_y - \sigma_r)\right] dr \\ \frac{h_R}{h_a} &= e^{\varphi(R)} \end{aligned}\right\} \quad \ldots\ldots [24]$$

Equations for Partially Plastic Disk

In order to use the same tabular work for the elastic and the partially plastic disk, Equation [17] can be written

$$\sigma_R = \frac{1}{h_R}\left[-\int_a^R g^*(r, R)S_r dr + \int_a^c g^*(r, R)S_r dr - \int_a^R \rho\omega^2 r h dr + \int_a^c \rho\omega^2 r h dr + H_c f^*(R) + h_c\sigma_{rc}\right] \quad \ldots\ldots [25]$$

where

$$f^*(R) = \int_c^R \frac{hE dr}{r^{2+\mu}} = f(R) - f(c)$$

$$f^*(r) = \int_c^r \frac{hE dr}{r^{2+\mu}} = f(r) - f(c)$$

$$g^*(r, R) = \frac{h}{r} + (1+\mu)\frac{r^\mu}{E}\{f^*(r) - f^*(R)\} = g(r, R)$$

The radial stress in the elastic portion of the disk is then

$$\sigma_R = \frac{1}{h_R}\left[-\int_a^R g(r, R)S_r dr + \int_a^c g(r, R)S_r dr - \int_a^R \rho\omega^2 r h dr + H_c\{f(R) - f(c)\} + h_c\sigma_{rc}\right] \quad \ldots\ldots [26]$$

The tangential stress in the elastic portion of the disk is then

$$\sigma_t = \sigma_r - S_r + \frac{E}{r^{1+\mu}}\left[(1+\mu)\left\{\int_a^r \frac{r^\mu S_r}{E} dr - \int_a^c \frac{r^\mu S_r}{E} dr\right\} + H_c\right] \quad \ldots\ldots [27]$$

Acknowledgment

The author wishes to express his appreciation to Dr. A. Nadai, Research Laboratory, Westinghouse Electric Corporation, for criticisms and suggestions, and to Mr. J. A. Perna of the Aviation Gas Turbine Division of Westinghouse Electric Corporation, for testing the adequacy of the method.

Appendix 1

Example. This example presents the design of a disk to operate under the following conditions:

N = 12,000 rpm
σ_{rb} = 13,000 psi
a = 0.75 in.
b = 6.00 in.
h_b = 1.314 in.

The temperature, modulus of elasticity, coefficient of thermal expansion, and thickness are tabulated against radial distance in Table 1, which shows the complete tabular form for those calculations which are independent of the assumption for radial stress. Table 2 shows the tabular form for those calculations, for the elastic and the partially plastic disk, which are dependent on the assumption for radial stress. Table 3 shows the calculations for the totally plastic disk. Fig. 2 shows the disk shape and the radial and tangential stresses that resulted for the elastic, partially plastic, and plastic conditions. Residual tangential stresses are shown also (difference between elastic and partially plastic stresses).

The following figures for the partially plastic disk illustrate the evaluation of boundary constants. From Equation [26]

$$\sigma_{Rb} = \frac{1}{h_b}\left[-\int_a^b g(r, R)S_r dr + \int_a^c g(r, R)S_r dr - \int_a^b \rho\omega^2 r h dr + \int_a^c \rho\omega^2 r h dr + H_c\{f(b) - f(c)\} + h_c\sigma_{rc}\right]$$

From the table for the partially plastic disk

$$13{,}000 = -235{,}000 - 22{,}000 + 0 + 10^6 H\left\{\frac{43.80 - 13.29}{1.314}\right\} + \frac{1.5 \times \sigma_{rc}}{1.314}$$

$$23.2 \times 10^6 H + 1.141\sigma_{rc} = 270{,}000$$

$$23.2 \times 10^6 H = \frac{23.2 \times 10^6}{E_c}(\sigma_{tc} - \sigma_{rc} + S_c) = 0.957\sigma_{tc} - 0.290\sigma_{rc} + 184{,}300$$

$$0.957\sigma_{tc} + 0.851\,\sigma_{rc} = 270{,}000 - 184{,}000 = 86{,}000 \ldots [a]$$

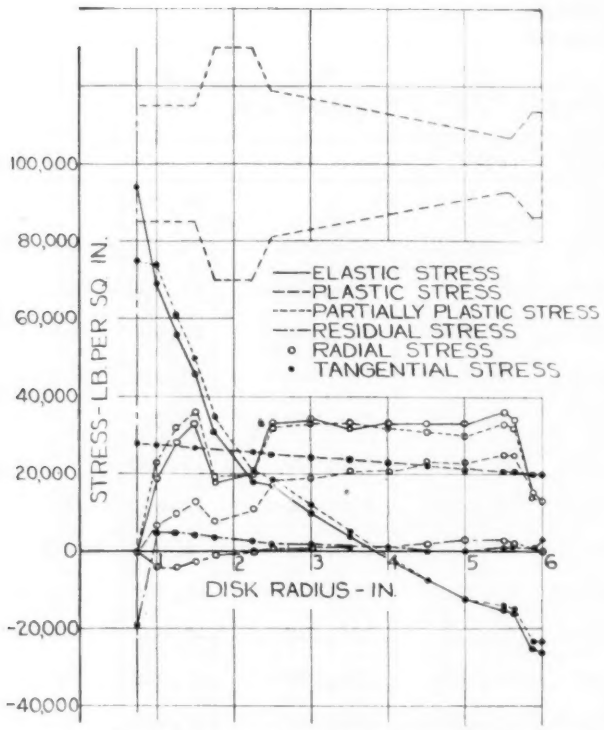

FIG. 2 DISK SHAPE AND RADIAL AND TANGENTIAL STRESSES

From the solution for the plastic disk

$$\sigma_{re} = 0.249\,\sigma_{ta} = 0.249 \times \frac{75}{74}\,\sigma_{t_c} = 0.253\sigma_{te} \ldots\ldots [b]$$

Combining Equations [a] and [b]

$$\sigma_{te} = \frac{86{,}000}{1.169} = 73{,}600$$

$$\sigma_{re} = 18{,}400$$

$$10^6 H = 10{,}800$$

In the numerical work for this example, the increment for integration of a function $F(r)$ was taken as

$$\frac{F(r) + F(r + \Delta r)}{2}\,\Delta r$$

This causes an appreciable error in $f(r)$ (column 10, Table 1), since column 9 has considerable curvature and slope for small values of r. For a closer evaluation of $f(r)$ and of σ_r, smaller increments of r or a more accurate averaging process should be used for small values of r.

Appendix 2

PARTIAL INTEGRATION OF REPEATED INTEGRAL

In the repeated integral

$$\int_a^R F(r)dr \int_a^r G(r)dr$$

let

$$F(r)dr = dv \qquad v = \int_a^r F(r)dr$$

$$\int_a^r G(r)dr = u \qquad du = G(r)dr$$

then

$$\int_a^R udv = \Big[uv\Big]_a^R - \int_a^R vdu$$

and substituting values for u, v, du, dv

$$\int_a^R F(r)dr \int_a^r G(r)dr$$

$$= \left[\int^r G(r)dr \int_a^r F(r)dr\right]_a^R - \int_a^R \left(\int_a^r F(r)dr\right) G(r)dr$$

$$= \int_a^R \left(\int_a^R F(r)dr - \int_a^r F(r)dr\right) G(r)dr$$

Nonlinear Theory of Elasticity With Small Deformations

By E. STERNBERG,[1] CHICAGO, ILL.

Previous investigations of nonlinear theory of elasticity have been concerned largely with the problem of finite deformations. In this paper the assumption of "infinitesimal" deformations is retained whereas Hooke's law is replaced by a general second-order approximation of nonlinear stress-strain laws. Applications to uniaxial tension and compression as well as torsion of right circular cylinders are considered in detail. The results obtained indicate second-order effects which were previously unnoticed because of the early linearization of the extended stress-strain relations.

Nomenclature

The following nomenclature is used in the paper:

W = strain-energy density (strain-energy function, elastic potential)
G = modulus of rigidity of classical theory
ν = Poisson's ratio of classical theory
E = modulus of elasticity of classical theory
$A' = G\frac{1-\nu}{1-2\nu}$, $B' = -2G$ = elastic parameters of classical theory
A, B, C, and $a = \frac{A}{G}$, $b = \frac{B}{G}$, $c = \frac{C}{G}$ = additional elastic parameters of nonlinear theory
$\epsilon_x, \epsilon_y, \epsilon_z; \gamma_{xy}, \gamma_{yz}, \gamma_{zx}$ = components of strain in Cartesian co-ordinates
r, θ, z = cylindrical co-ordinates
u, v, w = radial, transverse, and axial components of displacement in cylindrical co-ordinates
$\epsilon_r, \epsilon_\theta, \epsilon_z; \gamma_{r\theta}, \gamma_{\theta z}, \gamma_{zr}$ = components of strain in cylindrical co-ordinates
$\sigma_r, \sigma_\theta, \sigma_z; \tau_{r\theta}, \tau_{\theta z}, \tau_{zr}$ = components of stress in cylindrical co-ordinates
$\epsilon_1, \epsilon_2, \epsilon_3$ and $\sigma_1, \sigma_2, \sigma_3$ = principal strains and principal stresses
J_1, J_2, J_3 = invariants of strain tensor
ϵ, ρ = axial and transverse components of strain, respectively, in the uniaxial state of stress
$\sigma, s = \frac{\sigma}{G}$ = axial normal stress in the uniaxial state of stress
R, l = radius and length, respectively, of right circular cylinder
$I_0 = \frac{\pi R^4}{4}$ = polar moment of inertia of cross section
K = unit angle of twist
KR = characteristic angle of twist
M = resultant torque in torsion problem
P = resultant axial force in torsion problem

Introduction

The classical theory of elasticity involves two major approximations, i.e., the assumption of "infinitesimal deformations," and the linearization of the stress-strain relations. According to the first assumption, the space derivatives of the components of the displacement vector are considered small throughout the continuum so that the squares and products of these quantities may be neglected. The second assumption is pronounced in the form of Hooke's law. As a consequence of the foregoing approximations, the homogeneous system of basic equations of the classical theory is linear and thus admits the superposition of solutions.

Both hypotheses have been found useful for a wide variety of problems and elastic media. However, throughout the development of the theory of elasticity, problems have been encountered to which the linearization of the strain-displacement relations is not applicable. Hooke's law, in turn, though adequately representative of the behavior of most elastic materials under small strains, is subject to similar limitations. As is well known, there are solids which obey the linear stress-strain law only for a very limited range of strain, or which fail to do so altogether; for example, cast iron, numerous minerals, cement, and concrete. For the reasons mentioned, various generalizations of the classical theory have long been suggested. Among the more recent contributions, those of F. D. Murnaghan and M. A. Biot must be mentioned especially.

Most of the literature on nonlinear elasticity is primarily concerned with the treatment of finite deformations. In the present discussion the assumption of infinitesimal deformations is retained, whereas Hooke's law is extended to a general second-order approximation of nonlinear stress-strain relations for the homogeneous, isotropic medium. This extension is based on a generalization of the elastic potential, first introduced by W. Voigt.[2] There results a five-parameter theory of elasticity which contains the classical theory as a limiting case. This paper includes applications to uniaxial tension and compression of cylinders, and to torsion of right circular cylinders. Particular emphasis is placed on the interpretation of the solutions given. The approach used here differs from that of Voigt as the partial linearization of the newly gained law of elasticity is abandoned. In this way there appear important second-order effects previously unnoticed.

Extension of Elastic Potential and Generalization of Hooke's Law

The mathematical formulation of the concept of elasticity is based on the principle of conservation of energy. From the viewpoint of the energy-conservation laws of thermodynamics the ideal elastic behavior of a medium in the isothermal or adia-

batic state, under the influence of surface and body forces, necessitates the existence of a strain-energy function.[3] This strain-energy function, here denoted by W, in the case of a homogeneous medium is independent of the position vector and is assumed to depend exclusively on the components of the strain tensor and the temperature. Since the following discussion will be confined to isothermal conditions, any reference to the temperature may be omitted and $W = W(\epsilon_x, \ldots \gamma_{xy}, \ldots)$.

The principle of virtual displacements, under the supposition of infinitesimal deformations, yields the components of stress as partial derivatives of W with respect to the corresponding components of strain

$$\sigma_x = \frac{\partial W}{\partial \epsilon_x}, \ldots \tau_{xy} = \frac{\partial W}{\partial \gamma_{xy}} \ldots\ldots\ldots\ldots\ldots [1]$$

If the medium is isotropic, the elastic potential W must be invariant under orthogonal transformations of the co-ordinate system therefore depending solely on the invariants of the strain tensor; thus

$$W = W(J_1, J_2, J_3)$$

where

$$J_1 = \epsilon_x + \epsilon_y + \epsilon_z$$

$$J_2 = \epsilon_x\epsilon_y + \epsilon_y\epsilon_z + \epsilon_z\epsilon_x - {}^1/_4(\gamma^2_{xy} + \gamma^2_{yz} + \gamma^2_{zx}) \ldots [2]$$

$$J_3 = \begin{vmatrix} \epsilon_x & {}^1/_2\gamma_{xy} & {}^1/_2\gamma_{xz} \\ {}^1/_2\gamma_{yx} & \epsilon_y & {}^1/_2\gamma_{yz} \\ {}^1/_2\gamma_{zx} & {}^1/_2\gamma_{zy} & \epsilon_z \end{vmatrix}$$

Once $W = W(J_1, J_2, J_3)$ is known, the stress-strain relations are generated by Equation [1]. Hypotheses as to the specific form of the strain-energy function must derive their ultimate justification from experiment. Assuming W to be an analytic function of the invariants of strain, the elastic potential is represented by the power series

$$W = A'J_1^2 + B'J_2 + AJ_1^3 + BJ_1J_2 + CJ_3 + \ldots\ldots [3]$$

where the coefficients A', B', A, B, C, etc., are parameters depending on the elastic properties of the medium. The omission of the constant term from the series [3] merely indicates the choice of the arbitrary zero level of W at the origin. The absence of the term linear in the components of strain, that is, involving J_1 alone, conforms to the conventional agreement that all components of stress vanish in the unstrained state.

In the classical theory, where Hooke's law is valid, the linear stress-strain relations are obtained as a first-order approximation by neglecting in the expansion for W, all terms of degree higher than two in ϵ_x, ϵ_y, etc. The elastic potential then appears as the homogeneous, quadratic form in the components of strain, $W = A'J_1^2 + B'J_2$. Thus the third-degree invariant J_3 does not enter W at all. The coefficients A' and B' are usually expressed in terms of Poisson's ratio ν, and the modulus of rigidity G

$$A' = G\frac{1-\nu}{1-2\nu}, \quad B' = -2G \ldots\ldots\ldots\ldots [4]$$

If terms of higher degree are retained in the expansion for W, Equation [1] leads to a multiple constant nonlinear law of elasticity. Such an extension of the elastic potential is compatible with the assumption of infinitesimal deformations because of the influence of the new elastic constants. Moreover, it is warranted only if the experimentally determined coefficients of the higher powers of ϵ_x, ϵ_y, ... in the stress-strain relations, that is, the new elastic constants, are large compared to the geometric coefficients of the nonlinear terms in the exact strain-displacement relations.

In the present treatment, as in Voigt's paper,[2] all terms of W up to the third degree in ϵ_x, ϵ_y, ... are taken into account. The number of independent elastic parameters is thus extended to five. The corresponding stress-strain relations represent the most general second-order law of elasticity consistent with the assumptions made. According to Equations [1], [2], [3], and [4], these stress-strain relations are

$$\left.\begin{aligned} \sigma_x &= 2G\left[\epsilon_x + \frac{\nu}{1-2\nu}(\epsilon_x + \epsilon_y + \epsilon_z)\right] + 3A(\epsilon_x + \epsilon_y \\ &\quad + \epsilon_z)^2 + B[\epsilon_y^2 + \epsilon_z^2 + 2\epsilon_x\epsilon_y + 3\epsilon_y\epsilon_z + 2\epsilon_z\epsilon_x - \frac{1}{4}(\gamma_{xy}^2 \\ &\quad + \gamma_{yz}^2 + \gamma_{zx}^2)] + C\left(\epsilon_y\epsilon_z - \frac{1}{4}\gamma_{yz}^2\right) \\ \sigma_y &= \ldots, \sigma_z = \ldots \\ \tau_{xy} &= G\gamma_{xy} - \frac{1}{2}B(\epsilon_x + \epsilon_y + \epsilon_z)\gamma_{xy} - \frac{1}{4}C(2\epsilon_z\gamma_{xy} \\ &\quad - \gamma_{yz}\gamma_{zx}) \\ \tau_{yz} &= \ldots, \tau_{zx} = \ldots \end{aligned}\right\} \ldots [5]$$

The requirement of stable equilibrium of the medium in the unstrained state, in the classical theory, imposes the inequalities

$$G > 0, \quad -1 < \nu < \frac{1}{2} \ldots\ldots\ldots\ldots [6]$$

which are necessary and sufficient for the positive definite character of the quadratic form which represents the elastic potential in that case. Clearly, the foregoing inequalities remain necessary and sufficient for the positive definite character of the generalized W in a neighborhood of the origin. The new parameters A, B, and C, however, are not subject to any deductive limitations and in the absence of adequate experimental information, the discussion must proceed on the basis that these constants may assume any set of real values.

Both the equations of equilibrium in terms of stresses, and the equations of compatibility in terms of strains, are unaffected by the generalization of Hooke's law just given. An attempt to write these two systems of equations in terms of displacements and stresses, respectively, necessitates the solution of the stress-strain relations for the components of strain. This leads to highly inconvenient forms.

Because of this difficulty, the semi-inverse approach, i.e., starting with displacements, will in general be advantageous. The procedure may be outlined as follows: Guided by the corresponding classical solution, an appropriate system of displacements is assumed and the components of strain are computed. The components of stress then follow from Equations [5]. These are introduced into the equations of equilibrium which are subject to the boundary conditions of the problem. One thus arrives, generally, at three nonlinear differential equations, the solution of which may require methods of approximation. Such approximations will be based on the known classical solution in whose neighborhood the desired solution is bound to remain.

Uniform Tension and Compression of Cylinders

The object of studying the uniaxial state of stress is to examine the nature of the deviations from Hooke's law to which the present generalization is adaptable. This application should, furthermore, indicate the physical significance of the elastic constants.

[3] See, for example, "A Treatise on the Mathematical Theory of Elasticity," by A. E. H. Love, fourth edition, Cambridge, 1934, chapt. 3.

Referring the state of stress to its principal axes, let

$$\frac{\sigma_1}{G} = s, \sigma_2 = \sigma_3 = 0, \epsilon_1 = \epsilon, \epsilon_2 = \epsilon_3 = \rho$$

where s is the dimensionless axial normal stress, ϵ the corresponding component of strain, and ρ the transverse component of strain. With

$$a = \frac{A}{G}, \quad b = \frac{B}{G}, \quad c = \frac{C}{G}$$

Equations [5] now yield

$$(3a + b)\epsilon^2 + (12a + 5b + c)\epsilon\rho + (12a + 3b)\rho^2 + \frac{2\nu}{1 - 2\nu}\epsilon + \frac{2}{1 - 2\nu}\rho = 0 \ldots [7]$$

$$s = 2\epsilon + \frac{2\nu}{1 - 2\nu}(\epsilon + 2\rho) + 3a(\epsilon + 2\rho)^2 + b(4\epsilon\rho + 5\rho^2) + c\rho^2 \ldots [8]$$

Equation [7] relates the axial and the transverse components of stress and will be called Poisson's equation. The relation $\rho = \rho(\epsilon;\ \nu, a, b, c)$ represents a four-parameter family of conics, each member of which passes through the origin. For $a = b = c = 0$, Poisson's equation reduces to the classical straight line $\rho = -\nu\epsilon$, which is tangential to the family at $(\epsilon = 0, \rho = 0)$. The meaning of ν is now given by $\nu = \left.\frac{d\rho}{d\epsilon}\right|_{\epsilon=0}$. The Poisson curve is a hyperbola, parabola, or ellipse, according as the discriminant

$$13b^2 + c^2 + 36ab + 10bc + 24ac \gtrless 0$$

Elimination of ρ between Equations [7] and [8] leads to the stress-strain relation for the case of uniaxial tension or compression. In general, $s = s(\epsilon)$ is irrational. The family of stress-strain curves $s = s(\epsilon;\ \nu, a, b, c)$ passes through $(\epsilon = 0, s = 0)$, and at that point is tangential to the classical member $s = \frac{E}{G}\epsilon$. Here E is the modulus of elasticity of the linear theory, so that $E = 2G(1 + \nu)$. The new meaning of E is apparent from $E = \left.\frac{d\sigma}{\epsilon d}\right|_{\epsilon=0}$. Both $\rho = \rho(\epsilon)$ and $s = s(\epsilon)$ are, in general, double-valued. However, but one of the branches of the corresponding curves conforms to $\rho_{(\epsilon=0)} = 0$ and $s_{(\epsilon=0)} = 0$ and is thus physically significant. Furthermore

$$\rho(\epsilon;\ \nu, a, b, c) = -\rho(-\epsilon;\ \nu, -a, -b, -c)$$

$$s(\epsilon;\ \nu, a, b, c) = -s(-\epsilon;\ \nu, -a, -b, -c)$$

Hence, a reversal in sign of the new elastic constants gives rise to a reflection with respect to both co-ordinate axes of the Poisson curve as well as of the stress-strain curve.

An exhaustive treatment of the two four-parameter families of curves under consideration is cumbersome and serves no particular advantage from the viewpoint of the present discussion. Figs. 1 to 6, inclusive, show examples of Poisson curves and stress-strain curves for the hyperbolic, the parabolic, and the elliptic case referred to. It should be kept in mind that the values of ν, a, b, and c used in these and subsequent examples are purely arbitrary and were chosen with a view to illustration only.

The nature and magnitudes of the deviations from the classical straight lines depend on the new parameters a, b, and c which largely determine the slopes and curvatures of the curves in question. The corresponding influence of ν is of a higher order, since the variation of ν is known to be relatively insignificant. The dependence of the ratio of lateral and axial strains on ϵ is in agreement with results of tests performed on materials which do

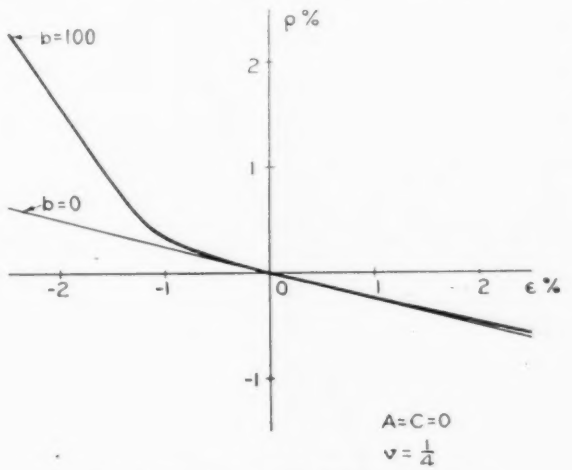

FIG. 1 POISSON CURVE, HYPERBOLIC CASE

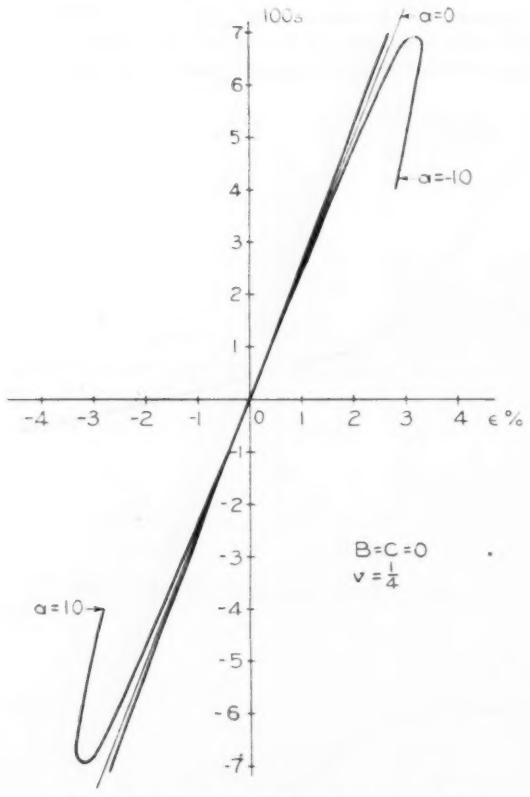

FIG. 4 STRESS-STRAIN CURVES, PARABOLIC CASE

not obey Hooke's law.[4] As a consequence of the second-order law of elasticity, $\rho(\epsilon)$ and $s(\epsilon)$ are no longer odd functions, which implies a behavior in tension different from that in compression.

It seems important that the extended elastic potential, in contrast to the classical approach, leads to a natural breakdown of the theory beyond a critical range of strain. In this connection Figs. 3 to 6, inclusive, are particularly instructive. Here both $\rho(\epsilon)$ and $s(\epsilon)$ are real only for a finite interval of ϵ, and stresses maintained at the levels corresponding to ϵ_{max} or ϵ_{min} would have to be interpreted as conditions of failure. For the homogeneous, uniaxial state of stress, $\sigma_{(\epsilon)} = \dfrac{dW_{(\epsilon)}}{d\epsilon}$. Hence the relative extrema and the zeros of $s(\epsilon)$ correspond to inflection points and relative extrema of $W(\epsilon)$, respectively. Clearly, values of ϵ which imply $W < 0$ are again physically insignificant, and the equilibrium consistent with $W = W_{max}$ is unstable (see, for example, Fig. 2).

It is seen that the generalized elastic potential affords a characterization of the phenomenon of yielding and lends itself to a representation of the transition to the plastic range.[5] This characterization is, however, purely descriptive in nature; an explanation of the phenomenon mentioned cannot be sought in the approach presented here.

TORSION OF CIRCULAR CYLINDERS

(a) *Differential Equations and Boundary Conditions of Problem.* Saint Venant torsion of circular cylinders has been treated in various ways under hypothesis of finite deformations.[6] Seth[5] furthermore draws attention to the added importance of determining higher-order effects arising in this problem because of their influence on the thermal and electrical conductivity of twisted wires. The treatment given by Voigt, on the basis of infinitesimal deformations and of the partially linearized second-order stress-strain law, leads to results which deviate essentially from those arrived at here.

Let R and l denote the radius and the length, respectively, of the right circular cylinder. Let (r, θ, z) be cylindrical co-ordinates with the origin at the center of the base circle and the z-axis coincident with the geometric axis of the cylinder. Let (u, v, w), $(\epsilon_r, \ldots \gamma_{r\theta}, \ldots)$, and $(\sigma_r, \ldots \tau_{r\theta}, \ldots)$ denote the corresponding components of displacement, strain, and stress, respectively.

Guided by the classical solution of the torsion problem as well as by considerations of symmetry, the displacement field is assumed as

$$u = u_{(r)},\ v = g_{(r)}z,\ w = \alpha z \ldots\ldots\ldots\ldots\ldots [9]$$

[4] Über das elastische Verhalten von Beton mit besondered Berücksichtigung der Querdehnungszahl, by H. Yoshida, J. Springer, Berlin, Germany, 1930.

[5] Qualitatively similar results have been obtained on the basis of finite deformations; see F. D. Murnaghan,[2] and "Finite Strain in Elastic Problems," by B. R. Seth, *Philosophical Transactions of the Royal Society of London*, series A, vol. 234, 1934–1935, pp. 231–264.

Kappus, *Zeitschrift fur angewandte Mathematik und Mechanik*, vol. 19, 1939, pp. 271–285, and 344–361; also, "Elastizitätstheorie zweiter Ordnung mit Anwendungen," by M. A. Biot, *Zeitschrift fur angewandte Mathematik und Mechanik*, vol. 20, 1940, pp. 89–99; B. R. Seth, loc. cit.[5]

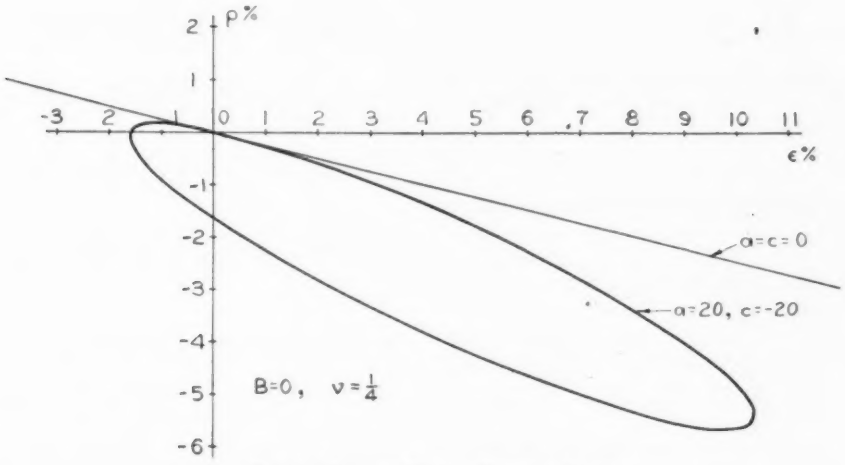

FIG. 5 POISSON CURVE, ELLIPTIC CASE

where the functions $u_{(r)}$, $v_{(r)}$, and the constant α are to be determined consistent with the equations of equilibrium and the boundary conditions. The strain-displacement relations for infinitesimal deformations now lead to the components of strain

$$\epsilon_r = \frac{du}{dr},\ \epsilon_\theta = \frac{u}{r},\ \epsilon_z = \alpha;\ \gamma_{r\theta} = \left(\frac{dg}{dr} - \frac{g}{r}\right) z, \gamma_{\theta z} = g,\ \gamma_{zr} = 0 \quad \ldots [10]$$

In accordance with Equations [10], the stress-strain relations Equations [5] take the form

$$\left.\begin{aligned}
\sigma_r &= 2G\left[\frac{du}{dr} + \frac{\nu}{1-2\nu}\left(\frac{du}{dr} + \frac{u}{r} + \alpha\right)\right] + 3A\left(\frac{du}{dr} + \frac{u}{r} + \alpha\right)^2 \\
&\quad + B\left\{\frac{u^2}{r^2} + \alpha^2 + 2\frac{u}{r}\frac{du}{dr} + 3\alpha\frac{u}{r} + 2\alpha\frac{du}{dr} - \frac{1}{4}\left[\left(\frac{dg}{dr} - \frac{g}{r}\right)^2 z^2 + g^2\right]\right\} + C\left[\alpha\frac{u}{r} - \frac{1}{4}g^2\right] \\
\sigma_\theta &= \ldots, \quad \sigma_z = \ldots \\
\tau_{r\theta} &= G\left(\frac{dg}{dr} - \frac{g}{r}\right) z - \frac{1}{2}B\left(\frac{du}{dr} + \frac{u}{r} + \alpha\right)\left(\frac{dg}{dr} - \frac{g}{r}\right) z \\
&\quad - \frac{1}{2}C\alpha\left(\frac{dg}{dr} - \frac{g}{r}\right) z \\
\tau_{\theta z} &= G\,g - \frac{1}{2}B\left(\frac{du}{dr} + \frac{u}{r} + \alpha\right) g - \frac{1}{2}C\frac{du}{dr}\,g \\
\tau_{zr} &= \frac{1}{4}C\left(\frac{dg}{dr} - \frac{g}{r}\right) gz
\end{aligned}\right\} \quad \ldots [11]$$

In the absence of body forces, the equations of equilibrium are

$$\left.\begin{aligned}
\frac{\partial\sigma_r}{\partial r} + \frac{1}{r}\frac{\partial\tau_{r\theta}}{\partial\theta} + \frac{\partial\tau_{rz}}{\partial z} + \frac{\sigma_r - \sigma_\theta}{r} &= 0 \\
\frac{\partial\tau_{rz}}{\partial r} + \frac{1}{r}\frac{\partial\tau_{\theta z}}{\partial\theta} + \frac{\partial\sigma_z}{\partial z} + \frac{\tau_{rz}}{r} &= 0 \\
\frac{\partial\tau_{r\theta}}{\partial r} + \frac{1}{r}\frac{\partial\sigma_\theta}{\partial\theta} + \frac{\partial\tau_{\theta z}}{\partial z} + \frac{2\tau_{r\theta}}{r} &= 0
\end{aligned}\right\} \quad \ldots\ldots [12]$$

The assumed system of displacements Equations [9] by aid of Saint Venant's principle is adaptable to the following loading casse:

Case 1: Pure torsion of a circular cylinder constrained against axial displacements of the end-sections.

Case 2: Pure torsion of an unconstrained cylinder.

The boundary conditions for Case 1 become

$$u_{(r=0)} = 0 \quad \ldots [13a]$$

$$\sigma_{r\,(r=R)} = 0 \quad \ldots [13b]$$

$$\tau_{r\theta\,(r=R)} = 0 \quad \ldots [13c]$$

$$\tau_{zr\,(r=R)} = \tau_{zr\,(z=0)} = \tau_{zr(z=l)} = 0 \quad \ldots [13d]$$

$$\iint \tau_{\theta z} r\,dS = M \quad \ldots [13e]$$

$$w_{(z=0)} = w_{(z=l)} = 0 \quad \ldots [13f]$$

where S denotes the region of the cross section, and M the magnitude of each of the couples applied to the end sections. In Case 2, the boundary conditions are identical with Equations [13], except for the condition of constraint Equation [13f] which is to be replaced by

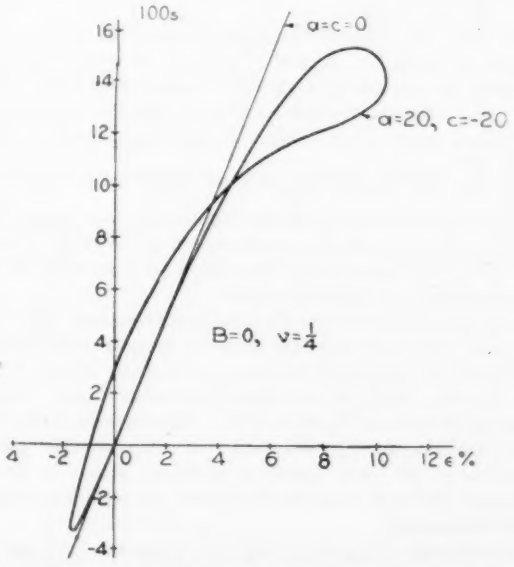

FIG. 6 STRESS-STRAIN CURVE, ELLIPTIC CASE

$$\iint_s \sigma_z dS = 0$$

(*b*) *Linearization.* Upon substitution of Equations [11] into Equations [12], the last two of the equations of equilibrium are seen to be satisfied identically by

$$g_{(r)} = Kr \quad \text{[14]}$$

With this determination of g, the first of Equations [12] becomes

$$\frac{d}{dr}\left(\frac{du}{dr}+\frac{u}{r}\right)+\frac{3}{2}\frac{(1-2\nu)}{(1-\nu)}a\frac{d}{dr}\left(\frac{du}{dr}+\frac{u}{r}+\alpha\right)^2 + \frac{(1-2\nu)b}{2(1-\nu)}\left\{2\alpha\frac{d}{dr}\left(\frac{du}{dr}+\frac{u}{r}\right)+\frac{1}{r}\left[2u\frac{d^2u}{dr^2}+\left(\frac{du}{dr}\right)^2-\frac{u^2}{r^2}\right]\right\} = 8Fr \quad \text{[15]}$$

where

$$F = \frac{(1-2\nu)(2b+3c)K^2}{64(1-\nu)} \quad \text{[16]}$$

Boundary conditions, Equations [13*c*] and [13*d*], are automatically satisfied for $v = Krz$. Conditions Equations [13*a*, *b*, and *f*] are disposed of by means of α and the two arbitrary constants appearing in the general solution of Equation [15]. Once $u_{(r)}$ is known, condition Equation [13*e*] is reached by determination of K.

From the foregoing observations, it is clear that the present problem hinges upon the solution of Equation [15]. Equation [15] is an ordinary differential equation of the second order and degree. A solution conforming to $u_{(r=0)} = 0$ may be obtained by means of a power series expansion, or through Piccard's method. In either case, the boundary conditions lead to transcendental equations in the constants of integration.

There are, however, two special instances for which closed, exact solutions are readily established. If $B = C = 0$, the desired integral of Equation [15] is $u_{(r)} = K_1 r$, K_1 being an arbitrary constant. Here, the solution both for Case 1 and Case 2 reduces to the well-known solution of the linear theory. Thus the presence of A alone in the generalized elastic potential does not give rise to any deviation from the classical results. If, in turn, $A = B = 0$, Equation [15] becomes linear. The exact solution for this case is given later.

In view of the difficulties inherent in the exact treatment of the general problem (A, B, and C present), it seems expedient to linearize the system of equations consisting of Equations [11] and [15]. The radial displacement $u_{(r)}$ and the axial component of strain α vanish identically in the classical solution. Hence u, α, $\frac{du}{dr}$, $\frac{d^2u}{dr^2}$, and any products of these quantities with powers of r, may be regarded as small of the first order in the present solution which must remain in the neighborhood of the classical solution. One is thus led to neglect in Equations [11] and [15] all second-degree terms of the type described.

It would be conceivable that the approximation suggested defeats the very purpose of the problem under consideration, and leads back to the trivial solution of the linear theory. Such is not the case, since the new elastic constants B and C enter the linear right term of Equation [15]. The essential difference between the linearized system and the corresponding system of equations of the linear theory of elasticity is that in the latter, Equation [15] is homogeneous whereas in the former it remains nonhomogeneous.

Substitution of Equation [14] into Equation [11] and subsequent linearization leads to

$$\left.\begin{aligned}
\sigma_r &= 2G\left[\frac{du}{dr}+\frac{\nu}{1-2\nu}\left(\frac{du}{dr}+\frac{u}{r}+\alpha\right)\right]-\frac{1}{4}(B+C)K^2r^2\\
\sigma_\theta &= 2G\left[\frac{u}{r}+\frac{\nu}{1-2\nu}\left(\frac{du}{dr}+\frac{u}{r}+\alpha\right)\right]-\frac{1}{4}BK^2r^2\\
\sigma_z &= 2G\left[\alpha+\frac{\nu}{1-2\nu}\left(\frac{du}{dr}+\frac{u}{r}+\alpha\right)\right]-\frac{1}{4}BK^2r^2\\
\tau_{\theta z} &= GKr-\frac{1}{2}B\left(\frac{du}{dr}+\frac{u}{r}+\alpha\right)Kr-\frac{1}{2}C\frac{du}{dr}Kr\\
\tau_{r\theta} &= \tau_{zr} = 0
\end{aligned}\right\} \quad \text{[17]}$$

Similarly, Equation [15] becomes

$$\frac{d}{dr}\left(\frac{du}{dr}+\frac{u}{r}\right) = 8Fr \quad \text{[18]}$$

The general solution of Equation [18] is

$$u_{(r)} = K_1 r + \frac{K_2}{r} + Fr^3$$

where K_1, K_2 are arbitrary constants, and Equation [13*a*] requires $K_2 = 0$. The constants K_1 and α are determined by Equations [13*b*] and [13*f*]; the components of stress are then computed from Equation [17], and $M = M_{(K)}$ follows from Equation [13*e*]. The complete solutions for Case 1 and Case 2 will be summarized.

(*c*) *Solutions.*

Case 1:

$$\alpha = 0,\ K_1 = \frac{(1-2\nu)K^2R^2}{64(1-\nu)}[(2b-c)-2\nu(2b+c)]. \quad \text{[19]}$$

$$\sigma_r = \frac{G[2(1-2\nu)b-(1+2\nu)c]K^2}{32(1-\nu)}(R^2-r^2) \quad \text{[20]}$$

$$\sigma_\theta = \frac{G[2(1-2\nu)b-(1+2\nu)c]K^2}{32(1-\nu)}(R^2-3r^2) \quad \text{[21]}$$

$$\sigma_z = \frac{GK^2}{16(1-\nu)}\{[4(2\nu-1)b+6\nu c]r^2+\nu[2(1-2\nu)b-(1+2\nu)c]R^2\} \quad \text{[22]}$$

$$\tau_{r\theta} = \tau_{zr} = 0$$

$$\tau_{\theta z} = GK[(1-\mu_1\mu_3K^2R^2)r-\mu_1\mu_3K^2r^3] \quad \text{[23]}$$

where

$$\left.\begin{aligned}
\mu_1 &= \frac{1-2\nu}{128(1-\nu)}\\
\mu_2 &= (2b+3c)(4b+3c)\\
\mu_3 &= [2b-c-2\nu(2b+c)](2b+c)
\end{aligned}\right\} \quad \text{[24]}$$

The resultant axial reaction $P = \iint_s \sigma_z dS$, so that

$$P = \frac{\pi GK^2R^2}{8}[(2\nu-1)b+\nu c] \quad \text{[25]}$$

$$M = \frac{\pi GR^4}{6}K[3-\mu_1(2\mu_2+3\mu_3)K^2R^2] \quad \text{[26]}$$

$$u = K_1 r + Fr^3,\ v = Kr,\ w = 0 \quad \text{[27]}$$

where K_1 and F are given by Equations [19] and [16], respectively.

For $A = B = 0$, the foregoing solution is exact if Equation [22] is replaced by, and P is computed consistent with,

$$\sigma_z = \frac{\nu GcK^2}{16(1-\nu)}[6r^2 - (1+2\nu)R^2] + \frac{(1-2\nu)^2Gc^2K^4}{4096(1-\nu)^2}[3r^2-(1+2\nu)R^2][9r^2-(1+2\nu)R^2] \quad [28]$$

Case 2:

$$\alpha = \frac{(1-2\nu)b - \nu c}{16(1+\nu)}K^2R^2 \quad [29]$$

$$K_1 = \frac{K^2R^2}{64(1-\nu^2)}\{4\nu(\nu-1)[(1-2\nu)b-\nu c] + (1-2\nu)(1+\nu)[2(1-2\nu)b-(1+2\nu)c]\} \quad [30]$$

σ_r and σ_θ as in Equations [20] and [21].

$$\sigma_z = \frac{G}{16(1-\nu)}[2(1-2\nu)b - 3\nu c]K^2(R^2-2r^2)$$

$\tau_{r\theta}$, τ_{zr}, $\tau_{\theta z}$, and M as in Case 1, provided μ_3 is replaced by

$$\mu_3' = \mu_3 + \frac{4(1-\nu)}{(1+\nu)(1-2\nu)}[(1-2\nu)b - \nu c]^2.$$

$$u = K_1 r + Fr^3, \; v = Kr, \; w = \alpha z$$

with K_1, F, and α as in Equations [30], [16], and [29], respectively.

(*d*) *Discussion of Results.* If $A = B = 0$, the foregoing results for Case 1 and Case 2 reduce to the classical solution. The new elastic constant A does not appear in the approximate solution given, and thus the influence of A in the problem under consideration is of a higher order than that of B or C. The nonlinear characteristics of the material give rise to a modification of $\tau_{\theta z(r)}$ and $M_{(K)}$, which now follow a parabolic law. In addition, there appear the "secondary" stresses σ_r, σ_θ, and σ_z which vanish identically in the classical solution.

The tangential displacement component $v = Kr$ coincides with that of the linear problem; hence the unit angle of twist is again constant. The radial displacement $u_{(r)}$, and the axial displacement $w_{(z)}$ of Case 2, are secondary in the foregoing sense. The cross sections remain circular but undergo a radial dilatation which, in Case 2, is accompanied by a uniform axial dilatation. The signs of the secondary components of stress and displacement, that is, whether they represent tension or compression, expansion or contraction, are governed by the relative values of the elastic constants ν, A, B, and C. The magnitudes of the deviations from the classical solution depend on these elastic constants and are proportional to the square or cube of the unit angle of twist in the approximation here considered.

The formulas for the torque $M = M_{(K)}$, Equation [26], and for the shear stress $\tau_{\theta z} = \tau_{\theta z(r)}$, Equation [23], require further and more detailed discussion.

According to Equation [26], $M = M_{(KR;\, R,\, G,\, \mu_1,\, \mu_2,\, \mu_3)}$ represents a family of cubical parabolas, each member of which passes through the origin, and is tangential at this point to the classical straight line $M = GKI_0$. By Equation [6], $G > 0$ and $-1 < \nu < \frac{1}{2}$. Furthermore, $R > 0$ and without loss of generality, $K \geq 0$. Since $2\mu_2 + 3\mu_3 \leq 0$ is incompatible with $\nu < \frac{1}{2}$ unless $b = c = 0$, and excluding the classical case, one has

$$\mu_1 > 0, \; 2\mu_2 + 3\mu_3 > 0 \quad [31]$$

Hence by Equation [26]

$M_{(KR)} = 0$ for $KR = 0$ and for $KR = K_0$, $M > 0$ for $0 < KR < K_0$ and $M < 0$ for $K_0 < KR$. $M = M_{max}$ for $KR = \frac{K_0}{\sqrt{3}}$ where $K_0 = \sqrt{\frac{3}{\mu_1(2\mu_2+3\mu_3)}}$ and K_0 is always real because of Equation [31]. Finally, $M < GKI_0$ for $0 < K$.

Thus, regardless of the values of R, ν, G, B, and C, the torque required to produce a prescribed angle of twist is less than that consistent with the linear solution. A typical $M_{(KR)}$ diagram is shown in Fig. 7. The question as to the physically significant range of KR must be decided by experiment. However, as in the case of uniform tension or compression an upper bound for this range is evident.

$$\int_0^{KR} M_{(KR)} d(KR)$$

is proportional to the total strain-energy, and clearly, values of KR which imply negative values of this integral must be excluded. Furthermore, a torque maintained at the level of M_{max} is to be interpreted as a condition of elastic failure, provided the corresponding angle of twist still belongs to the elastic range. In this way the breakdown of the theory, for strains beyond a critical range, is again seen to be inherent in the solution itself.

For the reason just mentioned, the discussion of $\tau_{\theta z} = \tau_{\theta z(r)}$ may be limited to

$$KR < \frac{K_0}{\sqrt{3}} = \frac{1}{\sqrt{\mu_1(2\mu_2+3\mu_3)}} \quad [32]$$

According to Equation [23],

$$\tau_{\theta z} = \tau_{\theta z(r;\, K,\, R,\, G,\, \mu_1,\, \mu_2,\, \mu_3)}$$

represents a family of parabolas passing through the origin. The parabolas degenerate into straight lines if and only if $\mu_2 = 0$, that is, if either $b = c = 0$ (classical case) or $b = \frac{-3c}{2}$ or $b = \frac{-3c}{4}$.

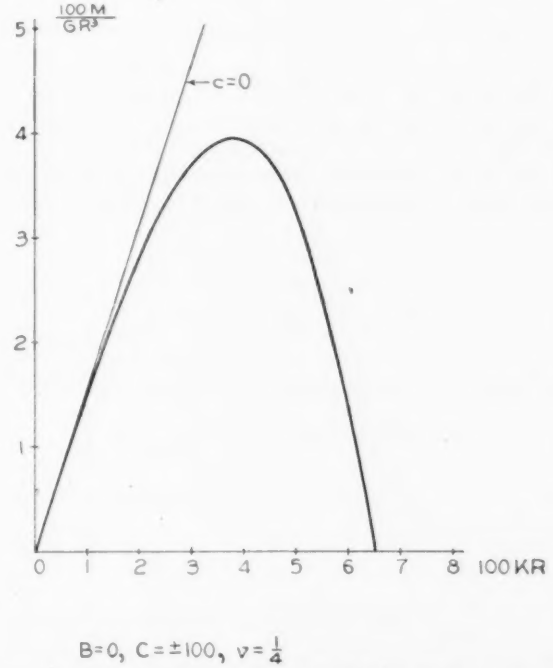

FIG. 7 TORSION, DIMENSIONLESS TORQUE VERSUS CHARACTERISTIC ANGLE OF TWIST; CASE 1

Again excluding the degenerated cases, let $\mu_3 \neq 0$. It follows from Equation [6] that

$$\mu_2 + \mu_3 > 0,\ \mu_2 + 2\mu_3 > 0 \quad \ldots\ldots\ldots\ldots [33]$$

The inequalities [31], [32], and [33] imply

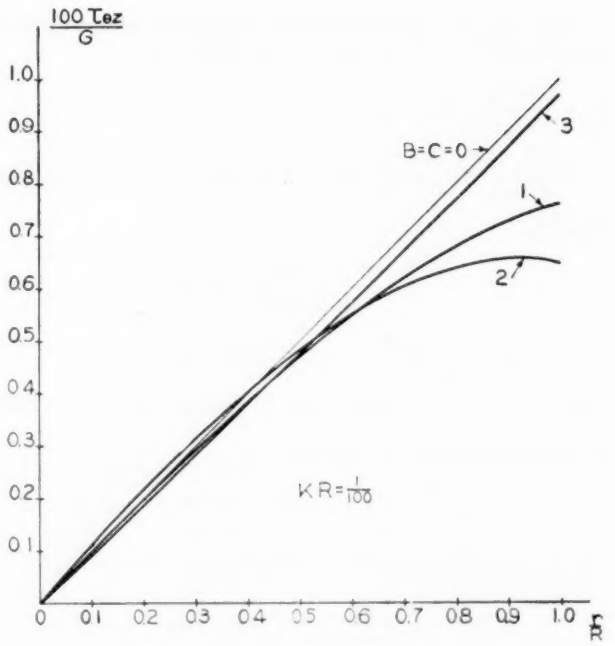
$$1 - (KR)^2\mu_1\mu_3 > 0 \quad \ldots\ldots\ldots\ldots\ldots [34]$$

Observing Equation [23], now classify as follows:

(*A*) $\mu_3 > 0$:

$\tau_{\theta z} = 0$ for $r = 0$ and $r = r_0$, $\tau_{\theta z} > 0$ for $0 < r < r_0$, $\tau_{\theta z} < 0$ for $r > r_0$, $\tau_{\theta z} = \tau_{\theta z\,\max}$ for $r = \dfrac{r_0}{\sqrt{3}}$, where

$$r_0 = \sqrt{\frac{1 - \mu_1\mu_3(KR)^2}{\mu_1\mu_2K^2}}\ \text{(real)} \quad \ldots\ldots\ldots\ldots [35]$$



Inequalities [32] and [33] imply $r_0 > R$, and thus a reversal of $\tau_{\theta z}$ is impossible. If the characteristic angle of twist $KR > \dfrac{1}{\sqrt{\mu_1(3\mu_2 + \mu_3)}}$, then $\dfrac{r_0}{\sqrt{3}} > R$ and in this instance $\tau_{\theta z}$ is increasing for $0 \leq r \leq R$. For larger values of KR, $\tau_{\theta z\,\max}$ is reached inside the boundary. In either case, however, it is readily seen that $\tau_{\theta z\max} < GKR$, regardless of the value of μ_3.

(*B*) $\mu_3 < 0$, $\mu_2 > 0$:

$\tau_{\theta z}$ is increasing for $0 \leq r \leq R$ and $\tau_{\theta z} < GKr$ for $0 < r \leq R$.

Since $\mu_3 < 0$, $\mu_3 \leq 0$ is excluded by [33], the foregoing classification is exhaustive. Thus, regardless of the values of R, ν, G, B, C, and for all physically significant values of K, the maximum shear stress $\tau_{\theta z\max}$ is less than that consistent with the linear theory. Since the foregoing discussion of $M_{(K)}$ and $\tau_{\theta z(r)}$ remains valid if μ_3 is replaced by μ_3', the conclusions apply equally to Case 2. Fig. 8 shows typical $\tau_{\theta z(r)}$ curves.

Although the error depends on the value of C, it is of some interest to compare the exact solution for $A = B = 0$, Case 1, with the approximate solution based on the linearization: for $C = 100G$, $KR = \dfrac{1}{100}$, $\nu = \dfrac{1}{4}$, the discrepancy in the values of $\sigma_{z\max}$ is approximately 1.3 per cent. In connection with Case 2, it should further be observed that a measurement of the radial dilatation $u_{(R)}$ and the axial dilatation $w_{(l)}$ would suffice for the determination of the new elastic constants B and C. However, in general, these secondary displacements may be expected to be so small as to render accurate measurements impracticable.

1 . . . $\nu = \frac{1}{8}$, $b = c = 100$; $\mu_2 > 0$, $\mu_3 > 0$.

2 . $\nu = \frac{1}{4}$, $b = 0$, $c = \pm 300$; $\mu_2 > 0$, $\mu_3 < 0$.

3 . . . $\nu = \frac{1}{4}$, $b = -100$, $c = 100$; $\mu_2 < 0$, $\mu_3 > 0$.

FIG. 8 TORSION, DISTRIBUTION OF SHEAR STRESS $\tau_{\theta z}$; CASE 1

In the solution given by Voigt,[2] $M_{(K)}$ and $\tau_{\theta z(r)}$ are identical with the classical solution because of the particular, and apparently too strong, linearization employed there. In view of the present results, Voigt's general assertion that the angle of twist remains a linear function of the torque, even upon application of the extended elastic potential, must be considered erroneous.

Compressible Flows Obtainable From Two-Dimensional Flows Through the Addition of a Constant Normal Velocity

By H. PORITSKY,[1] SCHENECTADY, N. Y.

This paper demonstrates that exact solutions of the flow of compressible fluids can be obtained by starting with two-dimensional steady-state flows and superposing upon them a velocity of constant magnitude and direction at right angles to the planes of the two-dimensional flows, while at the same time, the pressure, density, and temperature of the fluid at each point are unchanged. The procedure is demonstrated by several examples, one of which is of interest in connection with the discharge of exhaust gases from a gas engine through the tail cone and tail pipe in cases where the circulation has not been completely removed from the flow. Another example is the flow around a "sweepback" or "arrow" wing. This example is illustrated for supersonic flows on plane oblique shocks and on the Meyer-Prandtl expansion around an edge.

Introduction

SINCE comparatively few solutions of the problem of flow of compressible fluids at velocities comparable with sonic velocities are available, it is of interest to work out whatever simple examples can be furnished by theory to illustrate such flows. In the following it is shown that exact solutions of the flow of compressible fluids can be obtained by starting with two-dimensional steady-state flows and superposing upon them a velocity of constant magnitude and direction at right angles to the planes of the two-dimensional flow, while at the same time the pressure, density, and temperature of the fluid at each point are unchanged.

This procedure is illustrated by several examples. The first one is the two-dimensional compressible fluid flow furnished by a "vortex-source" or "vortex-sink;" the velocity distribution for this has been worked out by Binnie and Hooker, (1),[2] while the aspect of the flow lines is given by Ringleb, (2). The resulting three-dimensional flow, obtained by adding a constant axial velocity, is a flow which spirals about an axis and converges or diverges; it is of interest in connection with the discharge of exhaust gases from a gas engine through the tail cone and tail pipe in cases where the circulation has not been completely removed from the flow.

Another example of nontrivial flows, obtained from two-dimensional flows by the superposition of a constant normal velocity, is the flow around a "sweepback" or "arrow" wing. It is shown that by starting with the normal flow around a wing and superposing a constant velocity parallel to the span of the wing, one obtains the flow around a wing whose span is oblique to the flow vector, provided that the viscosity phenomena within the boundary layer be neglected. A sweepback wing is known to possess much higher stalling speeds at high Mach numbers and is of great interest in connection with high-speed aircraft.

The foregoing example is illustrated for supersonic flows on plane oblique shocks and on the Meyer-Prandtl expansion around an edge. It is shown that by superposing a normal velocity component on these well-known solutions, one obtains a compression shock and an expansion flow such as would occur to each side of a thin plate bounded by a straight edge placed so that its edge is oblique to the velocity vector of a supersonic stream.

Addition of Constant Normal Velocity Component to Two-Dimensional Flows

A constant velocity component

$$v_z = V = \text{const (in time and space)} \quad \ldots\ldots [1]$$

if added to a two-dimensional fluid flow of a compressible fluid, will result in a possible flow of that fluid. By a two-dimensional flow is meant a flow for which $v_z = 0$, and for which the velocity components v_x, v_y, and the pressure p, density ρ, and temperature T depend on x and y only. At the same time, we assume that p, ρ, T are not affected by the addition of the constant velocity component [1].

To prove the foregoing statement, we proceed to show that the equations of the fluid motion are still satisfied. We thus compare two cases, one of a two-dimensional flow F of a fluid in adiabatic compression, the other, a similar flow F', but with the constant axial velocity V added. For the flow F', the components of velocity v_x and v_y, and the pressure p, density ρ, temperature T are exactly the same functions of x and y as for F, and they are thus independent of z just as in the latter case. However, the aspect of the field of flow is different because of the addition of V in the z-direction.

The fluid-flow equations comprise the equation of continuity

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho v_x) + \frac{\partial}{\partial y}(\rho v_y) + \frac{\partial}{\partial z}(\rho v_z) = 0 \quad \ldots\ldots [2]$$

the dynamical equations

$$\left.\begin{aligned} a_x &= \frac{\partial v_x}{\partial t} + v_x\frac{\partial v_x}{\partial x} + v_y\frac{\partial v_x}{\partial y} + v_z\frac{\partial v_x}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial x} \\ a_y &= \frac{\partial v_y}{\partial t} + v_x\frac{\partial v_y}{\partial x} + v_y\frac{\partial v_y}{\partial y} + v_z\frac{\partial v_y}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial y} \\ a_z &= \frac{\partial v_z}{\partial t} + v_x\frac{\partial v_z}{\partial x} + v_y\frac{\partial v_z}{\partial y} + v_z\frac{\partial v_z}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial z} \end{aligned}\right\} \quad \ldots [3]$$

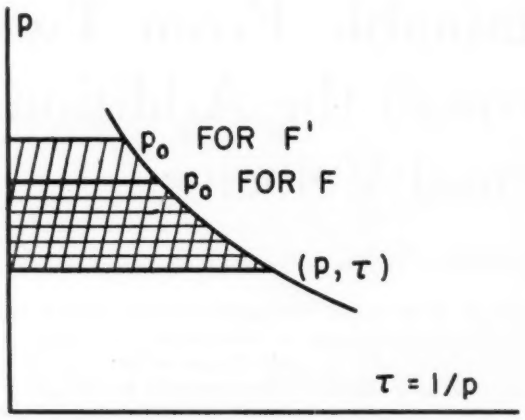

FIG. 1

and the assumption of an isentropic relation

$$p = p(\rho) = \frac{p_0}{\rho_0^k}\rho^k \quad \ldots\ldots [4]$$

between the pressure and density. For the two-dimensional flow F the last term on the left side of Equation [2] vanishes due to v_z being zero; for the modified flow F' it becomes

$$\frac{\partial(\rho v_z)}{\partial z} = V\frac{\partial \rho}{\partial z}$$

and vanishes due to the fact that ρ is independent of z. Hence Equation [2] is still satisfied. Similarly the terms $v_z\,\partial v_x/\partial z$, $v_z\,\partial v_y/\partial z$ in the first two Equations [3] vanish both for F and F', and every term in the first two Equations [3] retains its value in passing from F to F'. As regards the third Equation [3], its terms still vanish due to the constancy of v_z in time and space and to the vanishing of $\partial p/\partial z$.

An alternative proof is offered by referring the two-dimensional flow F to a set of axes, which are translated uniformly in the direction of the z-axis with velocity $-V$. Such a change of axes leads from one Newtonian system to another and does not affect the accelerations of the fluid particles; on the other hand the quantities, p, T, being static (that is, relative to a system moving with the local gas velocity) are not affected by the change of axes.

While in the foregoing we have neglected the effects of viscous (as well as of turbulent) shears, no assumption has been made in regard to whether the flow F possesses a scalar potential or not, that is, whether it is irrotational or not. If the two-dimensional flow is irrotational so that it possesses a velocity potential ϕ such that

$$(v_x, v_y) = \left(\frac{\partial \phi}{\partial x}, \frac{\partial \phi}{\partial y}\right) \quad \ldots\ldots [5]$$

then the addition of a constant v_z still leads to an irrotational field with

$$\phi + Vz \quad \ldots\ldots [6]$$

as its velocity potential. On the other hand, if the flow possesses vorticity so that no scalar velocity potential ϕ exists, then the addition of a constant v_z does not affect the vorticity either in magnitude or direction.

Under the assumptions of irrotationality, the Bernoulli equation

$$\left.\begin{aligned} \frac{\partial \phi}{\partial t} + \frac{v^2}{2} + P(\rho) &= \text{const} \\ P(\rho) &= \int \frac{dp}{\rho} \end{aligned}\right\} \quad \ldots\ldots [7]$$

follows from Equations [3], [4]. For steady flow this can be written as

$$\frac{v^2}{2} + P(\rho) = 0, \quad P(\rho) = \int_{p_0}^{p} \frac{dp}{\rho} = \int_{p_0}^{p} \tau\, dp \quad \ldots [8]$$

where $\tau = 1/\rho$ is the specific volume and p_0 the "stagnation pressure," that is, the pressure from which a gas at rest can be expanded isentropically to acquire a velocity v. While the same (p, ρ) curve obtains for the original motion and for the modified motion, the pressure p_0 is different for F, F' since $v^2/2$ differs by the constant amount $V^2/2$. The shaded areas in Fig. 1 represent the values of $v^2/2$ for the two-dimensional and the modified flows.

It may be shown that the inclusion of viscosity terms in the equations of motion does not affect the main conclusion reached in the foregoing. However, the boundary condition of zero slip has to be examined independently for F and F'

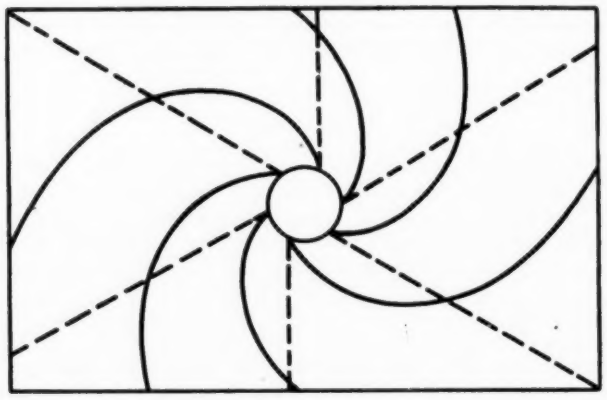

FIG. 2

APPLICATION TO A COMPRESSIBLE VORTEX SOURCE AND SINK

The flow lines of a compressible vortex source or sink may be found in Ringleb (2) and are reproduced here as Fig. 2. Two sets of flow lines are shown, one drawn as solid lines, the other as broken lines: they correspond to the two possible flows, one in which the velocity vanishes at infinity, the other one where it is everywhere supersonic, and the flow, if outward, is ever expanding. They are referred to as "converging" and "diverging" flows, respectively. Both flows are characterized by a natural boundary, a cylindrical surface at which the radial velocity component is equal to the local sound velocity (and the flow lines in the hodograph plane become tangent to the characteristics).

Addition of a constant velocity $v_z = V$ results in spiraling streamlines whose projection on the (x, y) plane have the same general aspect as in Fig. 2. The flow lines lie on proper surfaces of rotation any two of which may be regarded as possible boundaries. We proceed to plot the section of these surfaces made by an axial plane; these sections are obtained by neglecting the vortex component of velocity v_θ and plotting a curve by means of the relation

$$\frac{dr}{dz} = \frac{v_r}{v_z} = \frac{v_r}{V} \quad \ldots\ldots [9]$$

Binnie and Hooker tabulate and plot the velocity of the two-dimensional vortex source by utilizing the ratios

$$\left.\begin{aligned} R &= r/r^* \\ \theta &= v/a^* \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

where r^* is the radius at which the fluid velocity for the converging flow is equal to the local velocity of sound a^*. They consider the special case of convergent flow for which the streamlines make an angle of 45 deg with the circle $R = 1$ so that at $r = r^*$, $v_r = v_\theta = a^*/\sqrt{2}$. The limit circle (cylinder) is given by $R = 0.946$. We shall consider the same case.

Utilizing the Binnie-Hooker equations and introducing V_s, V_r as a ratio of v_s, v_r to a^* (even though r^* is no longer the radius at which the fluid velocity is equal to the local sound velocity), and Z as the ratio z/r, the following cases

$$V_s = V/a^* = 0.05, 0.1, 0.5$$

were examined for the convergent flow and are plotted in Fig. 3. The procedure followed in obtaining these consisted in subtracting from the two-dimensional resultant velocity θ the tangential component $V_\theta = \sqrt{2}/R$ leading to

$$V_R = \sqrt{\theta^2 - \frac{2}{R^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

then dividing by the proper V_s to obtain the ratio dR/dZ and plotting a curve with the slope dZ/dR.

Writing Equation [9] in the form

$$\frac{dZ}{dR} = \frac{V}{V_R}, \quad Z = V \int \frac{dR}{V_R} \quad \ldots\ldots\ldots\ldots\ldots [12]$$

it will be seen that the curves in Fig. 3 can be obtained from each other by proper "stretching" or "compression" in the z-direction of any one curve.

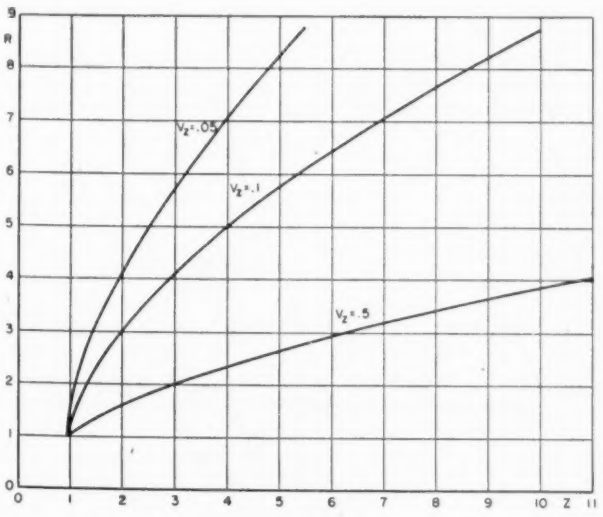

FIG. 3

For large R, the flow resembles incompressible flow so that

$$V_R = \text{const}/R \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

thus reducing Equations [12] to

$$Z = \text{const} \times R^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

that is, to parabolic shape. Only a two-parameter family of shapes can be obtained by the present method (by varying V_R/V_θ and V_R/V_s at $R = 1$). The outer and inner boundaries of the flow field are of the same shape. These restrictions are due to an inherent limitation of the method which does not allow variation of V_s with r.

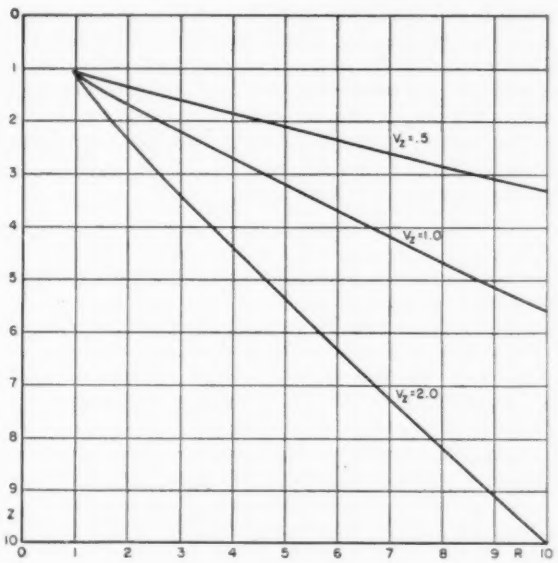

FIG. 4

Fig. 4 shows a similar (r, z) curve for the Binnie-Hooker example for the expanding flow and for

$$V_s = V/a^* = 0.5, 1, 2$$

These curves show very little curvature and now a conical surface is obtained at $R = \infty$.

SWEEPBACK OR ARROW WINGS

As a second application of the procedure for obtaining flows described in the first two sections, we consider the flow around "sweepback" or "arrow" wings, that is, around a pair of wings whose spans are inclined at an angle $\pm \sigma$ toward the main flow. It is known that with such wings higher Mach numbers may be attained before the onset of the "compressibility burble" with its resulting loss of lift and increase in drag.

Let σ be the angle of sweepback of a wing, and suppose that it is of infinite span, and that it is placed in a stream of velocity U. Resolve U into components $U \cos \sigma$, $U \sin \sigma$ normal to the wing span and parallel to it. Consider first the flow F corresponding to the velocity

$$U \cos \sigma \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

normal to the wing span, and let F' be the flow obtained from F by the addition of the component

$$U \sin \sigma \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

tangential to that span; then F' will represent the flow relative to the sweepback type of wing, provided the boundary-layer phenomena are negligible. As shown in the second section, the pressures for F and F' at corresponding points are equal. We thus arrive at the conclusion that the lift and drag experienced by a long wing of sweepback angle σ in a stream of velocity U is the same as that of the same wing in a stream of velocity $U \cos \sigma$ flowing normally to the wing span, the vectors correspond-

ing to U, $U \cos \sigma$, and the wing span being coplanar. In equation form

$$\left.\begin{aligned} \bar{L}(U) &= L(U \cos \sigma), \\ \bar{D}(U) &= \cos \sigma \, D(U \cos \sigma) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [17]$$

where L is the lift, D the drag, as functions of the speed, and bars indicate sweepback. The factor $\cos \sigma$ in the last term is due to the fact that the drag of the normal wing is normal to the wing and only the component of D in the direction of the main flow U is the drag proper, the other component tending to collapse the wing. Assuming similarly that the loss of lift and increased drag of F are not affected by the addition of the tangential velocity, it follows that

$$\bar{U}_{cr} = \sec \sigma \, U_{cr} \ldots\ldots\ldots\ldots\ldots\ldots [18]$$

where $\bar{U}_{cr}$, U_{cr} refer to the critical velocities of the inclined and of the normal wing, respectively.

Equations [17] are valid particularly at supersonic speeds where the drag is due primarily to wave resistance and not to boundary-layer phenomena. At subsonic speeds this is not the case. Assuming that the boundary-layer phenomena are determined by the pressure and velocities of the flow of a perfect compressible flow outside a thin boundary layer, we see that in comparing the normal and sweepback wings with their flows F, F', it will be found that the pressures at corresponding points are the same, but the velocities for the flow F' are larger than for the flow F. No simple relation between the boundary layers of the flows F, F' can be established, even if the sidewise acceleration of F' be neglected. While the pressure gradients inside the F boundary layer are smaller, this is made up for by added length of flow lines and (if the boundary-layer thickness is assumed to be the same) by increased viscous drag. It is therefore not surprising that while experimentally higher stalling speeds are observed with sweepback wings, the critical speeds do not increase as predicted by Equation [18]. Of course, further discrepancies between the theory outlined and actual tests are to be expected due to the finite span of an actual wing with the resulting interference at the fuselage or between the two wings at their intersection in case there is no fuselage, and at the wing tips.[3]

Oblique Plane Shock

As an application of the theory, we will consider in this section and the following the flow taking place at the leading edge of a thin flat plate (or flat wing) placed in a supersonic stream so that it is inclined to the direction of flow and so that its leading edge is oblique to the flow. On the compression side an oblique plane shock takes place which will now be discussed; the expansion on the other side will be treated in the next section.

Rankine and Hugoniot developed the equations for a normal plane shock,[4] based on continuity of mass, momentum, and energy considerations, and Meyer developed the corresponding relations for an oblique plane shock.[5] The resulting relations are represented in (3) as curves of constant pressure ratios $x = p_2/p_0$, $y = p_1/p_0$ in an $(\alpha, \beta\text{-}\alpha)$ plane, where as shown in Fig. 5, α, β are the angles between the velocity vectors before and after the shock, and the normal to the plane of the shock; p_1, p_2 the pressures before and after the shock; p_0 the stagnation pressure prior to the shock. In passing through the shock the gas suffers an increase in entropy through the conversion of some of the kinetic energy of the normal velocity into heat energy. As a result, the gas acquires a different stagnation pressure p_3. The ratio $z = p_3/p_0$ may be found from (3), where curves of constant y are plotted in an (x, z) plane.

We consider now a shock produced by a thin plate whose straight-edge boundary is placed obliquely to the stream flow. As shown in Fig. 6, we choose the x-axis in the direction of flow, and let the (x, y) plane $ABCD$ contain EF, the edge of the plate $EFGH$. Let σ be the angle of sweepback between EF and the y-axis, and let ω be the angle between the plate $EFGH$ and the (x, y) plane.

Let U, p, be the velocity and pressure of the gas stream under consideration. We introduce the flow F as the flow of velocity

$$U_1 = U \cos \sigma \ldots\ldots\ldots\ldots\ldots\ldots [19]$$

normal to the z-axis and to the edge EF and pressure p_1 impinging on the plate $EFGH$ at an angle of attack ω. From the Meyer relations and the curves in (3), the plane of shock $EIFJ$, the pressure p_2, and velocity U_2 are determined. The flow F' is now obtained by leaving the planes $EFGH$, $EFJI$ unchanged, superposing the velocity component

$$U \sin \sigma \ldots\ldots\ldots\ldots\ldots\ldots [20]$$

parallel to the edge EF on the flow to each side of the plane of shock $EFGH$, and leaving p_1, p_2 (and the densities ρ_1, ρ_2 and temperatures T_1, T_2) unchanged. To justify this procedure one cannot apply the arguments of the second section, since the flow is actually discontinuous and no longer isentropic. The justification follows directly by noting that the equations of conservation of mass, of momentum, and energy across the plane of shock in the flow F are still satisfied after the addition of the component $U \sin \sigma$ leading to F'.

It will be noted that the static pressure p_0, (as well as the stagnation pressure p_3 for F beyond the plane of shock) are no longer true stagnation pressures for the flow F'. A direct expression of these quantities in terms of the two geometric angles ω, σ might be of interest.

It is of interest to point out that the Meyer equations for oblique shock (for $\sigma = 0$) may be derived from the normal shock by the similar procedure of addition of the tangential velocity

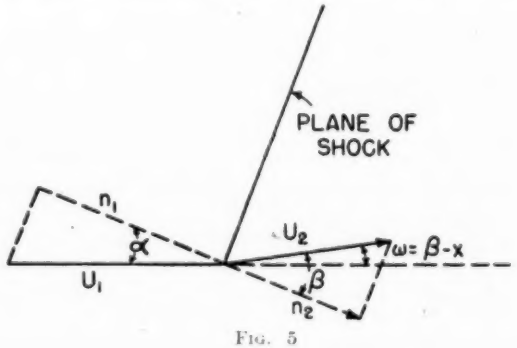

Fig. 5

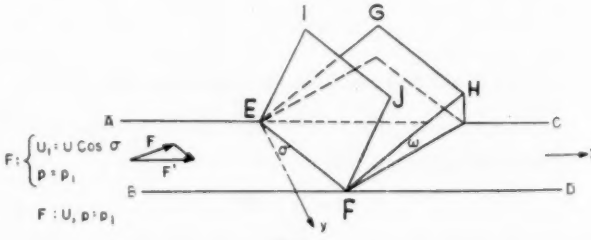

Fig. 6

[3] Since this was written, it has been pointed out to the author that the present theory of an oblique wing has been anticipated by Betz and others in Germany.

[4] See, for instance, reference (3), p. 217; reference (4), p. 325.

[5] Reference (3), p. 237; reference (4), p. 330.

component t to the discontinuous normal components n_1, n_2 to each side of the plane of shock.

It will be recalled that if ω is large and U_1, though supersonic, is close to sonic velocity, the shock equations of Meyer yield no solution. Under these conditions, the shock produced by a wedge of angle 2ω placed symmetrically in a supersonic flow U_1 differs considerably from the Meyer type; it is detached from the wedge; it has a curved shock locus with variable entropy increase along different stream lines; along the flow line through the corner (edge) of the wedge it is normal to flow. To the author's knowledge this flow has not been derived analytically, though many excellent schlieren figures of it are available in the literature. It may happen that U_1 in Equation [19] and ω fall in this range; the flow F' can still be derived from F by the addition of $U \sin \sigma$, but until more knowledge of the flow of the subsonic region of F becomes available, the foregoing is but an empty statement. However, even in the present state of the art, the range of velocities and angles within which this happens can be determined, though by the rather awkward procedure of looking for a solution of a different type (Meyer shock for $U_1 = U \cos \sigma$) and finding that it does not exist.

Oblique Prandtl-Meyer Expansion Around an Edge

A complete treatment of the two-dimensional expansion flow around a corner is given in (3)[6] and (4). The velocity as well as the pressure is constant along each of a family of straight lines through the origin (that is, planes through the edge); in the hodograph plane the velocity vector describes a characteristic curve, i.e., an epicycloid.

Addition of a constant velocity component parallel to the edge to the flow F permits one to handle flows F' which constitute an expansion around an edge of a dihedral angle of an oblique supersonic stream. The velocity and pressure are still constant over planes through the edge. In the hodograph space the velocity vector describes a plane curve (epicycloid) lying in a plane normal to the edge.

The oblique shocks of the preceding section and the oblique expansion around an edge can be utilized to obtain many features of the flow around a polyhedron placed in a supersonic stream, since this theory may be applied even when the successive edges encountered by the (bent) stream lines are not parallel to each other. However, at the vertices of the polyhedral angles, features not covered by this analysis arise at the juncture of the various regimes F'.

Discussion

Bending of Thin Curved Tubes[1]

ARTHUR MCCUTCHAN.[2] The author has rederived expressions to account for the greater flexibility of curved tubes subjected to bending both in the plane of the bend and perpendicular to the plane of the bend. Similar derivations by Wahl (1),[3] Hovgaard (2), and Vigness (3) have been published. Experimental verification of the greater flexibility of curved pipe has been presented by Wahl, Hovgaard, Vigness, and by Cope and Wert (4).

The range of curved tubes or pipes encountered in usual piping practice embraces values of the author's K expression above 0.075. The deflections in the plane of the bend found by tests described in the references cited verify the von Kármán formulas hence support the author's results as given in curves 1 and 7, Fig. 3 of the paper, for values of K above 0.075. (Note that K in this paper corresponds approximately to $h/3.3$ in Wahl's and Hovgaard's papers and that D corresponds to K or $1/K$ of those papers.)

For values of the author's K from 0.01 to 0.075, it would seem that some test substantiation that the author's curve 1 is preferable to the von Kármán's curve 2 is required. A difference of 5 to 1 in the flexibility factor D at the lower extremity of the K values is too great to accept without such proof.

The author's conclusion that the coefficient of deflection D also applies to bending perpendicular to the plane of the bend is not supported by the tests reported by Vigness (3). Curved tubes loaded by sidewise forces, torsion, or bending deflect more than solid sections due to flattening of the cross section at 45 deg to the plane of the bend, but the ratio is not the same as obtains in the case of bending in the plane of the bend.

If the author has some experimental evidence which can be given in support of his theoretical derivations, it would seem desirable to include it in the closure to his paper.

P. S. SYMONDS[4] AND IRWIN VIGNESS.[4] This paper presents a new solution to what is by now an old problem. The flexibility and stress-intensification factors which occur in curved tubes bent in the plane of curvature have been determined by von Kármán[5] and Hovgaard.[6] Their results are routinely used by engineers in the design of high-temperature high-pressure piping systems.[7] A recent paper[8] by one of the writers has extended the theory to bending out of the plane of curvature, to the same degree of approximation as that of von Kármán and Hovgaard.

Most of these solutions are expressed in terms of trigonometric series which converge rapidly. For tubes of commonly used wall thicknesses and bend radii, sufficient accuracy is usually obtained by neglecting all but the first term of the trigonometric series. Experimental results[6,8] show that the assumption that the bend radius is very large compared to the tube radius (made in all these solutions), as well as other simplifying approximations, are valid for bends of radii greater than 4 or 5 pipe diam.

When the quantity $\lambda \equiv tR/a^2$ (where t = wall thickness, R = bend radius, a = tube radius) is less than about 0.5, it is necessary to keep more than one term of the trigonometric series used in the solution. This was done by von Kármán in his original paper, in which results are given corresponding to 2- and 3-term solutions, and valid for $\lambda \geqslant$ about 0.1. Jenks[9] later presented values obtained by the use of sufficient terms to make them applicable to $\lambda \geqslant 0.05$. No derivation or experimental verification was given by Jenks, but his values were apparently obtained under the same assumption as von Kármán's, namely, that the bend radius is very large compared to the tube radius. When this condition is not satisfied, as, for example, in pipes having ratios R/a equal to 3 or 2, then these results may not be correct even though λ is sufficiently large. Calculations have been made by one of the writers, in which von Kármán's analysis was followed, but without neglecting a/R. The values of flexibility and stress factors for $R/a = 3$ and 2 were found to differ only slightly from each other and from those obtained by von Kármán and Jenks. These results are plotted in Fig. 1 of this discussion, together with the curve given by Beskin, using the more familiar notation λ rather than Beskin's K.

Unfortunately, while it is convenient to use these theoretical

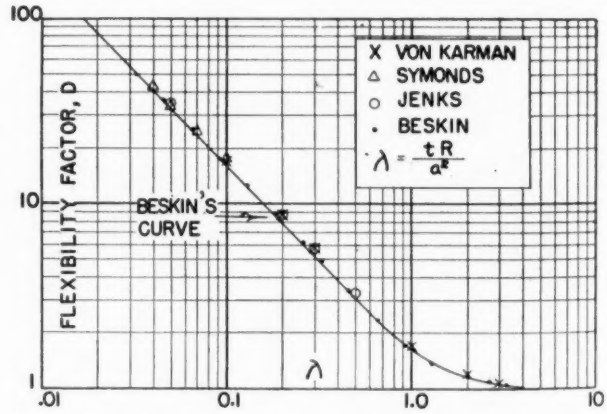

FIG. 1 COMPARISON OF CALCULATED FLEXIBILITY FACTORS FOR BENDING IN THE PLANE OF THE BEND

values, it must be recognized when working with short-radius bends that the actual flexibility factor depends greatly upon the type of restraints at the ends of the bends, which have been neglected in all of the theories. As an example, the experimental values of the flexibility factors (for pure bending in the plane of the bend) are given in the following table for tube bends having $R/a = 3, \lambda = 0.043$:

Bend	Flexibility factor
180° Bend with long tangents	37
90° Bend with tangents	32
90° Bend with flange at one end	18
90° Bend with flange at both ends	8

In the case of bending transverse to the plane of the bend, the measured flexibility factors are found to depend to an important extent upon how the loading is applied, and which deflection is measured (of the two major rotations and the displacement), as well as upon the end restraints. Considerable work has been done recently at the writers' laboratory on these problems, complete results of which will be published as soon as possible.

In examining the author's analysis, the following additional comments have occurred to us:

1 The "exactness" of the author's solutions should be qualified more explicitly than the author has done in his "Introduction." It is evident that fundamental approximations have been made in writing the strain-energy Equations [5] and [36] (applying to bending in the plane of the bend and transverse to this plane, respectively). In the in-plane bending case, for example, the assumptions are made, but not stated, that strain-energy terms, due to a transverse normal stress flow, due to any shear stresses, and due to axial local bending moments, are negligible in comparison with those arising from the longitudinal normal stress and the transverse local bending moments. In the transverse bending case, these assumptions, together with others, are also tacitly made. Most of these assumptions are plausible and probably justified, although some of those applying to transverse bending seem to be erroneous, according to experimental work that has been done at this laboratory. Solutions of this type can be shown to be sufficiently exact for any given purpose only by either (*a*) showing that, as more complete energy expressions are used, negligible changes in the final results are obtained, or (*b*) comparing results with those obtained experimentally. In this case probably only the latter test is practicable; such comparisons are cited by previous investigators (von Kármán, Hovgaard, Vigness, and others.) Mr. Beskin's analysis (particularly that for bending out of the plane of the bend) would have been more convincing if he had applied either of these tests.

2 We would appreciate having some additional information as to the meaning of the author's Equations [21], [22], [23], and [26], which are given as the equilibrium equations for an element of the tube wall in the transverse-bending case. The first three equations are readily derived for an element of sides $ad\theta$ and $(R - a\cos\theta)d\phi$ acted upon by the normal stress flows $\bar{n}_\phi$, $\bar{n}_\theta$, by the shear stress flow $\bar{q}$ ("along meridians and parallels"), by a local transverse bending moment $\bar{m}$, and by the fictitious normal pressure $\bar{W}$. However, the fourth equation of equilibrium for this stress system is

$$\frac{\partial}{\partial\theta}\left[\bar{m}\,(R - a\cos\theta)\right] = 0$$

Instead of this, the author quotes "the well-known relation for a circle," Equation [25], which he then modifies to take account of the variation of the element length around the circumference of the tube, obtaining Equation [26]. But Equations [25] and [26] pertain to a quite different set of stress flows, namely, that consisting of $\bar{n}_\theta$, $\bar{m}$, $\bar{W}$ and a radial shear flow V_θ on the sides $(R - a\cos\theta)d\phi$. By combining the four equilibrium equations of the element acted on by this system one obtains readily Equation [26]. This new system, however, does not yield Equations [21], [23] nor does the first system lead to Equation [26], in any way we have been able to discover. Further explanation of these equations would be helpful, in addition to the author's statement that "torsion and bending between adjacent sections are neglected."

3 As mentioned, experimental work done at the writers' laboratory indicates that some of the assumptions made in the analysis for the transverse-bending case are of questionable validity. In pure transverse bending, as the author says, all stresses are functions of both ϕ and θ. He then eliminates ϕ by assuming that "all flows and moments are of the same type as M_B and M_T." Thus for the case $M_B = M\cos\phi$, $M_T = M\sin\phi$, he writes $\bar{q}\,(\theta, \phi) = q(\theta)\sin\phi$, while $\bar{n}_\theta$, $\bar{n}_\phi$, $\bar{m}$, and $\bar{W}$ are all taken as proportional to $\cos\phi$.

This assumption, that stresses and displacements are proportional only to the corresponding moment, is a natural one, and one which we have made in our work. However, we have made many measurements of the diameter changes of 90-deg and 180-deg tube turns loaded so that the bending moment vanishes at either the one end or at both ends. All of these measurements show that the diameter change, as one goes around the bend, is not simply proportional to the bending moment. At the end of the bend where the bending moment is zero, the diameter change may be as much as $^1/_3$ or $^1/_2$ of the maximum value in the bend. This has a large effect on the deflection of the bend. These and many other tests we have made indicate that the simple concept of flexibility factor, as used by pipe-stress analysts, and as defined again by the author, is no longer applicable when a short-radius tube turn is loaded transversely. It is hoped that descriptions of these tests and analytical work will be published soon.

4 We are not clear what the third section of the paper, entitled, "Validity of Assumption That Ratio R/a Is Great—Corrections for Small Values of R/a," proves in regard to the bending of thin-walled curved tubes. It is, we believe, well known that in a solid curved bar, of thin rectangular section, the hyperbolic theory agrees well with the exact solution, both as to the maximum stresses and the bar deflection, even when R/a is as small as 2, while the linear-stress theory disagrees considerably in maximum stress values (about 35 per cent in error for $R/a = 2$), but is not so far off in the deflection values (about 5 per cent in error for $R/a = 2$).

We question whether these facts are a demonstration that a theory of thin-walled tubes which neglects "difference of length along the inner and outer circumferences" will be satisfactory with respect to deflections, but unsatisfactory with respect to stresses. While the errors could hardly be less than these, they might be much greater. The significant mechanism causing the increased flexibility of a thin-walled curved tube is the deformation of the cross section, and the resultant complete redistribution of stresses over the circumference. The effect of this redistribution is quite different from that of the redistribution of stresses which takes place in a solid curved bar. Hence it is difficult to see the application of the author's comparison with solid-bar results. As pointed out previously, the only convincing argument is either a more complete theoretical analysis of the actual problem, or experimental verification.

Author's Closure

It is extremely regrettable that Mr. McCutchan has not examined thoroughly the difference between the methods con-

sidered in the present paper and the preceding literature. A comparison is made herein.

1 The von Kármán theory has been derived from the same hypotheses as the author's theory, the only difference residing in the accuracy of the mathematical derivation. As pointed out in the author's paper, von Kármán has assumed that a 2- or 3-term expression may be used to represent the stress distribution. The author has used a series development, which enabled him to limit the error to any predetermined value. This method has shown that von Kármán's expression is valid in all the useful range of tube proportions, assuming that the physical hypotheses introduced either by von Kármán or by the author are justified. This justification is given by tests made in a fairly wide range, which validate both methods. Since von Kármán's results represent a first approximation of the author's results, the latter should be used in all the cases where there is a discrepancy between the two theories. However, the author's results may become incorrect if the physical and mathematical assumptions made by both von Kármán and the author are not satisfied. The author has already pointed out that the radius of curvature must be at least double that of the tube radius. In addition, the wall thickness must be sufficient to avoid local instability, a condition which defines an upper limit of the ratio a/t.

These considerations show why Mr. McCutchan is misled when he requires test to decide which, of von Kármán's results or the author's, must be considered as correct.

2 Mr. McCutchan makes a still greater error when he opposes the tests reported by Vigness[10] with the author's theoretical results. In the summary of his paper, Vigness[11] clearly indicates "A flexibility factor is obtained which is identical with that found for the bending of pipe in the plane of its bend." Further, Vigness[12] reproduces (Equations [3] and [35]) von Kármán's formula and states: "The rigidity factor is identical to that derived by von Kármán and Hovgaard for bending in the plane of the bend. It may now be applied generally to the flexural rigidity of tubes." The tests presented by Vigness confirm these conclusions, as it results directly from his Tables 3 and 4. This confirms the author's results, since the latter are nearly identical to Vigness-von Kármán expressions for the tube proportions used in the tests. At the same time, Mr. McCutchan's statement that the Vigness paper does not confirm the author's results is entirely invalidated.

In respect to tests presented in Table 1 of Vigness' paper, which Mr. McCutchan probably mistook as showing a difference between in-plane and out-of-plane bending, it must be noted that the values corresponding to $P = 1$ have been calculated by Vigness, using the hypothesis that the tube curvature has no influence on the out-of-plane bending. The discrepancy with test results is used as an argument by Vigness to prove that conventional methods must be revised, which is the object of his paper. The author, using the coefficient $D = 1.97$, resulting from the tube dimensions, finds by a strain-energy calculation that the end deflection (including bending and torsion) is $\Delta x = 0.064$ instead of the measured value 0.060, and the value 0.037 calculated by the Karelitz and Marchand (conventional) method.

These results show a difference of 7 per cent between the author's theory and the tests; difference easily explained by the fact that around each reversal of curvature, the sections are more rigid than found by the theoretical formula developed for constant curvature. The difference of 7 per cent indicates that 19 per cent of the tube length is not affected by the curvature effect (figure obtained when the torsional deflection is eliminated). In other terms, it can be assumed that the rigidity constant varies linearly between the value $1/EI$ and D/EI, the first value corresponding to the point of inflection, the second at some distance from it, chosen in such manner that the affected lengths represent 38 per cent of the tube development. This length represents 0.9 in. on either side of a point of inflection, a result which seems reasonable when compared with the average diameter of the tube, which is 0.72 in.

In conclusion, it can be stated that, in contradiction with Mr. McCutchan's assertion, his references confirm the validity of the author's theory, instead of disproving it.

A complete discussion of the points raised by Messrs. Symonds and Vigness would require a completely new paper and is beyond the scope of a closure. For this reason, only succinct indications are given hereinafter.

1 (*a*) It was felt that it is useless to insist on the simplifications made in the analysis of in-plane bending, which are conventional in stress analysis of thin tubes and of frames. It has been shown time and again that the moment of inertia of a thin tube can be calculated considering that all the material is concentrated along the mean circumference, and that axial loads and shears produce negligible deflections in thin frames, such as constituted by a slice of a tube. When the limit case of very thick tubes (solid sections, $t/a = 2$) is considered, the analysis developed in the third section of the paper shows that, in this case also, deformations due to transversal stresses (which are the limit of normal stresses and shears) are negligible, since the conventional formulas for straight beams can be used to calculate deflections (see Table 2). This, incidentally, explains one of the purposes of the third section (see comment 4). More specifically, the secondary effects are the following:

(*a*) *Axial Local Bending.* The total moment of inertia of a straight tube is

$$I_0 = \pi a^3 t + \frac{\pi a t^3}{4}$$

For a curved tube, the corrected value to be used in deflection computations is

$$\frac{\pi a^3 t}{D} + \frac{\pi a t^3}{4} = \frac{\pi a^3 t}{D}\left(1 + \frac{\lambda D}{4}\frac{t}{R}\right)$$

In this equation $\lambda = tR/a^2$. The factor $\lambda Dt/4R$ represents the correction due to axial local bending. Since $\lambda D = 1.6$ for a wide range of values of λ, the correction factor has the value $t/2.5R$ and is generally negligible. For the tube examined by Symonds and Vigness ($\lambda = 0.043$, $R/a = 3$; $t/a = 0.014$), the correction is 0.2 per cent. For this tube, the deflection coefficient has the theoretical value $D = 38$ (Fig. 3 of paper), against $D = 37$ measured for a 180-deg bend, without end restraint, which shows the degree of reliability of the formula developed in the paper.

(*b*) *Shears and Normal Stresses.* Shear flows V_θ and normal stress flows n_θ can be determined as functions of the basic quantities z and y

$$V_\theta = \frac{dm}{ad\theta} = \frac{dz}{d\theta}\frac{M}{2\pi R}; \quad n_\theta = V_\theta \cot\theta$$

in which

$$\frac{dz}{d\theta} = \Sigma \sin 2n\theta \,[b_{2n-1} - b_{2n+1}]$$

$$\frac{dz}{d\theta}\cot\theta = 1 + \Sigma \cos 2n\theta \,[b_{2n-1} + b_{2n+1}]$$

Thus the initial Equation [8] must be completed by the terms

$$pH^2\int_0^{2\pi}\left(\frac{dz}{d\theta}\right)^2 d\theta + H^2\int_0^{2\pi}\left(\frac{dz}{d\theta}\cot\theta\right)^2 d\theta$$

[10] See McCutchan's bibliography reference (3).
[11] Ibid., p. 105.
[12] Ibid., pp. 107 and 115.

with

$$H^2 = \left(\frac{t}{a}\right)^2 \frac{1}{12(1-\nu^2)}; \quad p = \frac{6E}{5G}$$

To expressions, Equations [13] and [14], must be added

$$pH^2\pi[(1-b_3)^2 + (b_3-b_5)^2 + \ldots.] + H^2\pi[2 + (1+b_3)^2 + (b_3+b_5)^2 + \ldots..]$$

Equations [15] must be completed by terms such as

$$pH^2[2b_{2n+1} - b_{2n-1} - b_{2n+3}] + H^2[2b_{2n+1} + b_{2n-1} + b_{2n+3}]$$

These modified equations lead to more accurate coefficients b. If the uncorrected coefficients b are used, a value of D can be obtained by simple addition of the terms corresponding to the deflections neglected heretofore. As these terms are relatively small, the corrections to the coefficients b are small and the correct value of D is very close to the value thus calculated, which is too high. The correction to expression, Equation [20], for D is

$$\frac{a^2}{4R^2}[2 + \Sigma(b_{2n-1} + b_{2n+1})^2 + p\Sigma(b_{2n-1} - b_{2n+1})^2] = \frac{a^2}{R^2}\omega$$

For $p = 3.25$, it is found

K	0.01	0.1	1
ω	2.5	1.43	1.54

Thus the corrected value of D, designated by D_c, is

$$D < D_c \leq D + \frac{a^2\omega}{R^2}$$

For a thick tube with a great curvature (say, $K = 0.1$ or $t = a/10$; $R = 3a$), the factor $a^2\omega/R^2$ is smaller than 0.1, which represents a relative error for D smaller than 2 per cent. For a thin tube the error is smaller. For the tube just examined

$$D_c = D + 25; \quad D = 38$$

and the error is smaller than 1 per cent.

For a solid rectangular section, the quantity $D_c - D$ is represented by column 5 of Table 2, which confirms the results established here. These results show that it is fairly simple to determine what terms can be neglected in an analysis of the type examined here; this contradicts Symonds' and Vigness' opinion, who feel that such an analysis is not practicable.

1 (*b*) The same simplifications have been used for the analysis of transverse bending. It has been specifically indicated in the paper that only the bending of each segment of the tube has been considered, while perpendicular local bending moments as well as torsion between segments have been neglected, which is the meaning of the sentence: "Torsion and bending between adjacent sections are neglected." An analysis similar to the one indicated under 1*a*—(*a*) would justify these simplifications, and an analysis similar to the one indicated under 1*a*—(*b*) would justify the fact that secondary normal stresses and shears have been neglected.

The equations for transverse bending are conventional equations of equilibrium of surfaces with a double curvature and can be found in any textbook on shell analysis. For instance, Love (5)[13] derives the following equations, in which the notations α and β correspond to θ and ϕ of the paper, respectively: Equation [45-1] corresponding to Equation [22] of the paper; Equation [45-2] to Equation [23]; Equation [45-3] to Equation [21]. The only difference resides in the fact that the fictitious load $\overline{W}$ is replaced by derivatives of shears such as

$$\frac{\partial[V_\theta(R - a\cos\theta)]}{\partial\theta}\frac{1}{a(R - a\cos\theta)}$$

which represent the actual value of the fictitious right-hand member of Equation [21]. Equation [25] or [26] is derived by combining equations such as Equations [21], [22], and the equations of equilibrium between moments and shears, which replace the obviously incorrect equation written by Symonds and Vigness

$$\frac{\partial}{\partial\theta}[\overline{m}(R - a\cos\theta)]$$

which should be (see Love's Equation [46–2])

$$\frac{\partial}{\partial\theta}[\overline{m}(R - a\cos\theta)] - \overline{V}_\theta(R - a\cos\theta)a = 0$$

Symonds and Vigness did not realize that there is only one system of stress flows and unit moments; this system is $\overline{n}_\theta$, $\overline{n}_\phi$, $\overline{V}_\theta$, $m = \overline{m}_\theta$ ($\overline{m}_\phi$, $\overline{V}_\phi$ and the torsion are neglected). For simplicity of presentation, this system has been divided into $\overline{n}_\theta$, $\overline{W}$, $\overline{n}_\theta$ and $-\overline{W}$, $\overline{V}_\theta$, $\overline{m}$, $\overline{n}_\theta$. The second system is a conventional loading of a ring and corresponds to the equations

$$\frac{\partial\overline{m}}{\partial\theta} = a\overline{V}_\theta; \quad \frac{\partial\overline{V}_\theta}{\partial\theta} = -a\overline{W} + \overline{n}_\theta; \quad \frac{\partial\overline{n}_\theta}{\partial\theta} = -\overline{V}_\theta$$

In these equations the length factor $1 - a\cos\theta/R$ has been omitted. Combination of these equations leads to Equation [25] or to the correct Equation [26] of the paper, if the length factor is introduced.

3 It is a classical result (6) for shells in form of surface of revolution that if a loading is a periodical function of the type $M_B = M_1\cos n\phi$; $M_T = M_2\sin n\phi$, all the internal stresses and strains are of the same form, provided the edge loads and displacements correspond to the corresponding boundary values defined by this solution. Thus there is no assumption made in this analysis, at least for a given system of edge conditions, which shows the error of Symonds' and Vigness' statement, "the assumptions . . . . are of questionable validity."

This analysis is as exact as the corresponding analysis for in-plane bending, in which it is considered that the stresses are the same in all sections, which is obvious for reason of symmetry. The same concept of symmetry, generalized to include the concept of orthogonality, explains why periodical solutions of different periods are independent on a shell in form of a surface of revolution. These facts have been applied for many years in the theory of shells of revolution, especially in the case of reinforced-concrete construction (7, 8).

With regard to the edge conditions, it can be indicated that the solution developed in this paper strictly follows the semi-inverse method invented by Saint Venant (9), which consists in finding an arbitrary solution of the equations of equilibrium and of deformation, in which edge conditions are disregarded. It is known that a change in edge conditions affects but slightly the general deflections of solid bodies. In recent years, especially in connection with aircraft structures, it has been realized that when thin structures are considered, edge conditions may have much greater importance. This is especially true for open shells in the form of beams, in which case edge conditions are the main factor in the determination of stresses, a fact which has led the author to suggest an extension of the Saint Venant principle for this case (10). In the case of closed beams the influence of the edge conditions is less important, but may not be negligible, as proved by the tests indicated by Symonds and Vigness for in-plane bending.

[13] Numbers in parentheses refer to the Bibliography at the end of this closure and follow numerically from the bibliography at the end of the McCutchan discussion.

As regards the transverse bending test indicated by Symonds and Vigness, the following can be noted: If the tests had been repeated by applying end moments on a 180-deg bend, the middle section would have been submitted to torque only and for pure reason of symmetry, its dimensions would not have changed. The argument against the mathematical derivation which has been put forward in this case is an example of incorrect conclusions drawn from test which do not correspond to the conditions chosen for a theoretical analysis.

If a refined theory of bending of curved tubes is to be developed, it must follow the conventional pattern established by Saint Venant: (*a*) Find a solution by a semi-inverse method, which has been the aim of the present paper; (*b*) find the variations to this solution which are due to changes of the end conditions. From the experience he has gathered in the problem of straight beams (11), the author feels that the solution of the problem of end effects is a fairly simple one, at least with regard to the theoretical analysis. The actual computation, however, may be somewhat lengthy. Basically, the method is as follows:

For a bend of angle α, it is necessary to add terms of the form $\cos \pi n\phi/\alpha$, $\sin \pi n\phi/\alpha$ to the existing terms, in order to obtain double infinite series in θ and ϕ. Then various edge conditions can be satisfied without great difficulty.

4 The fact that the ratio R/a has but a small influence on the rigidity is confirmed by the analysis that Symonds and Vigness have made on pipes having this ratio equal to 3 or 2. Thus their questioning on the validity of this fact seems superfluous.

As regards the third section of the paper, they believe, "It is well known that in a solid curved bar . . . . the hyperbolic theory agrees well with the exact solution . . . . as to . . . . the bar deflection." However, the purpose of Table 2 of the paper is not to confirm this belief, but on the contrary to show that it is erroneous. The hyperbolic theory is less correct than the straight beam theory with regard to deflections, although it is acceptable as regards stress distribution. The results for a rectangular section are obviously valid for very thick tubes. It is thus necessary to prove the point for thin tubes, a calculation which has precisely been made by Symonds and Vigness.

The true reason for which stresses are affected by the value of the ratio a/R while total deflections are practically unaffected resides in the fact that stresses are modified in an approximately linear manner by R/a, while the total deflection, which is obtained by adding strains on both sides of the neutral line, is affected by a factor proportional to $(a/R)^2$. In addition, the transversal stresses omitted in the hyperbolic distribution compensate to a great extent the previous effect, which causes the final coefficient of $(a/R)^2$ in the formula for deflection to be extremely small. If a complete analysis, introducing the factor (a/R) in an explicit manner, is required, the following method can be applied:

The general equations of equilibrium of shells of revolution under symmetric loading are conventional. The equations written by Timoshenko (12) can be applied. Combining the three equations of equilibrium, and omitting the longitudinal local bending (see 1*a*), the following equation can be established

$$\frac{1}{a^2}\left(\frac{d^3}{d\theta^3}+\frac{d}{d\theta}\right)[m(R+a\sin\theta)]+n\cos\theta+\frac{d}{d\theta}(n\sin\theta)=0$$

It can be shown that this equation can be replaced by

$$a^2 n=\frac{d}{d\theta}\left[\frac{1}{\sin\theta}\,\frac{d}{d\theta}\{m(R+a\sin\theta)\}\right]$$

If the unknown m is replaced by

$$m'=m(R+a\sin\theta)/R$$

this equation becomes identical to Equation [4] of the paper. However, the problem is modified because the strain-energy expression becomes

$$\frac{1}{2}\left[\int_0^{2\pi}\frac{n^2 d\theta}{Et}\left(1+\frac{a}{R}\sin\theta\right)+\int_0^{2\pi}\frac{m'^2 d\theta}{EI\left(1+\frac{a}{R}\sin\theta\right)}\right]$$

Thus with the same relation, Equation [9], between the two unknowns y and z, the quantity to be minimum is (instead of Equation [8])

$$K^2\int_0^{2\pi}y^2\left(1+\frac{a}{R}\sin\theta\right)d\theta+\int_0^{2\pi}\frac{Z^2 d\theta}{1+\frac{a}{R}\sin\theta}$$

Because of the existence of antisymmetric terms $\frac{a}{R}\sin\theta$ in this equation, the series Equations [11], [12] defining y and z must be completed by terms with opposite symmetry

$$y=2\Sigma(2n+1)b_{2n+1}\sin(2n+1)\theta+2\Sigma n g_n\cos n\theta$$

$$z=\Sigma(b_{2n-1}-b_{2n+1})\frac{\cos 2n\theta}{2n}+\Sigma(g_{n+1}-g_{n-1})\frac{\sin n\theta}{n}$$

After $1\Big/\left(1+\frac{a}{R}\sin\theta\right)$ is replaced by its series expansion and y and z are replaced by the foregoing developments, the equation for minimum strain energy can be replaced by simultaneous equations in which the coefficients b_{2n+1} and g_n are the unknowns. These equations are of more complicated form than Equations [15] and are functions of the two parameters K and a/R. A method of successive approximations can be applied since, for small values of a/R, the solution developed in the paper represents a first approximation. Thus for increasing values of a/R, each solution found for a given value of a/R is a first approximation for a somewhat greater value of this quantity, and the solutions for the whole range of useful values of a/R can be found.

It is presumed that these indications may prove useful for further developments of the theory of curved thin tubes.

similar to that reported by the author was carried out in the Research Laboratories for Mechanics of Materials at M.I.T. during the winter of 1940–1941. Although an initial phase of this program was completed by that time, the more extended study planned had to be postponed due to the writers' activities on other war research. In view of the similarity of the initial program with the present study reported by Mr. Davis, a summary of this work is included herein.

Tubular test specimens were machined from 2-in-diam bars of S.A.E. 1020 steel, cut from a 20-ft length of stock. The chemical analysis for this material was as follows:

C	Mn	P	S
0.20	0.55	0.009	0.027

Prior to machining, the bars were carefully annealed at 1650 F and furnace-cooled. All tubular specimens were drilled, reamed, and lapped to an internal diameter of 1.00 in. and were turned and polished giving a wall thickness of 0.1 in. Those tubes subjected to internal pressure and axial tension had a gage length of 4 in., while those tested under internal pressure and axial compression were machined to a 2-in. length. Torsion specimens were 12 in. long and $^1/_2$ in. diam over the test region. Details of the grips and equipment used may be found in a previously published paper.[4]

Prior to testing, all tubes were carefully scribed with a network of fine scratches such that the grid spacing was approximately 0.1 in. in both the axial and circumferential directions. These networks were scribed with a commercial diamond set in a jig. The tubes were mounted in a lathe with the scriber attached to the cross-feed, in such a manner that the cross-feed micrometer screw could be used for indexing. The grids then were measured carefully by means of a cathetometer, to the nearest 0.0001 in. All tubes were traversed with a dial-gage device,[4] so that the wall thickness at any point in the gridwork area was known to 0.0001 in. Finally, the outside diameters were measured throughout the test area.

The tubes were then subjected to internal pressure and axial load. The ratio of the internal pressure to axial load was maintained at a constant predetermined value throughout each test. No measurements were taken during the test, although the maximum and fracture loads were recorded. After rupture, the networks, wall thicknesses, and outside diameters of all tubes were again measured, following the same procedure as in the initial measurements.

Octahedral shearing strains were computed for all elements of the network in the region of fracture and the strains corresponding to the largest octahedral shearing strain were recorded as the fracture strains of the tube in question. In this connection it should be mentioned that the values determined were true strains.

The fracture stresses were admittedly more approximate. For cases where tubes ruptured with a circumferential crack, the minimum wall thickness and the average diameter around the circumference were measured and the stresses evaluated from expressions similar to Equations [14], [15], and [16] in the paper. Where axial fractures occurred, the minimum wall thickness was used, together with the diameter 90 deg from the point of fracture, assuming the tube was axially symmetrical before rupture and Equations [14], [15], and [16] again applied. The stresses so evaluated were average true stresses.

The results of this investigation are given in Table 1 of this discussion. The octahedral shearing strains $\bar{\gamma}_n$ at fracture vary from 0.980 in. per in. for pure tension to 0.592 for a ratio of $\bar{\sigma}_t/\bar{\sigma}_a$ of 2.465. The octahedral shearing stress, $\bar{\tau}_n$, remains reasonably constant over the range of stress ratios tested. Of particular interest is the constancy of the maximum principal shearing stress at fracture, varying from 44,500 to 48,600 psi. Each of the fracture principal strains was measured separately, thus their sum serves as a reasonable check on the measurements. It will be noted from Table 1 that the sum of the principal strains is quite small, although varying in sign, depending upon the stress ratio.

It will be seen that the variation of $\bar{\gamma}_n$ with stress ratio is not as severe in the M.I.T. tests as in those reported by the author. It is felt that the difference in the method of fracture-strain measurements is largely responsible for this. In cases where the rupture occurs circumferentially, fracture strains are accurately found from the wall thickness at the neck, and the average diameter at this point, since the tube remains essentially symmetrical with respect to the axis. Indeed the octahedral shearing strains for the two series of tests compare quite favorably for this type of fracture. However, when longitudinal rupture occurs, axial symmetry no longer exists, and diameter measurements are not a very reliable criterion for fracture strains. Use of an externally scribed network overcomes this difficulty, since tangential and axial elements at the point of fracture can be measured readily.

In the tests reported by the author, it was shown that fracture occurred when the principal shearing stress reached a critical value, but that this critical value was not the same in all directions. For example, the average shearing stress at fracture for those specimens which failed by a circumferential rupture was approximately 55,000 psi and for those which failed by a longitudinal crack the average shearing stress was about 40,000 psi.

In the M.I.T. tests reported herein, fracture occurred when the principal shearing stress reached a critical value, as reported by the author, but the critical value was very nearly the same in all directions. For example, the average principal shearing stress at fracture for those specimens which failed by a circumferential crack was 47,800 psi, while for those failing by a longitudinal crack, the average shearing stress was 47,000 psi.

It would appear that both the tests reported in the paper and

[4] "Combined Stress Experiments on a Nickel-Chrome-Molybdenum Steel," by J. M. Lessells and C. W. MacGregor, *Journal of The Franklin Institute*, vol. 230, August, 1940, pp. 163–182.

TABLE 1 RUPTURE DATA—M.I.T. TESTS; ANNEALED S.A.E. 1020 STEEL[a]

Ratio $\bar{\sigma}_t/\bar{\sigma}_a$	—1.00[b]	0	+0.534	+1.039	+2.115	+2.465	+3.195

[a] True stresses and true strains used throughout; stresses in psi units.
[b] The a and t directions here do not mean axial and tangential as in the other cases.

those included herein seem to favor the maximum-shearing-stress criterion for fracture for these materials. However, further work is needed to establish this fact definitely.

W. R. Osgood.[5] An investigation of combined stress could not be in better hands than those of the author, a careful experimenter; Dr. Nadai, a pioneer in the field of plasticity; and Captain Roop, a friend of research with a rare appreciation of the double role of theory and test. It is a constant source of pride also that our Navy Department fosters the highest type of engineering research, as exemplified by the co-operation of the David Taylor Model Basin in the author's investigation.

A few questions and remarks occur to the writer in reading the paper under discussion. It is not clear just how the notches of the impact specimens were oriented in relation to the bar. Was the notch in the transverse specimen parallel to the axis of the bar and that of the longitudinal specimen perpendicular to the radius normal to the specimen?

It seems that the machining operations after annealing may have introduced sufficient anisotropy to account for some of the difference in behavior of the specimens in the tangential and axial directions. There is some evidence for this possibility in Figs. 5, 6, 8, 9, and 22. If conditions were the same in the tangential and axial directions, the $\bar{\sigma}_a$-curves in Figs. 5, and 6 should coincide with the $\bar{\sigma}_t$-curves in Figs. 8 and 9, respectively. Actually, the curves in Figs. 8 and 9 lie below those in Figs. 5 and 6, respectively. On the other hand, the machining conditions for the two subsize specimens, Fig. 3, were identical, and the two curves for these specimens, Fig. 22, are practically identical, probably within the unavoidable limits of error of the tests.

Except for the specimen for which $\sigma_t/\sigma_a = 2$, the scatter in the points in Fig. 21 may well lie within the experimental error to be expected. If the scatter is greater than can be accounted for by the experimental error, it may be that anisotropy of the material accounts for it. The anomalous behavior of specimen "$\sigma_t/\sigma_a = 2$" may be due to mechanical properties different from those of the other specimens. Was it perhaps taken from the end of the original 18-ft bar?

Since isotropic engineering materials are a rarity, means of taking anisotropy into account are worth considering. For example, in analyzing tests of orthotropic materials, probably the commonest engineering type, it may be well to seek to make use of one or more significant properties associated with each of the three planes of symmetry. By way of illustration only, one might consider plots of

$$\bar{l}_n = \frac{2}{3}\sqrt{\bar{l}_{at}^2 + \bar{l}_{tr}^2 + \bar{l}_{ra}^2}$$

against

$$\bar{g}_n = \frac{2}{3}\sqrt{\bar{g}_{at}^2 + \bar{g}_{tr}^2 + \bar{g}_{ra}^2}$$

where

$$\bar{l}_{at} = \frac{1}{2}\left(\frac{\bar{\sigma}_a}{S_a} - \frac{\bar{\sigma}_t}{S_t}\right), \quad \bar{l}_{tr} = \frac{1}{2}\left(\frac{\bar{\sigma}_t}{S_t} - \frac{\sigma_r}{S_r}\right), \quad \bar{l}_{ra} = \frac{1}{2}\left(\frac{\bar{\sigma}_r}{S_r} - \frac{\bar{\sigma}_a}{S_a}\right)$$

and

$$\bar{g}_{at} = \frac{E_a}{S_a}\bar{\epsilon}_a - \frac{E_t}{S_t}\bar{\epsilon}_t, \quad \bar{g}_{tr} = \frac{E_t}{S_t}\bar{\epsilon}_t - \frac{E_r}{S_r}\bar{\epsilon}_r, \quad \bar{g}_{ra} = \frac{E_r}{S_r}\epsilon_r - \frac{E_a}{S_a}\bar{\epsilon}_a$$

S_a, S_r, S_t, E_a, E_r, E_t being parameters associated with the a, r, and t directions. It might be that such plots would show less scatter than plots of the octahedral shearing stress against the octahedral shearing strain. The S's might be secant yield strengths or tensile strengths, and the E's might be moduli of elasticity.

Were the stresses $\bar{\sigma}_t$ at rupture for specimens for which $\sigma_t/\sigma_a = 0.775$, 0.800, and 0.875 based upon the maximum internal diameter through the bulge? Presumably they were. If the mean internal diameter of the cross section through the bulge was used, the computed stresses would be too low.

The picture presented by the energy data, Table 2 of the paper, is a disturbing one. Unless the material were anisotropic, one would expect the same values of energy for $\sigma_t/\sigma_a = 0$ as for $\sigma_t/\sigma_a = \infty$ and for $\sigma_t/\sigma_a = 0.500$ as for $\sigma_t/\sigma_a = 2$. Actually these energies differ by factors of 7 and 8, respectively. It is hard to believe that the material was sufficiently anisotropic to account for any such great difference. The energies were presumably computed from "the areas under the curves of true stress versus natural strain which are shown in Figs. 5 to 14." As soon as necking or local bulging begins, as the author states, it is no longer possible to measure reductions of area and elongations locally in the neck or the bulge. Nor is it possible to measure stresses accurately.

When necking occurs, as for $\sigma_t/\sigma_a = 0$, positive stresses $\bar{\sigma}_t$ and negative strains $\bar{\epsilon}_t$ are undoubtedly set up, although the author gives $\bar{\sigma}_t = 0$ in Table 1. The same would apply for small values of $\sigma_t/\sigma_a > 0$. On the other hand, when unsymmetrical longitudinal bulging occurs, as for $\sigma_t/\sigma_a = \infty$, positive stresses $\bar{\sigma}_a$ and positive strains $\bar{\epsilon}_a$ are set up which are larger in the bulge because of the bulge than in the rest of the tube. At failure the stresses $\bar{\sigma}_a$ may be expected to be much larger in the bulge than the average stress $\bar{\sigma}_a$ for the entire cross section. The same would hold true for large values of $\sigma_t/\sigma_a < \infty$. Consequently, in Figs. 5 to 14 a $\bar{\sigma}_t$-curve for $\sigma_t/\sigma_a = 0$ is not negligible, and for values of $\sigma_t/\sigma_a > 0.762$ the last points of the $\bar{\sigma}_a$-curves are probably considerably low. If this is the case, $\int \bar{\sigma}_t\, d\bar{\epsilon}_t$ would be negative for $\sigma_t/\sigma_a = 0$, and $\int \bar{\sigma}_a\, d\bar{\epsilon}_a$ would be greater for $\sigma_t/\sigma_a > 0.762$ than given in Table 2; and the W values would be more nearly in line. If the picture in Table 2 cannot be explained in some such way as this, then the whole technique of making combined-stress tests by means of tubes is open to serious question, and we are left in a fine pickle.

The agreement of the various test results in Fig. 21 is so good, except at rupture, that one would like to believe it should be at rupture too, that is, one would like to believe that the octahedral shearing stress should be the same at rupture for all combinations of stress. And it may in fact be, for the reasons suggested in the preceding paragraph. In Fig. 21 the last point for each test may be just as inaccurate as the last points referred to in Figs. 5 to 14. The alternative is that the octahedral shearing stress-octahedral shearing strain law holds approximately up to rupture and then suddenly some other law dominates. This would be an unpleasant pill to swallow.

In the last paragraph of the section "Tests on Solid Specimens," the author states, "the mean diameter of the tube corresponds to the width." It seems to the writer that the mean circumference of the tube should correspond to the width, giving $M = 0.024$. This value of M fits as well as or better than $M = 0.074$ in the last line of Table 3.

Author's Closure

The author is pleased to have the test data of Drs. MacGregor and Coffin added to the discussion of his paper. It is encouraging to learn that they have been able to obtain such data without being troubled by what so obviously seems to be anisotropy in the material used by the author. The discussers believe that the method of measuring the strains at fracture may account for some

[5] Materials Engineer, National Bureau of Standards, Washington, D. C.

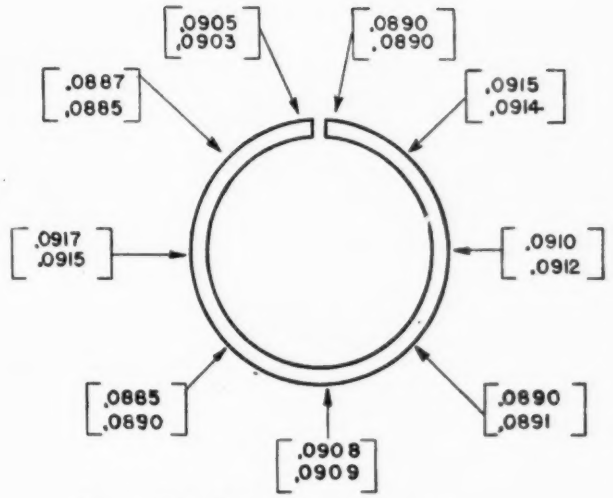

FIG. 1 WALL THICKNESS AT RUPTURE $\sigma_t/\sigma_a = \infty$

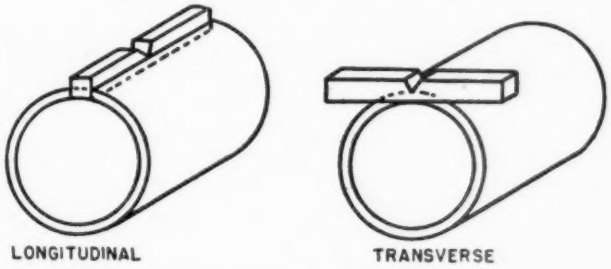

FIG. 2 ORIENTATION OF IMPACT SPECIMEN

of the apparent anisotropy. These methods of measuring strains at rupture may warrant some further discussion.

The scribed-network method will certainly yield the tangential and axial strains in the vicinity of the fracture. The only drawbacks involved are the tediousness of the process and the fact that the accuracy of any strain measurement decreases as the gage length is made shorter. For tubes where a local bulge might appear just before a longitudinal fracture occurs, this scribed network is undoubtedly the best of all known methods of determining the strains at fracture. In the tests reported in the paper there was no evidence of a localized bulge. Although, for safety reasons, the tubes had to be enclosed while they were under pressure, some of the tubes were measured shortly before fracture occurred. For example, in Fig. 9 of the paper it can be seen that the next to the last test point is quite close to the rupture point. Yet at that point the specimen was only 0.003 in. out of round. Furthermore, it cannot be said that the wall of the tube necked down in thickness at the point where fracture occurred.

Fig. 1 of this closure shows the wall thickness around the tube at the section where fracture started. These measurements which were made with ball-point micrometers show some irregularities in the wall thickness, but to the author they indicate that up to rupture the tube was loaded symmetrically and that the increase in mean circumference or mean diameter was a good measure of the tangential strain at fracture. If a scribed network had been used it is very probable that the results would have been unchanged.

An attempt will now be made to reply to Dr. Osgood's remarks. The sketch in Fig. 2 of this closure will answer the question concerning the orientation of the notches. About the anisotropy due to machining, the author can only admit the possibility of such a condition. However, such machining detriments as scratches and toolmarks would tend to lessen the strength of the specimen in the axial rather than in the tangential direction. The location, in the original bar, of a particular specimen is not known. The stresses at rupture in all specimens were based upon the dimensions of the tube at the location of the rupture and at the time the rupture occurred. For the specimens where $\sigma_t/\sigma_a = 0.775$, 0.800, and 0.875, respectively, there was no evidence of a bulge existing before the tubes ruptured. The author agrees with Dr. Osgood's statement in his last paragraph. It would have been more logical to have used the mean circumference as a measure of the effective width of the tubular specimen.

In regard to the energy data, the author is aware that many questions still remain to be answered. The energy represented by the stresses set up in the necked or bulged regions should be taken into account. This, unfortunately, is not easy to do. An attempt was made to calculate the tangential stress in the necked region of the pure-tension test. These calculations were based on assumptions that all bending stresses could be neglected and that the shape and thickness of the specimen could be represented by simple mathematical expressions. For energy determination it would be necessary to have, in addition to the stress, a history of the tangential strain, and since no record of the profile of the neck was obtained as the neck developed it would have required further assumptions to calculate the energy due to this component of the stress. For these reasons Table 2 of the paper does not contain the energies resulting from the stresses set up in the necked regions.

The Structural Efficiency of Wing Covers[1]

H. L. COX,[2] H. E. SMITH,[2] AND F. T. BARWELL.[2] The conception of "continued cellularization" introduced by the authors represents an interesting method of approach to the general problem and one which leads naturally to the conception of a continuous expanded filling in a sandwich structure. On the other hand, we suggest that the authors have been overhasty in applying this conception, and cannot accept their conclusion that "the ideal web has a vanishingly small area." It appears to us that the authors' Equation [4] is in error, because the cellular web has not the same effective flexural rigidity laterally as longitudinally. Lateral deformation can occur merely by flexure of the thin vertical faces in Fig. 2, the cells of the web being thus deformed in shear. When this effect is taken into account the buckling stress for the cellular web is reduced very considerably.

Moreover, even in relation to flexure longitudinally, the possibility of shear deformation of the webs must not be overlooked. In general the web of a beam fulfills two functions, (*a*) to hold the flanges at a fixed distance apart, and (*b*) to prevent relative lateral movement of the flanges. The effect of shear deformation in reducing the buckling stress of a beam is well known, and as the web is more and more highly "cellularized," the shear stiffness of the web will be progressively reduced. The conditions for the optimum structure when this effect is taken into account become very complex.

Nor is it safe to ignore the function (*a*) of the web. In ordinary structural engineering the thinnest practical webs fulfill this function virtually completely; but a highly cellularized structure must be much less adequate in this respect and the possibility of local wrinkling of the flanges of the beam occurring partly as

[1] By A. F. Donovan, Martin Goland, and J. N. Goodier, published in the March, 1945, issue of the JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 67, 1945, p. A-8.

[2] Department of Scientific and Industrial Research, Engineering Division, National Physical Laboratory, Teddington, Middlesex, England.

a result of extension or compression of the web through the thickness of the beam must be considered. The conditions governing this type of instability are not yet fully established; the problem presents special difficulties on account of the anisotropic characteristics of cellular webs. In addition there are indications that failure of the web to fulfill function (*a*) may very seldom represent a limiting design condition, because inadequacy to fulfill function (*b*) may usually be exclusively important. However, the possible unimportance of this "Brazier effect" in practical cases must not be presumed *ab initio*.

Expanded materials of the solid foam type represent a class of highly cellularized materials, and the development of sandwich structures follows the principles laid down by the authors. It is interesting therefore to notice that as the degree of expansion of a solid foam is increased, the mechanical properties are reduced more rapidly than the density; in particular for several materials there appears to be a critical density below which the materials become definitely spongelike. It is one of the aims of research at present in progress in this country to examine this correlation quantitatively and to attempt to establish a theoretical basis for the mechanical properties of foams in relation to the properties of the solid base material.

Finally we would refer to the work of two of the writers in relation to the problem of least weight of structures of more normal types.[3]

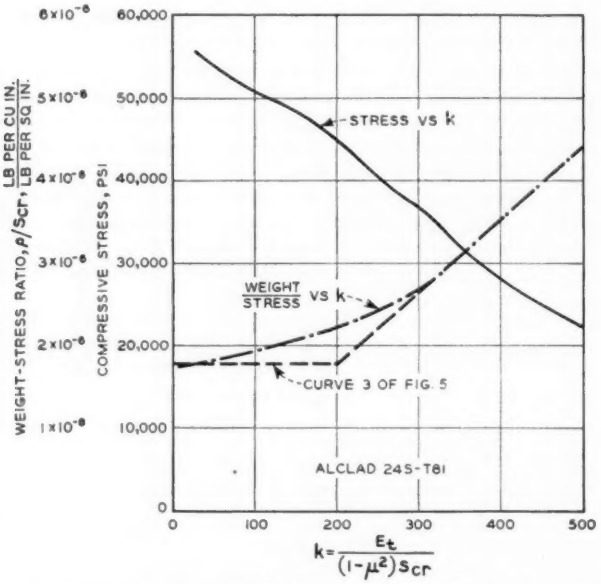

FIG. 1 TYPICAL COMPRESSIVE STRESS-STRAIN AND STRESS-TANGENT MODULUS CURVES

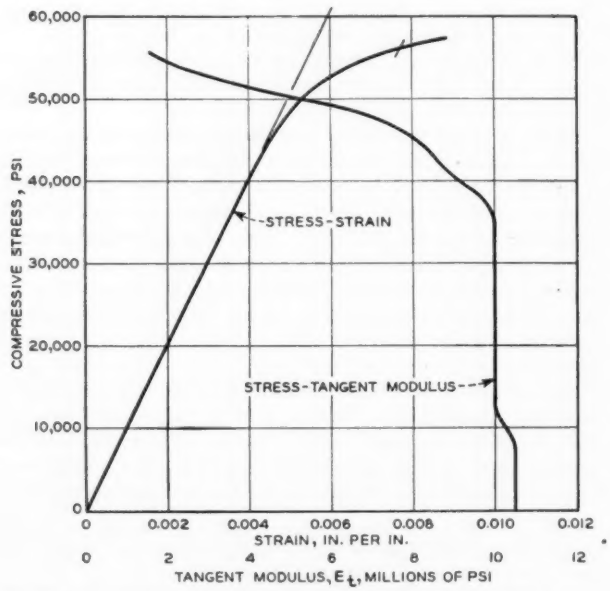

FIG. 2 RELATIONS BETWEEN *k* AND STRESS, AND BETWEEN *k* AND WEIGHT-STRESS RATIO

MARSHALL HOLT.[4] The suggestion made by the authors that the sharp bends in the curves of Fig. 5 of the paper might be relieved is a good one. As the curves are now drawn, it is tacitly assumed that the stress-strain curves are simply straight lines with a maximum value of stress equal to the compressive yield strength. Actually of course the stress-strain curves are not as simple as this since the curves depart gradually from the initial modulus line, and the yield strengths are merely arbitrarily chosen points on the curves. Any method used for rounding the curves in Fig. 5 should take into account the variable slope of the stress-strain curve and consequent variable effective modulus. Such a procedure for Alclad 24S-T81 is indicated in Figs. 1 and 2 of this discussion, in which the tangent modulus or slope of the stress-strain curve has been taken as the effective modulus.

A typical compressive stress-strain curve for Alclad 24S-T81, having a value of compressive yield strength equal to the minimum specified tensile yield strength, is shown in Fig. 1 herewith. Also shown is the relation between stress and tangent modulus. Fig. 2 shows the relation between stress and k as determined from Equation [14] of the paper, and the assumption that Poisson's ratio is constant for stresses above as well as in the elastic stress range. In this case

$$k = \frac{E_t}{(1 - \nu^2)S} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The curve for comparing weights of panels was obtained by plotting the foregoing values of k against the factor ρ/S. This curve for Alclad 24S-T81 is also shown in Fig. 2 of this discussion. When compared with curve 3 in Fig. 5 of the paper, also shown in Fig. 2 herewith, it appears to give a reasonable rounding. The other curves in Fig. 5 might be rounded in a similar manner. It would not be surprising if the relative positions of the curves change for restricted ranges of the value of k.

In the determination of the distribution efficiency of an actual panel by comparison of its weight with that of an ideal panel, it would seem more reasonable to make the comparison on the basis of the ultimate load developed by the actual panel. In the numerical example, the panel is unduly penalized since it was built sturdy enough to support 192,500 lb, but given credit for supporting only 146,500 lb. Perhaps the trouble lies in the definition of effective area and our inability to determine it exactly

AUTHORS' CLOSURE

The problem the authors originally set themselves was to formulate an ideal compression cover to belong to and serve as a standard for the whole class of stiffened sheet constructions which buckle in simple two-way flexure. It was realized, too late to affect the present paper, that preoccupation with the simple flexural type of deformation had led to an "ideal" construction which escapes this classification and that the problem must be

[3] Two papers in process of publication by the British Aeronautical Research Committee, in the R. and M. series, Nos. 1922 and 1923.

[4] Research Engineer, Aluminum Company of America, Aluminum Research Laboratories, New Kensington, Pa.

reconsidered, admitting shearing flexibility and extensibility of the core or webs in the direction of the thickness.

Apart from this, Equation [4] is not actually in error because the cellular web has not the same rigidity laterally and longitudinally. For since the limiting case is an evanescent web or core, there is no objection to making it cellular both ways like a building divided into small rooms. Moreover, so little core material is required to prevent premature buckling of the sheets on the core as an elastic foundation that the evanescent web could still reasonably be retained as the ideal. But when the requirement of shear rigidity is considered, it appears that an appreciable amount of material must be assigned to the core. When the shearing deformation of the core is important, the extensibility in the thickness, and variation of curvature through the thickness also become important, and the analysis becomes much more difficult, as Messrs. Cox, Smith, and Barwell have indicated.

It has been found possible, however, to arrive at the critical load of a sandwich plate (continuous isotropic core) taking all these things into account, and this solution is now at a stage where numerical evaluation for any given case is feasible. It is not obvious, however, that the continuous core represents the best use of the material. The method of weight comparison developed by Messrs. Cox, Smith, and Barwell is clearly of great value in determining the relative merits of various possible constructions. For the setting of a standard by which to measure structural efficiency, the question of what is the ideal construction remains open.

As Mr. Holt suggests it may, except where buckling is definitely not wanted, be preferable to make comparisons on the basis of ultimate loads. The load to be used must of course be calculated for the ideal standard. In beginning this study the authors chose first to regard buckling as failure, the difficulties of reliable calculation being then least.

A New Design Criterion for Wire Rope[1]

Shortridge Hardesty.[2] The design criterion developed by the authors, $B = 2T/UdD$, contains the *total* tension in the rope in the numerator, and the *unit* tensile strength of the wire in the denominator. It is interesting to note the form which the criterion takes when the unit tensile strength of the wire is replaced by the ultimate strength of the rope, which results in putting *total* values in both numerator and denominator.

Since the ultimate strength of the rope is approximately 85 per cent of the sum of the strengths of the individual wires, and since the metallic area of a wire rope is approximately $0.4d^2$ for a 6 × 19 construction, and not much different for other hemp-center constructions, the ultimate strength of the rope is approximately

$$U = 0.85\,Au = 0.85 \times 0.4d^2u = 0.34ud^2$$

in which U is the ultimate strength of the rope in pounds, and u is the ultimate strength of the wire in pounds per square inch. From this we find

$$u = \frac{3U}{d^2}$$

Substituting the foregoing value for the unit strength of the wire in the authors' criterion, there results

$$B = \frac{2Td}{3UD}$$

It will be noted that T/U is the safety factor of the rope, and that d/D is the ratio of the diameter of the rope to the diameter of the sheave. It is therefore evident that the criterion is merely the product of the safety factor by the rope-sheave diameter ratio, which factors have usually been considered the determining ones in wire-rope design.

The writer's principal experience with wire ropes has been in connection with vertical-lift bridges, for which purpose unusually long rope life is desired. The movable-bridge specifications of the American Railway Engineering Association require a safety factor of $^1/_{10}$ for counterweight ropes and $^1/_6$ for operating ropes, as the latter ropes can be replaced more readily. The rope-sheave ratio is required to be $^1/_{75}$ for counterweight ropes and $^1/_{45}$ for operating ropes. Substituting these values in the criterion given, there results

$$\text{Counterweight ropes } {}^2/_3 \times {}^1/_{10} \times {}^1/_{75} = 0.0009$$
$$\text{Operating ropes } {}^2/_3 \times {}^1/_6 \times {}^1/_{45} = 0.0025$$

The writer has considered the A.R.E.A. requirements for counterweight ropes unnecessarily conservative, and has generally used safety factors ranging from $^1/_8$ to $^1/_{7.5}$ and rope-sheave ratios ranging from $^1/_{80}$ to $^1/_{70}$. This means that in our practice the criterion has ranged between the two values

$${}^2/_3 \times {}^1/_8 \times {}^1/_{80} = 0.0011$$
$${}^2/_3 \times {}^1/_{7.5} \times {}^1/_{70} = 0.0013$$

Fig. 3 of the authors' paper indicates that the 0.0013 value is low enough to give long life for the rope, and that the 0.0011 value is well on the safe side.

B. L. Lonngren.[3] In making comparisons of wire ropes, running over sheaves, the writer has used for some time past a design criterion

$$C = \frac{\text{Breaking strength of rope}}{\text{Load on rope}} \times \frac{\text{Drum diameter}}{\text{Rope diameter}} = \frac{U_{\text{rope}}}{T} \times \frac{D}{d}$$

with the breaking strength of rope U_{rope} obtained directly from the rope manufacturers' catalogues. The quotient

$$\frac{U_{\text{rope}}}{T}$$

is the factor of safety in tension.

The breaking strength of a rope in tension is

$$U_{\text{rope}} = k_1 \times \frac{\pi d^2}{4} \times U$$

where U is the ultimate tensile strength of a wire in pounds per square inch, and k_1 is a constant, depending upon the rope cross section, which multiplied with the rope area gives the net wire area in square inches. If $k_1 \times \frac{\pi}{2}$ is marked k, criterion C can be written

$$C = k \times \frac{d^2U}{2T} \times \frac{D}{d} = k \times \frac{UdD}{2T}$$

assuming that $k = 1$, it is interesting to note that

[3] Engineer, Bucyrus Erie Company, South Milwaukee, Wis. Mem. A.S.M.E.

$$C = \frac{UdD}{2T}$$

or the inverted expression for

$$B = \frac{2T}{UdD}$$

as proposed by the authors.

Authors' Closure

The authors were pleased to learn that the values of T/U' and d/D chosen by Mr. Hardesty on the basis of his extensive experience led to the figure for B, suggested by their interpretation of the published experimental data. They feel, however, that this fact emphasizes all the more a trouble with present design.

The usual design procedure, as given by Mr. Hardesty and stated in wire-rope handbooks, catalogues, and articles, is to choose the rope to carry the tensile force and then fix the sheave diameter in ratio to the rope diameter. Obviously this procedure leads to a safe and useful wire-rope-and-sheave combination. One of the main points of the paper was that such a design is only one of many having as long a life. Some other rope, possibly a much larger one on a considerably smaller sheave, might be better suited to the job.

The transformation of $B = 2T/UdD$ to const$(T/U')(d/D)$ was given and analyzed in our complete report to the Whiting Corporation. However, rather than being a preferred form, it should be avoided, because it will lead the designer to continue to think in terms of tension and bending separately and so unduly restrict his choice of rope and sheave. Furthermore, the multiplication of two stresses is not physically in line with our usual concepts of design. The authors believe that the dimensionless number B in its proposed form is most convenient for practical use. It has the decided advantage of indicating substitution of a fatigue limit for the ultimate strength when the action of wire rope is more clearly understood and the controlling stress definitely known.

The criterion C, apparently used successfully by Mr. Lonngren, serves as a welcome additional check. It also, however, is split into two terms and so may restrict desirable freedom of choice.

Thermodynamic Properties of Air

Thermodynamic Properties of Air. By Joseph H. Keenan and Joseph Kaye. John Wiley & Sons, Inc., New York, N. Y., 1945. Cloth $7^1/_2 \times 10$ in., iii and 73 pp., $2.25.

Reviewed by John G. Lee[1] and Newman A. Hall[2]

In his earlier volume on the "Thermodynamic Properties of Steam," Professor Keenan established basic data which has become authoritative for analytical work on steam power. The presentation and basis for the present companion volume on the "Thermodynamic Properties of Air" is of such excellent caliber that it will be accepted as equally authoritative.

Recent spectroscopic research has provided a physical basis for accurate thermodynamic data on gases that wholly supersedes earlier calorimetric measurements. The properties of nitrogen and oxygen as established by Johnston and interpolated by Heck[3] form the basis for the tables.

A comparison with a recent recalculation of the basic thermodynamic data[4] indicates a maximum difference in constant pressure specific heat of less than $^2/_{10}$ of 1 per cent. It is very probable, accordingly, that future refinements will have a negligible effect on the acceptance of these tables as standard.

The data is arranged in a manner similar to that of the earlier abbreviated presentation under the same title.[5] The arrangement of tabular data is very convenient for the solution of practical problems.

The small effect of molecular interaction forces in air at low pressures permits the assumption of the perfect equation of state. Accordingly, the primary energy functions may be expressed as functions of temperature alone. Table 1 presents enthalpy, internal energy, and constant-pressure entropy with reference to a base temperature of 400 F abs. In the same table are given isentropic pressure and volume ratios relative to the state at 400 F abs. The tabular intervals are 1 F from 300 F abs to 3000 F abs, and 10 F from 3000 F abs to 6500 F abs.

Table 2 lists the isothermal entropy change, $R \log_e N$, for pressure ratios N at tabular intervals of 0.01 from 1 to 10.

Table 3 lists constant volume and constant pressure specific heat, specific heat ratio, velocity of sound, and critical mass flow for the temperature range 200 F abs to 6400 F abs; and viscosity, thermal conductivity, and Prandtl number for the range 400 F abs to 2400 F abs.

A series of functions of pressure ratio and polytropic exponent are listed in Tables 4 through 9. Four-place logarithmic tables to the base 10 and base e are included as well as Fahrenheit and Centigrade conversion tables. A convenient listing of conversion factors completes the volume.

A full discussion of the source material for Tables 1 and 3 is given. Also included are a series of examples amply illustrating the use of all the tables.

Theoretical Analysis of Perforated Shear Webs

By CHU-KIA WANG,[1] DENVER, COLO.

This paper presents theoretical studies on perforated shear webs. The procedures provide for the analysis of the plane-stress condition in an infinitely long plate of finite width with a plain circular hole and in a rectangular or square plate with a circular hole, which may be plain, or reinforced with rim, or ring, or both. Numerical results are obtained for infinitely long and square plates with plain holes of different sizes, and in the case of square plates, also with various ways of reinforcing.

Nomenclature

The following nomenclature is used in the paper:

- F = stress function
- F_a = approximate stress function
- F_t = true stress function
- n = an integer
- m = particular value of n
- i = number of terms in series considered
- x, y = rectangular co-ordinates
- ρ, θ = polar co-ordinates
- $\widehat{xx}, \widehat{yy}, \widehat{xy}$ = stress components in rectangular co-ordinates
- $\widehat{\rho\rho}, \widehat{\theta\theta}, \widehat{\rho\theta}$ = stress components in polar co-ordinates
- q = uniform shearing stress along edges of shear web
- N, S = normal and tangential co-ordinates
- $2a, 2b$ = dimensions of rectangular panel
- f, g, p, q = arbitrary coefficients in stress function
- h = radius of circular hole
- k = outer radius of ring
- t = thickness of plate
- H, K = indexes referring to region H (ring) and region K (outside of ring)
- μ = Poisson's ratio
- A = sectional area of rim
- σ = direct normal stress in rim
- u, v = radial and tangential displacements

Introduction

A flat rectangular plate under the action of pure uniform shearing stress along its edges is a common structural member. Such a plate may be called a shear web. For purposes of weight saving or access, one or more circular holes may be made in the middle of the shear web. The holes may be plain or reinforced around the rim in various ways. Shear webs with plain or reinforced circular holes in them are called perforated shear webs.

The determination of the stress components at any point of a perforated shear web presents itself as a problem of theoretical analysis. Howland and Stevenson[2] had a rigorous mathematical solution for the analysis of the stresses in a perforated strip, when the boundary conditions at the parallel edges and those around the hole were known. Hengst[3] obtained an approximate solution of the tangential stresses at the rim of a plain circular hole in the center of a square plate under the action of equal tensile stresses on the four sides, or the action of equal tensile and compressive stresses on the two pairs of opposite sides. Timoshenko[4] used the theory of bending of curved bars in obtaining an approximate solution of the stress condition around a circular hole reinforced with a bead. Gurney[5] had an exact solution for plane-stress distribution of the problem of an infinite plate with a circular hole reinforced by a rectangular bead. Beskin[6] determined the stress distribution around strengthened circular holes in plates subjected to edge loads at infinity. The present paper deals with the stress analysis of an infinitely long plate of finite width with a plain circular hole and of a finite rectangular plate with a circular hole, either plain or reinforced in various ways.

Infinitely Long Plate of Finite Width With a Plain Circular Hole

Let F be the Airy's stress function. Then the stress components are:

In rectangular co-ordinates

$$\widehat{xx} = \frac{\partial^2 F}{\partial y^2} \quad \widehat{yy} = \frac{\partial^2 F}{\partial x^2} \quad \widehat{xy} = -\frac{\partial^2 F}{\partial x \partial y} \qquad [1]$$

In polar co-ordinates

$$\widehat{\rho\rho} = \frac{1}{\rho^2}\frac{\partial^2 F}{\partial \theta^2} + \frac{1}{\rho}\frac{\partial F}{\partial \rho} \quad \widehat{\theta\theta} = \frac{\partial^2 F}{\partial \rho^2} \quad \widehat{\rho\theta} = -\frac{\partial}{\partial \rho}\left(\frac{1}{\rho}\frac{\partial F}{\partial \theta}\right) \qquad [2]$$

The solution of a two-dimensional stress problem is to find F such that $\widehat{xx}$, $\widehat{yy}$, $\widehat{xy}$, as expressed by Equation [1], or $\widehat{\rho\rho}$, $\widehat{\theta\theta}$, $\widehat{\rho\theta}$, as expressed by Equation [2] satisfies prescribed values at the specified boundaries with the further requirement that $\nabla^4 F = 0$.

In the present case, following the procedure of Howland and Stevenson,[2] let

$$F = F_0 + F_1 + F_2 + F_3 + F_4 + \ldots$$

F_0 is the stress function for an infinite plate under action of pure shear; F_1 cancels the shearing and normal stresses at the rim of the hole, but introduces undesirable stresses at the straight boundaries $x = \pm a$, Fig. 1. Also, F_2 cancels such stresses at

[6] "Strengthening of Circular Holes in Plates Under Edge Forces," by Leon Beskin, Journal of Applied Mechanics, Trans. A.S.M.E., 1944, p. A-140.

the straight boundaries but introduces new stresses around the hole. Again, F_1 cancels such stresses around the hole, and so on.

For an infinite plate under action of pure shearing stress q

$$F_0 = -qxy = -\frac{1}{2} q\rho^2 \sin 2\theta \quad \ldots\ldots\ldots\ldots [3]$$

from which

$$\widehat{\rho\rho} = +q \sin 2\theta \quad \widehat{\theta\theta} = -q \sin 2\theta \quad \widehat{\rho\theta} = +q \cos 2\theta$$

The next stress function F_1 must be constructed to cancel these values of $\widehat{\rho\rho}$ and $\widehat{\rho\theta}$ on the circle $\rho = h$. If we assume

$$F_1 = \left(\frac{F_2^{(0)}}{\rho^2} + G_2^{(0)}\right) \sin 2\theta$$

the relevant stress components are

$$\widehat{\rho\rho} = -2\left[\frac{3F_2^{(0)}}{\rho^4} + \frac{2G_2^{(0)}}{\rho^2}\right] \sin 2\theta \quad \widehat{\theta\theta} = +\frac{6F_2^{(0)}}{\rho^4} \sin 2\theta$$

$$\widehat{\rho\theta} = +2\left[\frac{3F_2^{(0)}}{\rho^4} + \frac{G_2^{(0)}}{\rho^2}\right] \cos 2\theta$$

and these will be found to cancel the tractions on the circle $\rho = h$ if

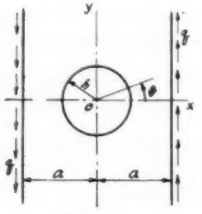

FIG. 1

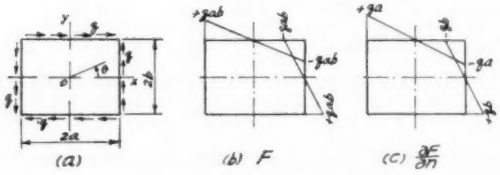

FIG. 2

$$F_2^{(0)} = q\left(-\frac{1}{2} h^4\right) \qquad G_2^{(0)} = q\,(+h^2)$$

Thus

$$F_1 = q\left[h^2 - \frac{1}{2}\frac{h^4}{\rho^2}\right] \sin 2\theta \quad \ldots\ldots\ldots\ldots [4]$$

It is to be noted that $F_0 + F_1$ gives the stress function for an infinitely large plate with a circular hole under action of pure shear

$$F_0 + F_1 = q\left[-\frac{\rho^2}{2} + h^2 - \frac{1}{2}\frac{h^4}{\rho^2}\right] \sin 2\theta \quad \ldots\ldots [5]$$

The general form[7] of the solution of the type considered can be expressed by

$$\sum_1^\infty F_n = \sum_1^\infty \left\{\frac{f_{2n}}{\rho^{2n}} + \frac{g_{2n}}{\rho^{2n-2}} + p_{2n}\rho^{2n} + q_{2n}\rho^{2n+2}\right\} \sin 2n\theta. \quad [6]$$

According to Howland and Stevenson,[2] the coefficients in Equation [6] can be evaluated as follows

$$\left.\begin{aligned} f_{2n} &= \sum_{(r)} F_{2n^{(r)}} \qquad p_{2n} = \sum_{(r)} P_{2n^{(r)}} \\ &= \sum_{p=1}^{\infty} \left\{{}^{2n}\kappa_{2p} f_{2p} + {}^{2n}\mu_{2p} g_{2p}\right\} \\ g_{2n} &= \sum_{(r)} G_{2n^{(r)}} \qquad q_{2n} = \sum_{(r)} Q_{2n^{(r)}} \\ &= \sum_{p=1}^{\infty} \left\{{}^{2n}\nu_{2p} f_{2p} + {}^{2n}\omega_{2p} g_{2p}\right\} \end{aligned}\right\} \ldots [7]$$

where

$$\left.\begin{aligned} F_{2n^{(r+1)}} &= \sum_{p=1}^{\infty} \left\{{}^{2n}s_{2p} F_{2p^{(r)}} + {}^{2n}t_{2p} G_{2p^{(r)}}\right\} \\ G_{2n^{(r+1)}} &= \sum_{p=1}^{\infty} \left\{{}^{2n}u_{2p} F_{2p^{(r)}} + {}^{2n}v_{2p} G_{2p^{(r)}}\right\} \\ {}^{n}s_p &= h^{2n}\left\{(n-1)\,{}^{n}\kappa_p + n h^2\,{}^{n}\nu_p\right\} \\ {}^{n}u_p &= -h^{2n-2}\left\{n\,{}^{n}\kappa_p + (n+1)h^2\,{}^{n}\nu_p\right\} \\ {}^{n}t_p &= h^{2n}\left\{(n-1)\,{}^{n}\mu_p + n h^2\,{}^{n}\omega_p\right\} \\ {}^{n}v_p &= -h^{2n-2}\left\{n\,{}^{n}\mu_p + (n+1)h^2\,{}^{n}\omega_p\right\} \end{aligned}\right\} \ldots [8]$$

Values of ${}^{n}\kappa_p$, ${}^{n}\mu_p$, ${}^{n}\nu_p$, and ${}^{n}\omega_p$ for even values of p and n are given by Howland and Stevenson.[2]

The numerical procedure is as follows, for a particular value of h:

1 Compute ${}^{n}s_p$, ${}^{n}t_p$, ${}^{n}u_p$, and ${}^{n}v_p$ for various even values of p and n.

2 With known values of $F_2^{(0)}$ and $G_2^{(0)}$ as base, compute $F_{2n}^{(r+1)}$ and $G_{2n}^{(r+1)}$ for increasing values of n and r.

3 Compute f_{2n}, g_{2n}, p_{2n}, and q_{2n} for increasing values of n. After the arbitrary constants in the stress function $F = F_0 + \sum_1^\infty F_n$ have been thus determined, the stress components follow directly by the application of Equation [2].

Rectangular Plate With a Plain or Reinforced Circular Hole

The stress function F, for the case of a rectangular plate with a circular hole, either plain or reinforced with rim only, can be expressed as the sum of an infinite series in sin $2n\theta$ with four arbitrary coefficients in each term. If only i terms are considered, then $2i$ of the conditions required for the determination of the $4i$ coefficients are supplied by the boundary conditions at the rim of the hole. The assumption that the area integral of the square of the difference between the true $\nabla^2 F$ and that as approximated by the sine series shall be a minimum, an assumption which was introduced by Hengst,[3] furnishes the other $2i$ conditions. An application of Green's theorem in the plane reduces this area integral to a line integral around the boundary. The compatibility condition $\nabla^4 F = 0$, by nature of the assumed expression for the stress function, is always satisfied. With a finite number of terms in the series, the boundary conditions at the straight edges are only approximately satisfied; the degree of approximation depends on the number of terms used in the series.

Let the stress function approximated by the first i terms of the series be

[7] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., New York, N. Y., 1934, p. 114.

$$F = \sum_1^i \left(\frac{f_{2n}}{\rho^{2n}} + \frac{g_{2n}}{\rho^{2n-2}} + p_{2n}\rho^{2n} + q_{2n}\rho^{2n+2} \right) \sin 2n\theta \ldots [9]$$

from which

$$\frac{\partial F}{\partial \rho} = \sum_1^i \left(\frac{-2nf_{2n}}{\rho^{2n+1}} - \frac{2(n-1)g_{2n}}{\rho^{2n-1}} + 2np_{2n}\rho^{2n-1} + 2(n+1)q_{2n}\rho^{2n+1} \right) \sin 2n\theta \ldots [10]$$

$$\widehat{\rho\rho} = \sum_1^i \left(\frac{-2n(2n+1)f_{2n}}{\rho^{2n+2}} - \frac{2(n+1)(2n-1)g_{2n}}{\rho^{2n}} - 2n(2n-1)p_{2n}\rho^{2n-2} - 2(n-1)(2n+1)q_{2n}\rho^{2n} \right) \sin 2n\theta \ldots [11]$$

$$\widehat{\theta\theta} = \sum_1^i \left(+ \frac{2n(2n+1)f_{2n}}{\rho^{2n+2}} + \frac{2(n-1)(2n-1)g_{2n}}{\rho^{2n}} + 2n(2n-1)p_{2n}\rho^{2n-2} + 2(n+1)(2n+1)q_{2n}\rho^{2n} \right) \sin 2n\theta \ldots [12]$$

$$\widehat{\rho\theta} = \sum_1^i \left(+ \frac{2n(2n+1)f_{2n}}{\rho^{2n+2}} + \frac{2n(2n-1)g_{2n}}{\rho^{2n}} - 2n(2n-1)p_{2n}\rho^{2n-2} - 2n(2n+1)q_{2n}\rho^{2n} \right) \cos 2n\theta \ldots [13]$$

$$\nabla^2 F = \widehat{\rho\rho} + \widehat{\theta\theta} = \sum_1^i \left(-\frac{4(2n-1)g_{2n}}{\rho^{2n}} + 4(2n+1)q_{2n}\rho^{2n} \right) \sin 2n\theta$$

Let

$$-\frac{4(2n-1)}{\rho^{2n}} \sin 2n\theta = \phi_{2n}{}^g \qquad 4(2n+1)\rho^{2n} \sin 2n\theta = \phi_{2n}{}^q$$

Then

$$\nabla^2 F = \sum_1^i (g_{2n}\phi_{2n}{}^g + q_{2n}\phi_{2n}{}^q) \ldots [14]$$

Let Q be the area integral of the square of the error in $\nabla^2 F$

$$Q = \int\int \left[\nabla^2 F - \sum_1^i (g_{2n}\phi_{2n}{}^g + q_{2n}\phi_{2n}{}^q) \right]^2 dxdy = \min$$

In order that Q be a minimum, the following conditions must be satisfied for each value of m

$$\frac{\partial Q}{\partial g_{2m}} = 0 \qquad \frac{\partial Q}{\partial q_{2m}} = 0$$

Then

$$\frac{\partial Q}{\partial g_{2m}} = \int\int \frac{\partial}{\partial g_{2m}} \left[\Delta^2 F - \sum_1^i (g_{2n}\phi_{2n}{}^g + q_{2n}\phi^q{}_{2n}) \right]^2 dxdy = 0$$

or

$$\int\int \left[\nabla^2 F - \sum_1 (g_{2n}\phi_{2n}{}^g + q_{2n}\phi_{2n}{}^q) \right] \frac{\partial}{\partial g_{2m}} \left[\nabla^2 F - \sum_1^i (g_{2n}\phi_{2n}{}^g + q_{2n}\phi_{2n}{}^q) \right] dxdy = 0$$

or

$$\sum_1^i \int\int (g_{2n}\phi_{2n}{}^g + q_{2n}\phi_{2n}{}^q)\phi_{2m}{}^g dxdy = \int\int \nabla^2 F \phi_{2m}{}^g dxdy \ldots [15]$$

The right side of Equation [15] can be written as

$$\int\int \nabla^2 F \phi_{2m}{}^g dxdy = \int\int (\phi_{2m}{}^g \nabla^2 F - F\nabla^2 \phi_{2m}{}^g) dxdy = \int_c \left(\phi_{2m}{}^g \frac{\partial F}{\partial N} - F \frac{\partial \phi_{2m}{}^g}{\partial N} \right) dS \ldots [16]$$

because $\nabla^2 \phi_{2m}{}^g = 0$ and by use of Green's theorem in the plane.[8] Substitution of Equation [16] into Equation [15] gives

$$\sum_1^i \int\int (g_{2n}\phi_{2n}{}^g + q_{2n}\phi_{2n}{}^q)\, \phi_{2m}{}^g dxdy = \int_c \left(\phi_{2m}{}^g \frac{\partial F}{\partial N} - F \frac{\partial \phi_{2m}{}^g}{\partial N} \right) dS \ldots [17]$$

In the same way, from $\dfrac{\partial Q}{\partial q_{2m}} = 0$

$$\sum_1^i \int\int (g_{2n}\phi_{2n}{}^q + q_{2n}\phi_{2n}{}^q)\phi_{2m}{}^q dxdy = \int_c \left(\phi_{2m}{}^q \frac{\partial F}{\partial N} - F \frac{\partial \phi_{2m}{}^q}{\partial N} \right) dS \ldots [18]$$

There are i equations each from Equations [17] and [18]. Thus $2i$ conditions are obtained for the determination of the constants in the stress function Equation [9].

The right side of Equation [17], or Equation [18] is the line integral around both the external and the internal boundaries. F_t and $\dfrac{\partial F_t}{\partial N}$ around the external boundary depend only on the external loading and can be readily determined.[9] F_i and $\dfrac{\partial F_i}{\partial N}$ around the internal boundary are both equal to zero for a plain hole, but are not yet known when the hole is reinforced with a rim. Nevertheless, we can substitute the approximate values of F_a and $\dfrac{\partial F_a}{\partial N}$, found by substituting h for ρ in Equations [9] and [10], into the right side of Equation [17] or Equation [18] for the internal boundary. Then we can transpose these terms involving f_{2n}, g_{2n}, p_{2n}, and q_{2n} to the left side. It should be noted that if the line integral goes counterclockwise at the external boundary, it must go clockwise at the internal boundary.

Expressions for the boundary conditions at the edge of the hole will now be considered. For a plain circular hole, $\widehat{\rho\rho}_h = 0$ and $\widehat{\rho\theta}_h = 0$ at $\rho = h$. Thus

$$\widehat{\rho\rho}_h = \sum_1^i \left\{ -\frac{2n(2n+1)f_{2n}}{h^{2n+2}} - \frac{2(n+1)(2n-1)g_{2n}}{h^{2n}} - 2n(2n-1)p_{2n}h^{2n-2} - 2(n-1)(2n+1)q_{2n}h^{2n} \right\} \sin 2n\theta = 0 \ldots [19]$$

[8] "Advanced Calculus," by William F. Osgood, The Macmillan Co., New York, N. Y., 1935, p. 224.

[9] "Graphostatics of Stress Functions," by H. M. Westergaard, Trans. A.S.M.E., vol. 56, 1934, pp. 141–150.

$$\widehat{\rho\theta}_h = \sum_1^i \left\{ + \frac{2n(2n+1)f_{2n}}{h^{2n+2}} + \frac{2n(2n-1)g_{2n}}{h^{2n}} - 2n(2n-1)p_{2n}h^{2n-2} - 2n(2n+1)q_{2n}h^{2n} \right\} \cos 2n\theta = 0 \quad [20]$$

In order to insure that the middle member of Equation [19] vanishes, the coefficients of $\sin 2\theta$, $\sin 4\theta \ldots \sin 2i\theta$ must each be zero. The same is true for Equation [20]. Thus $2i$ conditions are derived. When the hole is reinforced with a rim of area A, the equations of equilibrium of a segment of rim in the radial and tangential directions, Fig. 3, give

FIG. 3

$$\sigma A = \widehat{\rho\rho}_h ht \quad [21]$$

$$A\frac{\partial\sigma}{\partial\theta} + \widehat{\rho\theta}_h ht = 0 \quad [22]$$

Also, at $\rho = h$, the circumferential strain in the rim must be equal to that of the plate, or

$$\sigma = \widehat{\theta\theta}_h - \mu\,\widehat{\rho\rho}_h \quad [23]$$

Eliminating σ by the use of Equation [23], we have Equations [21] and [22] in the form

$$A\widehat{\theta\theta}_h - (\mu A + ht)\widehat{\rho\rho}_h = 0 \quad [24]$$

$$A\frac{\partial\widehat{\theta\theta}_h}{\partial\theta} - \mu A\frac{\partial\widehat{\rho\rho}_h}{\partial\theta} + \widehat{\rho\theta}_h ht = 0 \quad [25]$$

Making coefficients of $\sin 2\theta$, $\sin 4\theta \ldots \sin 2i\theta$ in Equations [24] and [25] each equal to zero, we derive $2i$ conditions.

For the case of a rectangular plate with a circular hole reinforced with a ring only or with both rim and ring, two different stress functions will have to be assumed, one for the ring (region H), and the other for the region outside of the ring (region K). Thus $8i$ conditions are required for the determination of the $8i$ arbitrary coefficients in the two assumed stress functions F_H and F_K: $2i$ from the boundary conditions at the rim (region H); $2i$ from the fundamental assumption by applying Equations [17] and [18] to region K; $4i$ from the continuity conditions at the outer circumference of the ring. These continuity conditions are as follows:

For equilibrium of forces at the common circular boundary $\rho = k$

$$\widehat{\rho\rho_k}^H t_H = \widehat{\rho\rho_k}^K t_K \quad [26]$$

$$\widehat{\rho\theta_k}^H t_H = \widehat{\rho\theta_k}^K t_K \quad [27]$$

For compatibility of displacements u in the radial direction and v in the tangential direction

$$u_k^H = u_k^K \quad [28]$$

$$v_k^H = v_k^K \quad [29]$$

Expressions for u and v are as follows:

$$u = \sum_1^i \left\{ + \frac{2n(1+\mu)f_{2n}}{\rho^{2n+1}} + \frac{2[(n+1)+\mu(n-1)]g_{2n}}{\rho^{2n-1}} - 2n(1+\mu)\rho^{2n-1}p_{2n} - 2[(n-1)+\mu(n+1)]\rho^{2n+1}q_{2n} \right\} \sin 2n\theta \quad [30]$$

$$v = \sum_1^i \left\{ - \frac{2n(1+\mu)f_{2n}}{\rho^{2n+1}} - \frac{2[(n-2)+\mu n]g_{2n}}{\rho^{2n-1}} - 2n(1+\mu)\rho^{2n-1}p_{2n} - 2[(n+2)+\mu n]\rho^{2n+1}q_{2n} \right\} \cos 2n\theta \quad [31]$$

NUMERICAL APPLICATIONS

For the infinitely long plate of finite width with a plain circular hole, numerical work is done for five cases with $h = 0.1a$, $0.2a$, $0.3a$, $0.4a$, and $0.5a$ (see Table 1).

For the plate with finite dimensions, numerical computation is done only for a square shear panel, which is antisymmetrical with respect to the x- and y-axes and symmetrical with respect to the lines $\theta = \pm \frac{\pi}{4}$. Therefore, in the expression for the stress function, n can only be odd. Only two terms, $n = 1$ and $n = 3$, are used in all examples. The variables considered in the different cases are as follows:

(*a*) Square shear panel with a plain circular hole:

5 examples; $h = 0.1a$, $0.2a$, $0.3a$, $0.4a$, or $0.5a$ (see Table 2).

(*b*) Square shear panel with a circular hole reinforced with rim only:

15 examples; $h = 0.1a$, $0.2a$, $0.3a$, $0.4a$, or $0.5a$.

Amount of reinforcing = 40 per cent, 100 per cent, or 200 per cent of original hole material (see Table 3).

(*c*) Square shear panel with a circular hole reinforced with ring only:

6 examples; $h = 0.5a$ $\quad t_H = 3t_K$ or $2t_K$

Amount of reinforcing = 40 per cent, 100 per cent, or 200 per cent of original hole material (see Table 4).

(*d*) Square shear panel with a circular hole reinforced with both rim and ring:

6 examples; $h = 0.5a$ $\quad t_H = 3t_K$ or $2t_K$

Amount of reinforcing = 40 per cent, 100 per cent, or 200 per cent of original hole material (see Table 5).

Curves for selected cases are presented as Figs. 4 to 6.

Check on Boundary Conditions

As previously stated, the solution of a two-dimensional stress problem is to find a stress function F, such that the resulting stresses satisfy prescribed values at the specified boundaries with the further requirement that $\nabla^4 F = 0$. In the present problem, no matter how many terms are used in the sine series for the

ary by Green's theorem in the plane. Thus, let F_t and F_a be the true and approximate stress functions. Then

$$Q = \int\int (\nabla^2 F_t - \nabla^2 F_a)^2 dxdy = \min$$

$$Q = \int\int (\nabla^2 F_t - \nabla^2 F_a)^2 dxdy = \int\int [(\nabla^2 F_t - \nabla^2 F_a)(\nabla^2 F_t - \nabla^2 F_a) - (F_t - F_a)(\nabla^4 F_t - \nabla^4 F_a)]dxdy$$

$$= \int_c \left[\nabla^2(F_t - F_a)\frac{\partial}{\partial N}(F_t - F_a) - (F_t - F_a)\nabla^2\frac{\partial}{\partial N}(F_t - F_a)\right] dS = \min$$

At the internal boundary: When the hole is plain, F_t, $\frac{\partial F_t}{\partial N}$, F_a, and $\frac{\partial F_a}{\partial N}$ are all zero; when there is a rim, F and $\frac{\partial F}{\partial N}$ at the circular boundary are treated as unknowns. So the error minimized, or the quantity Q, is due to incomplete satisfaction of the boundary conditions around the external boundary only.

The stresses $\widehat{xx}$ and $\widehat{xy}$ at the straight edges of the square shear panel are computed for five cases. At the right edge, $\widehat{xx}$ should be zero and $\widehat{xy}$ should be $+q$. The errors in $\widehat{xx}$ and $\widehat{xy}$ at the right edge from the mid-point to the upper right corner for the five cases are plotted in Fig. 7. The errors at the corners are quite large, especially for large holes. However, the disturbance across the upper right corner, which amounts to a force very nearly perpendicular to the diagonal, is compression when two

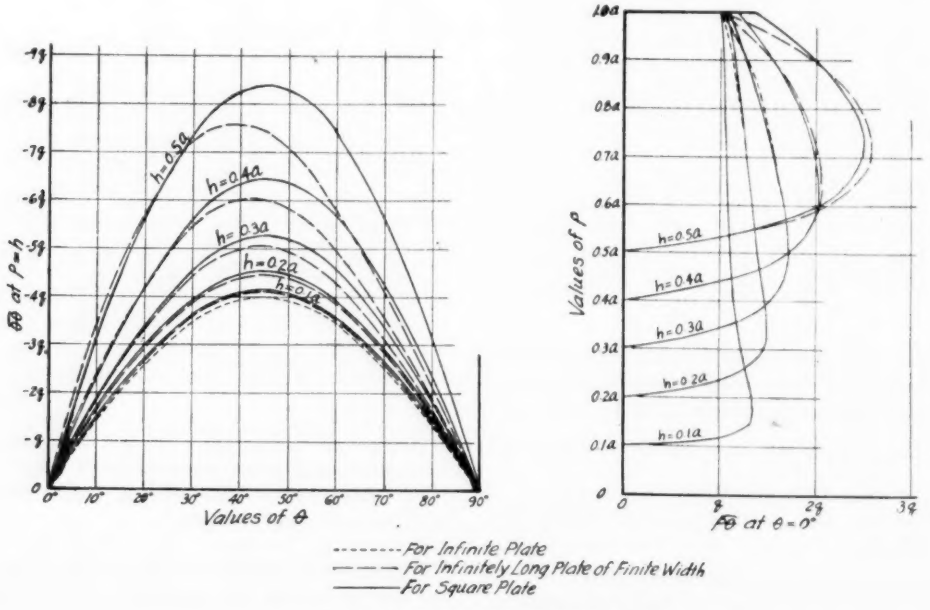

FIG. 4 PLAIN PERFORATIONS IN SHEAR WEBS

stress function, the compatibility condition $\nabla^4 F = 0$ and the internal boundary conditions are always satisfied. It is then logical to conclude that the fundamental assumption, that the area integral of the square of error in $\nabla^2 F$ shall be a minimum, must have something to do with the external boundary. This area integral can be reduced to a line integral around the boundterms are used and is tension when three terms are used. Thus the computed stress concentrations at the rim of the hole tend to be too large for two terms and too small for three terms. The closeness between the maximum $\widehat{\theta\theta}$ values 8.35q and 8.316q for the plain circular hole $h = 0.5a$ shows that the effect of corner disturbance is small.

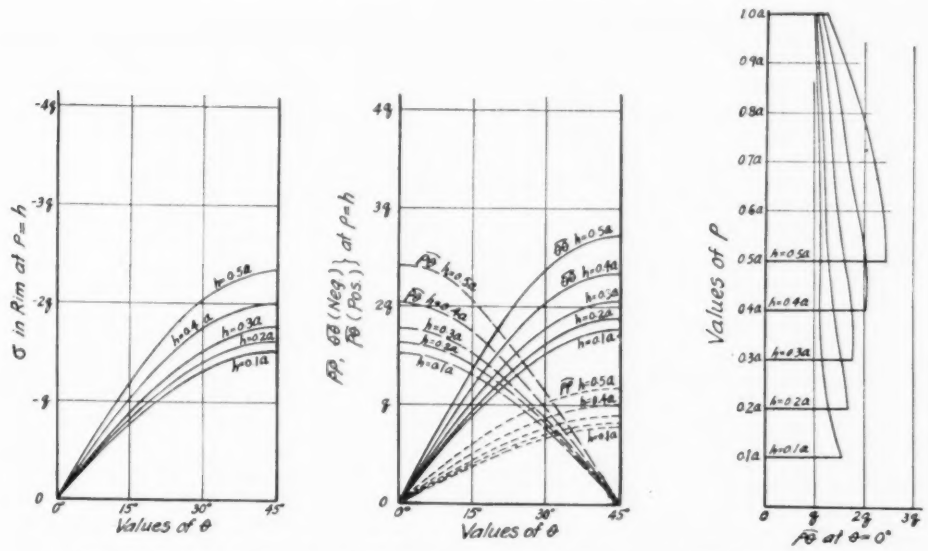

FIG. 5 SQUARE SHEAR PANEL WITH CIRCULAR HOLE REINFORCED WITH RIM ONLY
(Amount of reinforcing = 100 per cent hole material.)

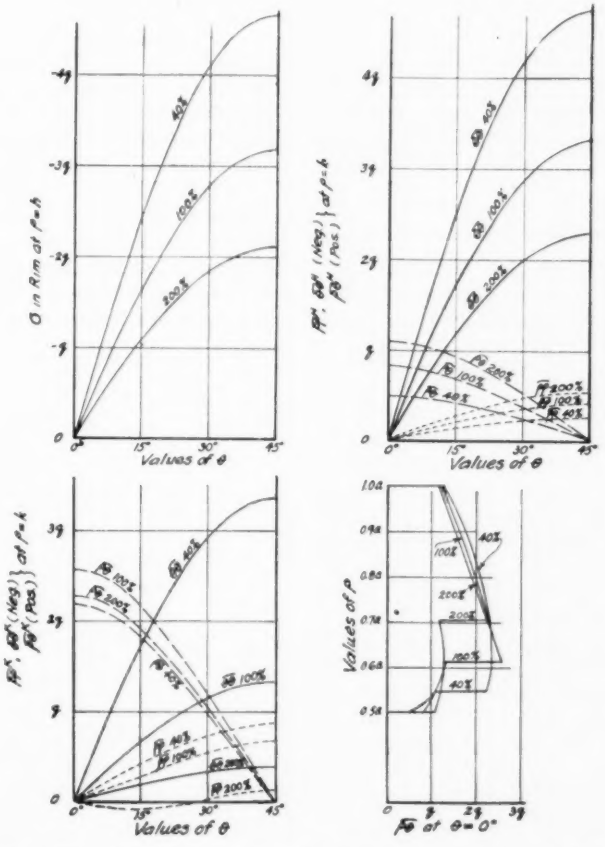

FIG 6 SQUARE SHEAR PANEL WITH CIRCULAR HOLE; EQUAL REINFORCEMENT IN RIM AND RING, $t_H = 2t_K$

DISCUSSION

The theoretical results, though giving some indication of the effects of such variables as hole diameter, amount and ways of reinforcement, etc., must await experimental data for justification. The chief uncertain factors are (1) the abrupt change of thickness at the outer radius of the ring where in the theoretical analysis the stresses are assumed to be uniformly transmitted from the thin plate to the thick ring, and (2) the nonuniform transmission of stress through the riveted or welded connection, while in the analysis the whole piece is considered monolithic.

The uncertainty involved in applying the theoretical results to flanged holes for the purpose of web-lightening in aeronautical

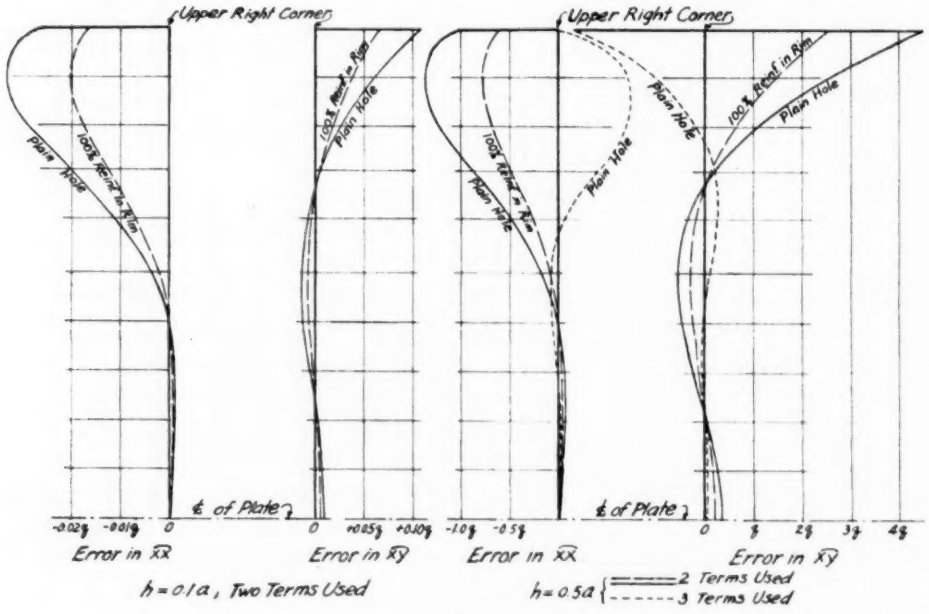

FIG. 7 CHECK ON BOUNDARY STRESSES

structures is even much greater. The flange is usually turned in one way at an angle. The action of this eccentric rim is unknown. When experimental data become available, the theoretical results may help the interpretation in regard to such variables as the hole diameter-panel length ratio, and the flange size.

ACKNOWLEDGMENT

The portion of the paper dealing with plain perforations was done while the author was a member of the Structures Department of the Research Laboratory, Curtiss-Wright Corporation, Airplane Division. The author wishes to thank Mr. Martin Goland, of the laboratory, for his suggestion of the problem. The balance of the paper is based on a thesis submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Engineering in the Graduate School of the University of Illinois. The thesis is written under the joint adviserships of Profs. T. C. Shedd, N. M. Newmark, and H. S. Stillwell; to all three the author is much indebted. Special appreciation is due to Professor Newmark for his numerous suggestions in the theoretical justification of the method and in the arrangement and wording of this paper.

On the Velocity Distribution of Turbulent Flow in Pipes and Channels of Constant Cross Section

By CHI-TEH WANG,[1] PROVIDENCE, R. I.

This paper follows the Prandtl conception of momentum transport and gives a critical examination of the so-called Prandtl-Nikuradse formula and the von Kármán formula for the velocity distribution of the turbulent flow in tubes or channels at large Reynolds number. It shows that both formulas would not give a good picture of the turbulent flow near the center of the conduit, and indeed they actually do not. A new formula for the velocity distribution is developed from a study of the mixing-length distribution across the section. This new formula checks quite well with the experiments and yields the same skin-friction formula as derived by von Kármán and Prandtl, which itself is in very good agreement with experiments.

Nomenclature

The following nomenclature is used in the paper:

u, v, w = mean velocities at any point in direction of and perpendicular to axis of pipe, respectively
u', v' = velocity fluctuation in x- and y-directions, respectively
$\overline{u'v'}$ = time mean value of $u'v'$
y = distance from wall
r = radius of circular pipe or half the distance between walls of a channel
u_{max} = u at $y = r$
$\xi = y/r$
$\eta = 1 - \frac{y}{r}$
τ = shearing stress at any point
τ_0 = shearing stress at wall
ρ = mass density of fluid
$v_* = \sqrt{\tau_0/\rho}$ = "friction velocity"
μ = coefficient of viscosity
ν = kinematic viscosity
ln = natural logarithm
κ = von Kármán's universal constant
k = linear parameter defining wall roughness
l = Prandtl's mixing length
R = $u_{max} r/\nu$ = Reynolds number
u = average velocity in pipe or channel
$c_f = \tau_0/\frac{1}{2}\rho(u_{max})^2$ = coefficient of friction
δ_l = thickness of laminar sublayer

[1] Assistant Professor of Aeronautical Engineering, Daniel Guggenheim Airship Institute, Akron, Ohio (now on leave of absence); Research Associate, Brown University.

Presented at a meeting of the Applied Mechanics Division, Cincinnati, Ohio, October 3, 1945, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Introduction

The turbulent flow in tubes and channels of constant cross section has been successfully described by the so-called logarithmic laws bearing the names of Prandtl-Nikuradse and von Kármán. Both von Kármán's original derivations (1, 2)[2] and those given by Prandtl (3, 4) have been based primarily on von Kármán's conception of turbulent-flow-pattern similarity.

These logarithmic laws give a very good agreement between theory and experiments in connection with skin friction; but a rather poor agreement in connection with the velocity distribution across the tube or channel. This poor agreement in velocity distribution was first questioned by Gurjienko (5) in his study of the skin-friction problem for an airship. Goldstein (6) further cast doubts on the exactness of the similarity theory. The problem was subsequently discussed by Millikan (7) and von Mises (8). In fact, von Kármán (9) himself has pointed out that the strict similarity of the actual motion is too severe a restriction and can hardly be expected to exist in regions of finite extent.

Von Kármán (9) has further pointed out that the development of turbulence depends on the balance between the transfer of energy from the mean motion into the fluctuations and the dissipation due to fluctuations, and the equations based on this conception would be expected to give a satisfactory theory of turbulence. Although the author shares this view with von Kármán, until such a theory can be developed to a practical form, the classical mixing-length theory, nevertheless, is still the only theory so far which furnishes a reasonable physical picture of the turbulent flow.

This paper follows the Prandtl conception of momentum transport and gives a critical examination of the so-called Prandtl-Nikuradse formula and the von Kármán formula for the velocity distribution of the turbulent flow in tubes or channels at large Reynolds number. It shows that both formulas would not give a good picture of the turbulent flow near the center of the conduit, and indeed they actually do not. A new formula for the velocity distribution is developed from a study of the mixing-length distribution across the section. This new formula checks quite well with the experiments and yields the same skin-friction formula as derived by von Kármán and Prandtl, which itself is in very good agreement with experiments.

Review of Fundamental Concepts

The first detailed theoretical investigations of turbulence are due to Reynolds (10). By considering the time mean of the equations of motion of an incompressible turbulent fluid, Reynolds has shown that the spatial and temporal oscillations of the velocity occurring in the mixing movement affect the average motion like an internal friction. Taking a simple two-dimensional flow in which

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

$$u = u(y), \qquad v = w = 0$$

the Reynolds expression for the total frictional stress in turbulent flow is

$$\tau = \mu \frac{du}{dy} - \overline{\rho u'v'} \quad \ldots\ldots [1]$$

The first part is the viscous or laminar friction. The second part is contributed by turbulence and is the apparent or turbulent friction. This turbulent friction can be interpreted as due to the momentum transfer from layer to layer because of the velocity fluctuations. As in the case of the flow just mentioned, the excess of momentum in the direction of the mean flow carried by the fluid per unit volume is $\rho u'$, and the fluid volume passing through a unit area perpendicular to the y-direction is equal to v'.

Experiments have shown that in the turbulent flow along a wall, there exist roughly three regions. Near the wall there is a thin layer called the laminar sublayer in which the rate of shear is very great while the turbulent velocity component perpendicular to the wall is very small, so that the turbulent stress is insignificant compared with the laminar stress. Farther from the wall there is another region in which the turbulent stresses and the laminar stresses are of the same order of magnitude. Finally, further out there is a region in which the laminar stresses may be neglected in comparison with the turbulent stresses.

For flows in pipes and channels in the important range of high Reynolds number, experiments indicate that the laminar sublayer is very thin, and the laminar friction is a negligible part of the total friction except in the immediate neighborhood of the wall. Equation [1] can then be written as

$$\tau = -\overline{\rho u'v'} \quad \ldots\ldots [2]$$

Prandtl then proposed the hypothesis that in the turbulent exchange lumps of fluid are supposed to transfer momentum from one layer to another just as molecular agitation transfers properties like heat and momentum in a nonturbulent fluid. The transfer of momentum is supposed to be affected by the motion of lumps of fluid which leave a layer in which their momentums are those of the mean flow in the neighborhood, and move in a direction transverse to the mean flow through a distance l. At this point they are supposed to mix with the surrounding fluid, so that their momentums become identical with the average momentum of the fluid in that region.

Let us pass now to a continuous flow exemplified in Fig. 1 by a velocity curve $u = u(y)$, o-o being a plane parallel to the axis of the main motion. Assume that there is a turbulent mixing process present, with cross-current pulsating velocities $\pm v'$. Let l be the distance from o-o to some other layer b-b where a particle, animated by the pulsating vertical velocity v', could reach a layer adjacent to o-o and be embedded there. Following a simple reasoning, one may put

$$\overline{|u'|} = \text{const} \cdot l \cdot \frac{du}{dy} \quad \ldots\ldots [3]$$

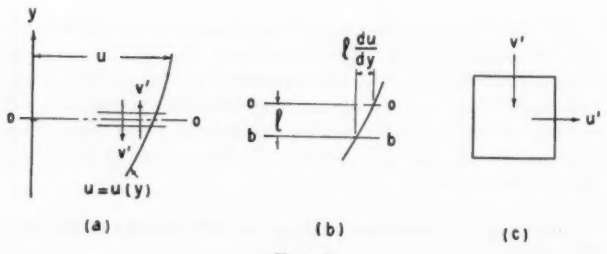

FIG. 1

where $\frac{du}{dy}$ is the local velocity gradient at o. From the continuity condition, to maintain constancy of mass, the velocity fluctuations in the axis and in the cross-current directions must compensate each other (see Fig. 1c), and therefore on the average the components u' and v' must be of the same order. One may then write

$$\overline{u'v'} = \text{const} \cdot \overline{|u'|} \cdot \overline{|v'|} = \text{const} \cdot l^2 \cdot \left(\frac{du}{dy}\right)^2 \quad \ldots\ldots [4]$$

where $\overline{|u'|}$ and $\overline{|v'|}$ are the time mean values of the absolute values of u' and v', respectively. Since l is a relative measure of the flow pattern, one may define l by writing

$$\tau = \rho l^2 \left(\frac{du}{dy}\right)^2 \quad \ldots\ldots [5]$$

where l is the Prandtl mixing length of momentum transport.

In circular pipes or in channels, it is known that

$$\tau = \tau_0 \left(1 - \frac{y}{r}\right) \quad \ldots\ldots [6]$$

where τ_0 is the shearing stress at the wall. By combining Equations [5] and [6], we have

$$\tau_0 \left(1 - \frac{y}{r}\right) = \rho l^2 \left(\frac{du}{dy}\right)^2 \quad \ldots\ldots [7]$$

or

$$\frac{l}{r} = \frac{v_* \sqrt{1-\xi}}{\frac{du}{d\xi}} = \frac{v_* \sqrt{\eta}}{-\frac{du}{d\eta}} \quad \ldots\ldots [8]$$

where $\xi = y/r$, and $\eta = 1 - \xi$, and $v_* = \sqrt{\frac{\tau_0}{\rho}}$.

Distribution of Mixing Length Across Conduit

Equation [8] gives the relationship at a point between the mixing length, the friction velocity v_*, the velocity gradient, and the position of the point. It seems important to investigate the existence of any law which might govern the distribution of the mixing length.

Following the experimental results by Fritsch (11), von Kármán obtains the "velocity-defect law" at large Reynolds number as

$$\frac{u_{\max} - u}{v_*} = f(\xi) \quad \ldots\ldots [9]$$

This law is assumed to hold throughout the flow, except in the immediate neighborhood of the wall, and the function f is a function of the position of the cross section of the conduit only. Differentiating Equation [9], we have

$$-\frac{1}{v_*}\frac{du}{d\xi} = f'(\xi)$$

and combining it with Equation [8], we have

$$\frac{l}{r} = -\frac{\sqrt{1-\xi}}{f'(\xi)} = g(\xi) \quad \ldots\ldots [10]$$

where g is another function of the position of the cross section of the conduit only. Therefore, we have proved that the mixing

length at high Reynolds number is independent of the Reynolds number, the friction velocity, and the wall roughness, but depends only on the position of the cross section. A review of Nikuradse's experiments (12, 13) indicates the correct relationship of Equation [10]. Experimental mixing-length distributions have been calculated by Nikuradse, and he shows that, for Reynolds numbers greater than 6×10^4, the mixing-length distribution, both in the smooth and rough pipes, can be represented by a single curve when $\frac{l}{r}$ is plotted against $\frac{y}{r}$.

From the consideration of symmetry, the $\frac{l}{r}$ versus $\frac{y}{r}$ curve must be symmetrical with respect to the axis of the conduit. Since this curve must have a continuously turning tangent at the axis, the slope of the curve there must be zero. These considerations lead to the assumption that this curve can be represented by the following series

$$\frac{l}{r} = a + b\eta^2 + c\eta^4 + \ldots \quad [11a]$$

$$= (a + b + c + \ldots) + (-2b - 4c + \ldots)\xi + (b + 6c + \ldots)\xi^2 + \ldots \quad [11b]$$

Now consider a region near the wall. The paths of the particles perpendicular to the flow are bounded by the wall; and they tend to be zero in the neighborhood of a smooth wall, and of the order of magnitude of the depths of the irregularities in a rough wall. Therefore, l must tend to zero as we approach the smooth wall, but toward a relatively small finite value if the wall is somewhat rough.

Furthermore, let us limit ourselves to a narrow strip near the wall, in which the change of shearing stress can be neglected. If we suppose that l is determined by the configuration of the boundaries and by the physical constants, then l and y are the only lengths which enter directly into the problem. The other quantities which enter are μ, ρ, and the constant value τ_0 of the shearing stress. Only two independent dimensionless combinations can then be formed, namely, l/y and yv_*/ν. When the influence of viscosity is neglected, we have

$$\frac{l}{y} = \kappa$$

where κ is von Kármán's universal constant and has been determined to be equal to 0.4.

Therefore, in the region near the wall but outside the laminar sublayer, the mixing-length distribution curve must be of the form

$$\frac{l}{r} = \kappa\xi + \text{higher-order terms in } \xi \quad [12]$$

Equation [11] applies to a region $\epsilon_1 \leq \xi \leq 1$, where ϵ_1 is a small positive quantity, and Equation [12] applies to a region $0 < \xi \leq \epsilon_2$, where ϵ_2 is another small positive quantity. Assume there is a region $\epsilon_1 \leq \xi \leq \epsilon_2$ in which Equation [11], and Equation [12] can be applied. If we take the first three terms in Equation [11a], the foregoing discussion would give us the following two relations

$$\left.\begin{aligned} a + b + c &= 0 \\ -2b - 4c &= 0.4 \end{aligned}\right\} \quad [13]$$

Another relation must be furnished in order to determine these constants uniquely, and this relation can be obtained from Nikuradse's mixing-length distribution curve. We must note here that since a numerical differentiation is necessary to compute l, the process is usually inaccurate, especially toward the axis of the conduit where l is determined by two small quantities. A point on the curve at $\frac{y}{r} = 0.5$ is therefore arbitrarily chosen; since it is as good as any, it gives $\frac{l}{r} = 0.116$. Substituting into Equations [11], we have

$$a + 0.25b + 0.0625c = 0.116 \quad [14]$$

Solving Equations [13] and [14] simultaneously, we obtain

$$a = 0.14, \quad b = -0.08, \quad c = -0.06$$

It is very interesting to see that these constants have exactly the same values given by Prandtl to approximate Nikuradse's experimental curve.

Equation [11] can now be written as

$$\frac{l}{r} = 0.14 - 0.08\,\eta^2 - 0.06\,\eta^4 \quad [15]$$

and checks very well with Nikuradse's curve, Fig. 4. This is the mixing-length equation applied to both smooth and rough pipes or channels at large Reynolds number except in the immediate neighborhood of the wall.

Examination of Prandtl-Nikuradse and von Kármán Formulas for Velocity Distribution

It has been shown in the foregoing section that in a region near the wall, τ can be regarded as equal as constant τ_0 and $\frac{l}{y} = \kappa$. Substituting these relationships into Equation [5] and integrating, Prandtl gives the following wall velocity formula for velocity distribution near the wall

$$\frac{u}{v_*} = \frac{1}{\kappa} \ln \frac{yv_*}{\nu} + c \quad [16]$$

where c is a constant. Applying this formula to his experimental data, Nikuradse found that it can be applied with a good approximation even up to the middle of the tube. By substituting the boundary condition that at $y = r$, $u = u_{max}$, Nikuradse obtains

$$\frac{u_{max} - u}{v_*} = -\frac{1}{\kappa} \ln \xi \quad [17]$$

This is the so-called Prandtl-Nikuradse formula.

Von Kármán assumes a similar pattern of the turbulent flow and has put forth his assumption of the mixing length as

$$l = \frac{du}{dy} \Big/ \frac{d^2u}{dy^2} \quad [18]$$

Substituting Equation [18] into Equation [7] and integrating, von Kármán's formula for velocity distribution is as follows

$$\frac{u_{max} - u}{v_*} = -\frac{1}{\kappa} [\ln (1 - \sqrt{\eta}) + \sqrt{\eta}] \quad [19]$$

Plots of Equation [17] with $\frac{u_{max} - u}{v_*}$ against $\ln \xi$ and Equation [19] with $\frac{u_{max} - u}{v_*}$ against $[\ln(1 - \sqrt{\eta}) + \sqrt{\eta}]$ are shown in Figs. 2 and 3. It is seen that the experimental points do not lie on the respective straight lines. Gurjienko (5) suggests the use of two κ's for approximating the experimental values, but there does not seem any theoretical justification. It may be

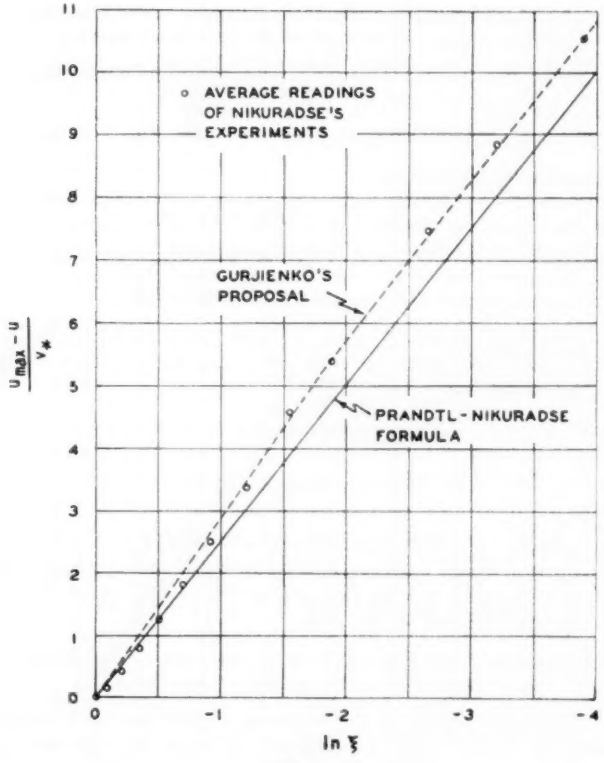

FIG. 2

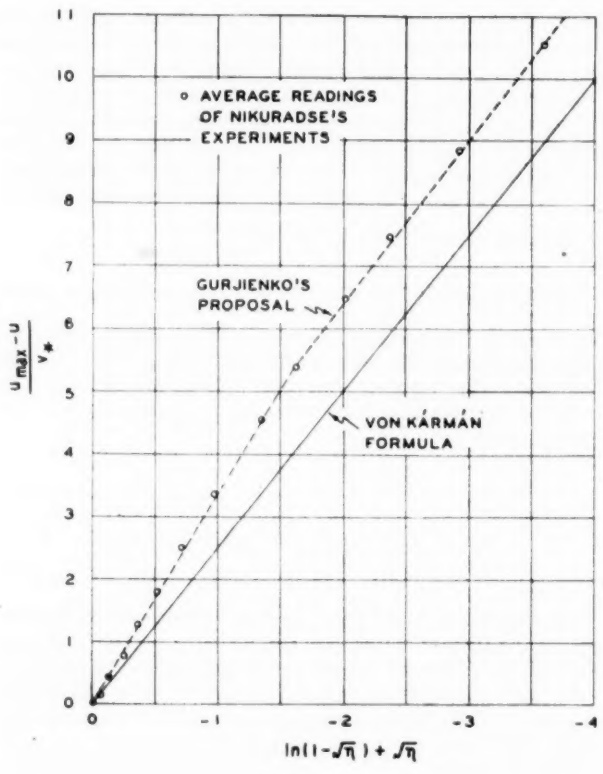

FIG. 3

pointed out here that Equation [16] fits the experimental results (4, 12) much better than Equation [17]. This difference is due to the fact that the boundary condition at the middle of the pipe is used in deriving Equation [17], whereas it is not used in Equation [16]. Equation [16] gives a good over-all fit to the experimental data except near the middle of the tube.

It is worth while to mention another inconsistency in the two formulas mentioned. The velocity gradients in the Prandtl-Nikuradse and von Kármán formulas are, respectively

$$\left.\begin{aligned}\left(\frac{du}{d\xi}\right)_P &= \frac{v_*}{\kappa}\frac{1}{\xi}\\ \left(\frac{du}{d\xi}\right)_K &= \frac{v_*}{2\kappa}\frac{1}{1-\sqrt{1-\xi}}\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [20]$$

at the center of the pipe. Both expressions give finite values of the velocity gradient. The result appears to be inconsistent, as naturally the velocity curve must pass through the maximum with zero velocity gradient there.

Substituting $\frac{du}{d\xi}$ from Equation [20] into Equation [8], the mixing lengths of the Prandtl-Nikuradse and von Kármán formula are, respectively

$$\left.\begin{aligned}\left(\frac{l}{r}\right)_P &= \kappa\,\xi\sqrt{1-\xi}\\ \left(\frac{l}{r}\right)_K &= 2\kappa\sqrt{1-\xi}\,(1-\sqrt{1-\xi})\end{aligned}\right\} \quad \ldots\ldots [21]$$

Equations [21] are plotted in Fig. 4. The inconsistencies of mixing lengths of both formulas with the Nikuradse curve may furnish a good explanation why these formulas do not check with experiments near the center of the pipe.

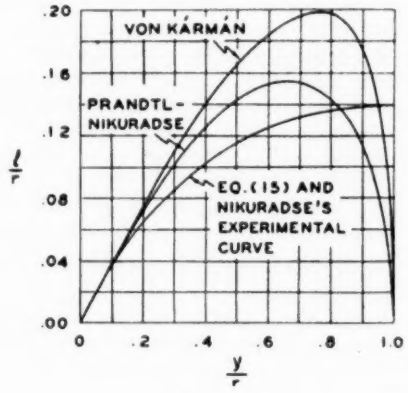

FIG. 4

Comparing Figs. 2 and 3, we find that the Prandtl-Nikuradse formula gives a better approximation to the experimental results than the von Kármán formula. This is again clearly seen in Fig. 4; but it must be noted that this better agreement with the experiments is purely accidental because $\frac{l}{r}$ was assumed to be equal to $\kappa\,\xi$ in the original derivation; therefore, the entirely different form of $\frac{l}{r}$ obtained in Equations [21] can be explained in no other way than as an accident.

NEW FORMULA FOR VELOCITY DISTRIBUTION

A formula for the velocity distribution can be derived from the expression for the mixing length as given by Equation [15]. Equation [15] can be written as

$$\frac{l}{r} = 0.06\,(1-\eta^2)(2.33+\eta^2)$$

Expanding in partial fractions

$$\frac{1}{\left(\frac{l}{r}\right)} = \frac{1}{0.2}\left(\frac{1}{1-\eta^2}+\frac{1}{2.33+\eta^2}\right) \quad [22]$$

Substituting Equation [22] into Equation [8] and rearranging, we obtain

$$-\frac{1}{v_*}\frac{du}{d\eta} = \frac{\sqrt{\eta}}{0.2}\left(\frac{1}{1-\eta^2}+\frac{1}{2.33+\eta^2}\right) \quad [23]$$

or

$$-\frac{1}{v_*}\int du = \frac{1}{0.2}\left(\int \frac{\sqrt{\eta}\,d\eta}{1-\eta^2}+\int \frac{\sqrt{\eta}\,d\eta}{2.33+\eta^2}\right)$$

Letting $x = \sqrt{\eta}$, there results

$$-\frac{1}{v_*}\int du = \frac{1}{0.2}\left(\int \frac{2x^2\,dx}{1-x^4}+\int \frac{2x^2\,dx}{2.33+x^4}\right) \quad [24]$$

Equation [24] can easily be integrated.[3] After substituting the boundary condition that $u = u_{max}$ at $\eta = 0$ into the resulting expression, the equation becomes

$$\frac{u_{max}-u}{v_*} = \frac{1}{\kappa}\left\{\ln\frac{1+\sqrt{\eta}}{1-\sqrt{\eta}} - 2\tan^{-1}\sqrt{\eta} - \frac{1}{\sqrt{2a}}\ln\frac{\eta+\sqrt{2a\eta}+a}{\eta-\sqrt{2a\eta}+a} + \sqrt{\frac{2}{a}}\tan^{-1}\frac{\sqrt{2a\eta}}{a-\eta}\right\} \quad [25]$$

where $\kappa = 0.4$ and $a = \sqrt{2.33} = 1.53$. Equation [25] is applied to both smooth and rough pipes or channels at large Reynolds number, except in the immediate neighborhood of the wall. The limit of "large" Reynolds number from Nikuradse's experiments is $R > 6 \times 10^4$.

The formula is plotted in Fig. 5 and checks very well the experimental results. The velocity gradient is given by Equation [23] and is zero at the center of the pipe. Thus this formula does not have the inconsistency of the other formulas.

The skin-friction, or wall velocity, formulas can be derived from Equation [25] when it is applied to the region near the wall ($\epsilon_1 < \xi < \epsilon_2$). Note that $\eta = 1-\xi$. For the region near the wall, $\xi << 1$, and $\sqrt{1-\xi} \cong (1-{}^1/_2\,\xi)$. Equation [25] can then be written as

$$\frac{u_{max}-u}{v_*} \cong \frac{1}{\kappa}\left\{\ln\frac{1+1-\frac{\xi}{2}}{1-1+\frac{\xi}{2}} - 2\tan^{-1}\left(1-\frac{\xi}{2}\right) - \frac{1}{\sqrt{2a}}\ln\frac{1-\xi+\sqrt{2a}\left(1-\frac{\xi}{2}\right)+a}{1-\xi-\sqrt{2a}\left(1-\frac{\xi}{2}\right)+a} + \sqrt{\frac{2}{a}}\tan^{-1}\frac{\sqrt{2a}\left(1-\frac{\xi}{2}\right)}{a-1+\xi}\right\}$$

$$\cong -\frac{1}{\kappa}\ln\xi + c \quad [26]$$

[3] By using from Dwight's "Integration Table" (14) formulas 170.2 and 171.2.

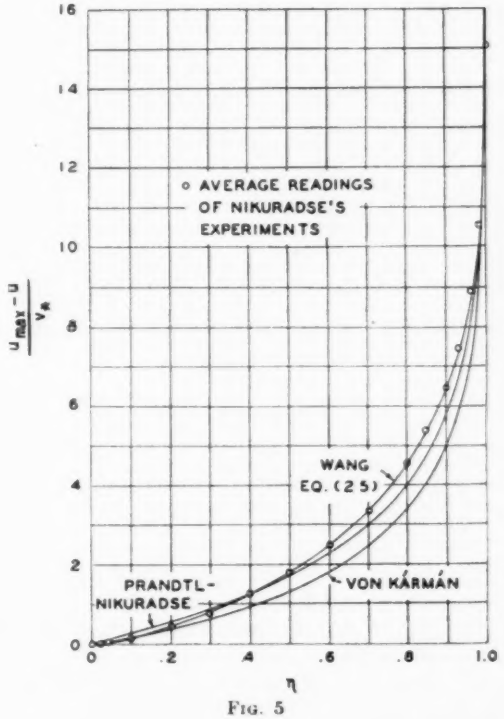

FIG. 5

Equation [26] can be easily transformed into Prandtl's wall velocity formula, which is applied to the outside of the laminar sublayer. Thus we see that for small ξ, our formula is exactly the same as Prandtl's wall velocity formula, and it is applied to a much larger region than we have expected. It can be actually applied to a region from the laminar sublayer to the axis of the conduit.

Here we shall divide the turbulent flows into three categories or regimes, as follows:

(*a*) One in which the roughness is so small as to have no effect, conditions being the same as if the wall were ideally smooth. We shall refer to this as "smooth-wall flow."

(*b*) One in which viscosity or rather Reynolds number has no effect and the roughness is the controlling factor. We shall refer to this as "rough-wall flow."

(*c*) An intermediate or transition regime between (*a*) and (*b*) in which both viscosity and roughness are important.

In the case of "smooth-wall flow," the thickness of the laminar sublayer and the velocity outside the sublayer can only depend on the friction at the wall, the viscosity, and the fluid density. On the basis of dimensional considerations, the velocity $u_{\delta lam}$ just outside the laminar sublayer may be expressed as

$$u_{\delta lam} = Av_* \quad [27]$$

and the thickness of the layer as

$$\delta_{lam} = B\frac{\nu}{v_*} \quad [28]$$

By applying Equation [26] to the outside of laminar sublayer and combining with Equations [27] and [28], we have

$$u_{max} = \frac{v_*}{\kappa}\left(\ln\frac{v_* r}{\nu} + C'\right) \quad [29]$$

where C' includes the constants A, B, C, etc. Introducing the coefficient of friction

$$C_f = \frac{\tau_0}{\frac{1}{2}\rho u_{max}^2}$$

and Reynolds number

$$\mathbf{R} = \frac{u_{max} r}{\nu}$$

we have

$$\frac{\kappa\sqrt{2}}{\sqrt{C_f}} = \ln\left(\mathbf{R}\sqrt{C_f}\right) + C'' \quad [30]$$

where $C'' = C' - \ln\sqrt{2}$. With the constant determined by Nikuradse, the skin-friction formula is

$$\frac{1}{\sqrt{C_f}} = 1.77 \ln\left(\mathbf{R}\sqrt{C_f}\right) + 3.54 \quad [31]$$

In the case of "rough-wall flow," we may start with Equation [26] and follow Prandtl's reasoning to obtain the formula

$$\frac{u}{v_*} - 2.5 \ln\frac{y}{k} = 2.5 \ln\frac{v_* k}{\nu} + 5.5 \quad [32]$$

as given by Prandtl (4), where k is a linear parameter defining the wall roughness introduced by von Mises (15).

It is seen that Equation [25] leads to the same skin-friction formulas as derived by von Kármán and Prandtl.

Conclusion

The turbulent flow in a tube is not isotropic in nature. The description of the state of turbulence by the statistical theory therefore becomes quite complicated. Although von Kármán has presented a detailed discussion of the Couette problem or the two-dimensional flow with constant shearing stress from the point of view of energy transport and dissipation, and vorticity dissipation, the extension of his theory to the case of pressure flow in pipes or channels seems to be difficult to carry out.

At present, it seems that one has to be satisfied with the semi-empirical mixing-length theory and to use the more accurate formula for velocity distribution as derived in this paper. Obviously, this new formula is much more complicated than the original logarithmic laws. When an approximate velocity profile is needed, the Prandtl-Nikuradse formula is recommended, because not only is it simpler in form, but it also gives a better agreement with the experimental results than the von Kármán formula. The different formulas are plotted to compare with Nikuradse's experimental results in Fig. 5.

Measurements of Friction in a Pipe for Subsonic and Supersonic Flow of Air

By J. H. KEENAN[1] and E. P. NEUMANN,[2] CAMBRIDGE, MASS.

The apparent friction coefficient was determined experimentally for the flow of air through smooth pipes at subsonic and supersonic velocities. Values of the Mach number ranged from 0.27 to 3.87, and of Reynolds number from 1×10^5 to 8.7×10^6. In supersonic flow the results were found to be strongly influenced by the presence of oblique shocks formed at the junction of nozzle and pipe. The effect of these shocks on the coefficient of friction was determined. Nozzle forms were devised which eliminated the shocks and their effects. It was found that at distances from the pipe inlet greater than 50 diam the apparent coefficient of friction for compressible flow at Mach numbers greater or less than 1 is approximately equal, for equal Reynolds numbers, to the coefficient of friction for incompressible flow with completely developed boundary layer. Mach numbers greater than 1 are rarely maintained for lengths greater than 50 diam. For attainable lengths, the coefficient of friction is a function of the ratio of length to diameter and the Reynolds number, with the Mach number at entrance determining the maximum attainable length.

Nomenclature

The following nomenclature is used in the paper:

a = cross-sectional area of test pipe, sq ft
D = diameter of test section, ft
d = throat diameter of nozzle, in.
F = wall friction force, lb
G = mass rate of flow per unit area, lb per sq ft per sec
g = acceleration given to unit mass by unit force, ft per sec per sec
h = enthalpy, ft-lb per lb
k = ratio of specific heats
L = length of test section, ft
$\mathbf{M}$ = Mach number $= V/\sqrt{gc_p(k-1)T_m J}$
p = pressure, psfa
$\mathbf{R}$ = Reynolds number, GD/μ
T = temperature, deg F abs
T_m = mean stream temperature at a given cross section of test pipe, deg F abs
T_i = mean stream temperature at the initial state of fluid stream, i.e., where $V = 0$ (deg F abs)
V = mean velocity of fluid stream at given cross section of test pipe, ft/sec
v = specific volume, cu ft per lb
w = mass rate of flow, lb per sec
x = distance along test section, ft

λ = friction coefficient $= \dfrac{\tau}{\frac{1}{2}\rho V^2}$

$\lambda = \left(\int_{x=0}^{x=L} \lambda dx\right) \Big/ L$

λ_c = friction coefficient calculated from

$$\frac{1}{\sqrt{4\lambda_c}} = -0.8 + 2 \log \mathbf{R}\sqrt{4\lambda_c}$$

with $\mathbf{R}$ based on T_m

λ_i = friction coefficient calculated from preceding equation with $\mathbf{R}$ based on T_i

μ = mean stream viscosity $= 1.147 \times 10^{-5} \dfrac{491.6 + 205.2}{T_m + 205.2} \left(\dfrac{T_m}{491.6}\right)^{3/2}$ lb/(ft sec)

ρ = mass density $\left(\dfrac{1}{vg}\right)$

τ = friction force per unit of wall surface, psf
θ = angle between walls of entrance nozzle

Subscripts:

i refers to initial state of fluid stream where velocity is zero
1 and 2 refer to arbitrary datum sections along test pipe

Constants used in calculations:

k = ratio of specific heats, 1.4
c_p = specific heat at constant pressure, 0.240 Btu/F lb
J = number of ft-lb in 1 Btu = 778.3

Introduction

The effect of friction on the flow of compressible fluids in pipes of uniform cross-sectional area was investigated analytically by Grashof (1)[3] and Zeuner (2), who arrived at a relationship between velocity and friction coefficient for perfect gases. Stodola (3) showed that the curves of Fanno permit a general graphical treatment for any law of friction. Frössel (4) presented the first extensive measurements of friction coefficients for the flow of air through a smooth tube with velocities above and below the velocity of sound. His measured coefficients for both subsonic and supersonic compressible flow appear to be in excellent agreement at corresponding Reynolds numbers with coefficients measured for incompressible flow. Keenan (5) presented experimental data on commercial pipe for the flow of water and for the flow of steam at subsonic velocities. These indicated that the friction coefficient is the same for the same Reynolds number for an incompressible fluid and for subsonic flow of a compressible fluid.

In the subsonic region the measurements of Frössel and of

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.
Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper

Keenan were in accord in that they revealed no variation of the friction coefficient which was peculiar to compressible fluids. In the supersonic region the measurements of Frössel pointed to a similar conclusion. Frössel's data for this region were published as a chart[4] which, despite its small scale, seemed to reveal great irregularities in the data. The friction coefficients, which were computed from the derivatives of the curves through the experimental points, must have been subject to great uncertainty.

Object of Investigation

Some preliminary investigations (6) into supersonic flow of air which were made in the laboratory of mechanical engineering at the Massachusetts Institute of Technology indicated friction coefficients appreciably different from those reported by Frössel. The present investigation was undertaken in an attempt to resolve this disagreement and to obtain some dependable experimental data on supersonic flow with friction. In order to tie the investigation into previous studies of the flow of incompressible fluids, some measurements of subsonic flow were included.

Test Apparatus

The arrangement of the test apparatus is shown in Fig. 1. Air is supplied by either a two-stage steam-driven compressor or a rotary electric-driven compressor. At the discharge from the compressor is a receiver to smooth out fluctuations in flow. For some tests a dehumidifying system was used to remove moisture from the air leaving the compressor. This dehumidifying system consists of a cooling coil followed by a heating coil. It is connected into the system as shown in Fig. 1.

The air stream is introduced into the test pipe through a rounded-entrance nozzle of circular cross section. Details of the nozzles used in different tests are shown in Figs. 2 to 5, inclusive.

[4] Reference (4), Fig. 7.

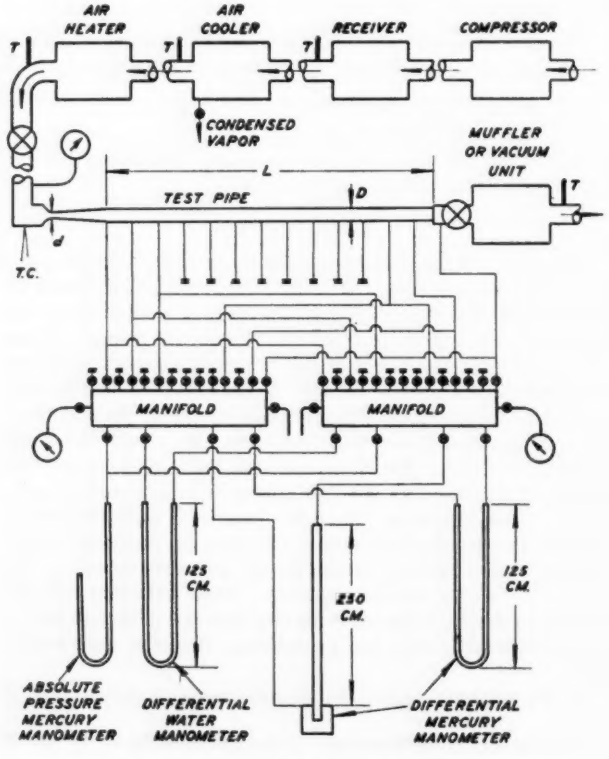

Fig. 1 Diagram of Test Apparatus

The test pipe is in each instance a piece of standard drawn-brass tubing. For the subsonic tests the inside diameter of the tube was 0.375 in. For the supersonic tests three tubes were used having inside diameters of 0.4375, 0.498, and 0.945 in., respectively.

The air stream leaving the test pipe is discharged either to the atmosphere or to an ejector which uses steam as the primary fluid.

The pressure measurements, from which the friction coefficients are calculated, were made at holes of 0.020 in. diam drilled in the tube wall. To avoid a burr at the inside edges of the pressure holes, the inside of the test pipe was carefully polished with fine emery cloth. Connections between the pressure holes, manifolds, and manometers are made with $^1/_4$-in. copper tubing.

All pressure differences were measured with simple U-tube manometers. In the supersonic test the pressures in the test pipe were generally small fractions of an atmosphere. They were measured with an absolute mercury manometer. With the aid of a sliding marker on the manometer scales, pressure differences could be read to 0.01 cm. Pressures higher than 50 psig before the inlet nozzle were measured with a calibrated Bourdon gage; lower pressures were measured with a mercury column.

The temperature of the air stream in front of the nozzle could be measured by either a copper-constantan thermocouple or a mercury-in-glass thermometer. Readings were usually made with the thermometer.

The discharge coefficient for the 0.375-in-diam subsonic nozzle was determined by means of a gasometer. The discharge coefficients for each supersonic nozzle were obtained from the A.S.M.E. data on nozzle coefficients (7).

Method of Testing

The air compressor was started and sufficient time allowed to elapse to obtain steady-state conditions before any readings were taken. Temperature readings were taken at definite intervals of time. Pressure differences between a given pair of taps were measured on either a mercury manometer or a water manometer, depending on the magnitude of the difference to be measured. In order to establish a continual check against possible leakage from either of the two manifolds, pressure differences were recorded for each pair of taps, with the higher pressure first in one manifold and then in the other. To check against possible leakage from the connections between the pressure taps and the manifold, a soap-and-water solution was applied at each connection. For the supersonic runs, where the pressures measured were below atmospheric pressure, the manometer system was tested by subjecting it to a pressure higher than atmospheric before starting a test.

Results of Tests

Apparent Friction Coefficient. The results of these tests are shown principally in terms of the apparent friction coefficient λ. This term is intended to represent for any cross section of the stream the quantity

$$\frac{2\tau}{\rho V^2}$$

where τ denotes the shear stress at the pipe wall, ρ the mean density, and V the mean velocity. In reality the apparent friction coefficient is defined in terms of the measured quantities, flow per unit area and pressure, through the equations

$$h_i = \frac{G^2 v^2}{2g} + \frac{k}{k-1} pv \quad \ldots\ldots\ldots\ldots\ldots [1]$$

$$\lambda = \frac{gD}{2G^2(x_2 - x_1)}\left[\frac{c_p T_i J(k-1)}{2k}\left(\frac{1}{v_1^2} - \frac{1}{v_2^2}\right) - \frac{G^2}{g}\frac{(k+1)}{2k}\ln\frac{v_2}{v_1}\right] \quad [2]$$

which were derived in reference (5).

In terms of L/D, k, and $\mathbf{M}$ for a perfect gas Equation [2] becomes

$$\lambda = \frac{D}{4L}\left\{\frac{1}{2k}\left[\frac{2 + \mathbf{M}_1^2(k-1)}{\mathbf{M}_1^2} - \frac{2 + \mathbf{M}_2^2(k-1)}{\mathbf{M}_2^2}\right] - \left(\frac{k+1}{k}\right)\ln\sqrt{\frac{[2 + \mathbf{M}_1^2(k-1)]\mathbf{M}_2^2}{[2 + \mathbf{M}_2^2(k-1)]\mathbf{M}_1^2}}\right\} \quad [3]$$

Equation [2] is identical with the statement

$$\lambda = \frac{2\tau}{\rho V^2}$$

if the velocity across each section is so nearly uniform that the mean velocity found from the flux of kinetic energy is identical with that found from the flux of momentum, or if the flux of momentum and the flux of kinetic energy do not change from section to section.

The flow of an incompressible fluid in a pipe at a great distance downstream from the entrance satisfies the latter condition. The flow of a compressible fluid satisfies neither condition. It is probable, however, that the former is nearly satisfied in compressible flow at a great distance downstream from the entrance,

provided that the longitudinal pressure gradient is not inordinately large.

The magnitude of the true friction coefficient ($2\tau/\rho V^2$) can be found only from a determination of the magnitude of the shear stress at the pipe wall. If the shear stress is to be measured directly, the experimental difficulties are formidable; if it is to be deduced from pressure measurements, either the analytical difficulties or the uncertainties introduced by supposition are likely to prove discouraging.

The apparent friction coefficient, on the other hand, may be rather simply deduced from common types of measurement. Moreover, when its value is known it may be readily applied to the design of passages.

The adoption of the apparent friction coefficient for reporting the results of measurements of the type presented here will facilitate comparison between data from different sources. The calculation of the apparent friction coefficient involves the simplest calculation and the minimum extraneous hypothesis consistent with reducing the measurements to a basis of comparison. The test of Frössel (4) and Keenan (5) have been so presented.

In all subsequent paragraphs the term "friction coefficient" is to be interpreted to mean "apparent friction coefficient," as defined by Equation [2].

The variation in pressure along the length of the test pipe is shown in Fig. 6. For test 1 the pressure in the exhaust space after the end of the pipe was below the sound pressure, that is, the pressure at the state of maximum entropy; consequently, the flow through the pipe was the maximum flow corresponding to the initial condition of the air stream. For test 2 the air stream was throttled behind the pipe, and for tests 3 and 4 in front of the pipe, to produce pressures at the pipe exit in excess of the sound pressure, which resulted in turn in a flow less than the maximum flow for the existing initial conditions.

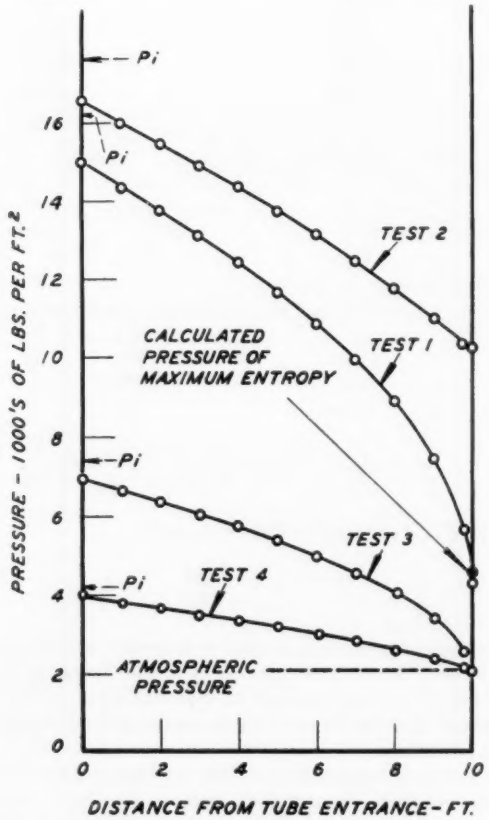

FIG. 6 PRESSURE DISTRIBUTION ALONG TEST PIPE FOR SUBSONIC FLOW

In Fig. 7 the arithmetic mean of the friction coefficients, corresponding to the intervals of pipe length between pressure taps for each test, is plotted against the arithmetic mean of the Reynolds number. The length interval from 0 to 1 ft was omitted from the calculation of the mean because the velocity profile was doubtless changing greatly in this interval. The last 3 inches of length were also omitted because of the effect on velocity and pressure distribution of the abrupt discharge into the exhaust space. Thus the data in Fig. 7 correspond to a well-developed boundary layer, and as stable a velocity profile as the conditions of compressible flow permit.

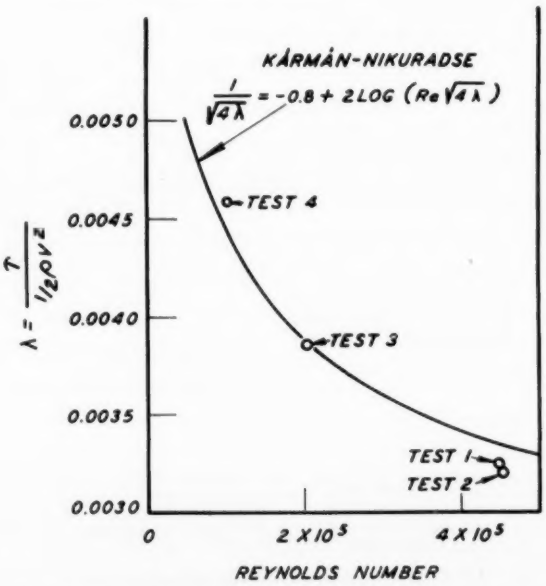

FIG. 7 FRICTION COEFFICIENTS FOR SUBSONIC FLOW COMPARED WITH THOSE FOR INCOMPRESSIBLE FLOW

The von Kármán-Nikuradse relation between friction coefficient and Reynolds number for incompressible flow is shown by the curve in Fig. 7. The greatest discrepancy between the present results and this curve is of the order of 3 per cent, which is approximately the degree of uncertainty in the present measurements.

Figs. 8 and 9 show the variation along the length of the tube of friction coefficient, mean temperature, and Mach number for tests 1 and 2. The values of friction coefficient for incompressible flow, corresponding to the Reynolds number at each point along the length of the pipe, are shown by the dash curve in Fig. 8. In test 1 the Mach number ranges from 0.32 to 1 and in test 2 from 0.3 to 0.47. In both tests, however, the agreement between the measured friction coefficients and those for incompressible flow is consistently good. This agreement confirms the conclusion reached by Keenan and by Frössel that for subsonic velocities the friction coefficient is a function of the Reynolds number and is not appreciably affected by change in the Mach number.

SUPERSONIC FLOW

Length of Test Pipe. The length of the test pipe for supersonic tests is limited by the divergence ratio of the nozzle that feeds the pipe. In supersonic flow in a pipe the pressure increases and the velocity decreases in the direction of flow. For a sufficiently

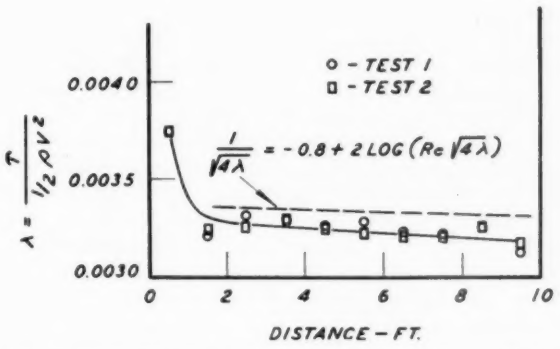

FIG. 8 FRICTION COEFFICIENT AGAINST DISTANCE ALONG PIPE FOR SUBSONIC FLOW

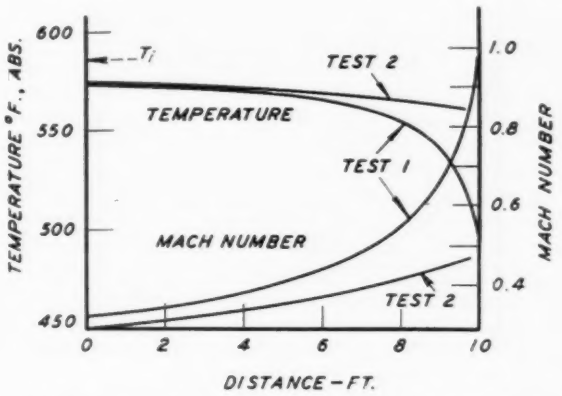

FIG. 9 TEMPERATURE AND MACH NUMBER AGAINST DISTANCE ALONG PIPE FOR SUBSONIC FLOW

low pressure in the exhaust space, the length of supersonic flow may be increased by lengthening the pipe until the velocity at the exit of the pipe has been reduced to the velocity of sound. Any further increase in the length of the pipe will decrease the length of supersonic flow, because a transverse shock will be established upstream from the previous exit section and velocities downstream from the shock will be subsonic. The maximum length of supersonic flow attained in the present tests is 50 diam.

The Nozzle. If the junction between the divergent nozzle passage and the test pipe is not properly designed, an oblique shock wave will form at or near the junction. This wave will extend down and across the stream until it encounters the opposite wall and then will reflect back and forth along the length of the pipe. Fig. 10, from the thesis of Huron and Nelson (8), shows such oblique waves in a two-dimensional nozzle. Since in crossing the oblique shock the pressure rise in the stream is almost discontinuous, measurements of pressure variation along the test pipe become difficult to interpret. Moreover, it appears probable that the existence of the shock stimulates thickening of the boundary layer and so influences strongly the magnitude of the friction coefficient. Under extreme conditions the oblique shock may initiate separation of the stream from the wall.

With the aid of the method of Shapiro (9), nozzles were designed so as to introduce the stream into the test pipe without the formation of an oblique shock of sufficient intensity to affect the measured pressures. Fig. 11 (from reference 8) shows the flow

FIG. 10 SCHLIEREN PHOTOGRAPH OF OBLIQUE SHOCK FRONTS FORMED AT ENTRANCE TO TUBE OF RECTANGULAR CROSS SECTION
(Divergence ratio = 3.50, θ = 30 deg, depth of passage perpendicular to plane of photograph = 0.400 in., cross-sectional area of parallel passage = 0.280 sq in. Exposure time 1/10 sec. Photograph from reference 8.)

FIG. 11 SCHLIEREN PHOTOGRAPH OF NOZZLE WITH TRANSITION LENGTH FROM DIVERGENT PASSAGE TO PARALLEL PASSAGE DESIGNED TO AVOID OBLIQUE SHOCK FRONTS
(Divergence ratio = 3.50, depth of passage perpendicular to plane of photograph = 0.400 in., cross-sectional area of parallel passage = 0.280 sq in. Exposure time 1/10 sec. Photograph from reference 8.)

from a two-dimensional nozzle which is comparable to the test nozzles and which was designed by the same method. The first photographs taken, by the Schlieren method, of flow through this nozzle showed a clear field in both nozzle and tube. In order to make visible the pattern of flow and to demonstrate that shock waves if present would be discernible, the walls of the nozzle and the parallel passage were knurled. Each rib of the knurling set up a disturbance of small magnitude which extended across the stream in the manner of an oblique shock. Since the presence of these small disturbances could be detected, the presence of an oblique shock would also be detected. The walls at the junction of the nozzle and tube and for a short interval in the passage a little distance downstream from the junction were left unknurled to permit a shock to be more readily distinguished, but none appeared.

Effect of Angle of Divergence. To determine the effect on the apparent friction coefficient of oblique shocks in the test pipe, a series of tests were made using entrance nozzles with conical divergent sections of different angles of divergence θ. The junction of the nozzle and pipe were in each case a sharp corner.

The variation in pressure along the test pipe for various values of the angle of divergence is shown in Fig. 12. For an angle of 24 deg the pressure decreases along the first 10 diam of pipe length. This decrease appears to be an extension of the expansion from the nozzle into the test pipe. It is doubtless caused by separation of the stream from the walls of the nozzle.

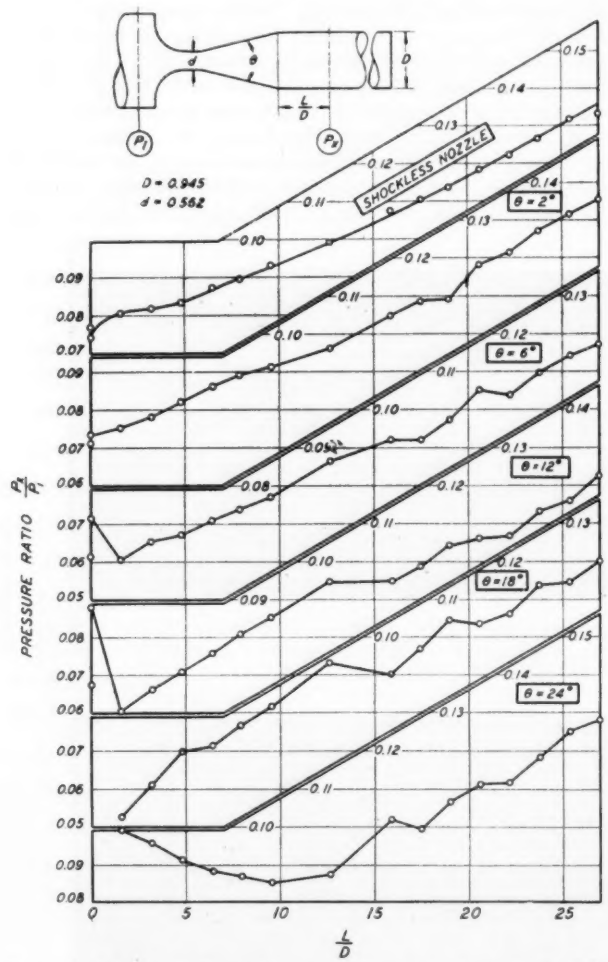

Fig. 12 Pressure Ratio Against Distance Along the Pipe Using Entrance Nozzles With Different Angles of Divergence (θ)

θ deg	Mach number at nozzle exit
2	2.08
6	2.29
12	2.16

For angles of 12 deg or less, the rise in pressure across the corner at the junction was measured by means of pressure taps located immediately before and after the corner. The measured pressure rise is shown in each instance by the interval between the two points at zero value of L/D. The ratio of pressures across the joint varies from 1.30 for an angle of 12 deg to 1.03 for an angle of 2 deg. The departure from 1 in the latter figure is hardly in excess of the uncertainty in the pressure measurements. For an angle of 6 deg, the ratio is 1.16. The analysis of Meyer (10) indicates a pressure ratio of 1.22 across the oblique shock arising from a change of direction of 3 deg at a Mach number of 2.29. This analysis is applicable only to two-dimensional flow which the flow near the tube wall should approximate. The experimental and analytical values appear to be of the same order of magnitude.

It may be seen in Fig. 12 that as the angle of divergence decreases, the pressure rise at the junction decreases, and the curve of pressure against distance becomes smoother. With a nozzle designed for shock-free conditions the curve becomes smooth and the rise in pressure at the junction becomes zero within the precision of the pressure measurements.

Although measurements made under other than shock-free conditions are not considered valid, a study was made of the effect on the apparent friction factor of nozzles of the ordinary type. Such nozzles were used, presumably, by Frössel who gave no indication that he had developed a special nozzle for the purposes of his tests. The friction coefficients, computed from the curves in Fig. 12, are plotted in Fig. 13 against the angle of divergence of the nozzle. These friction coefficients are the mean coefficients for the interval of length between values of L/D of 1.59 and 27—approximately the same as that used by Frössel.

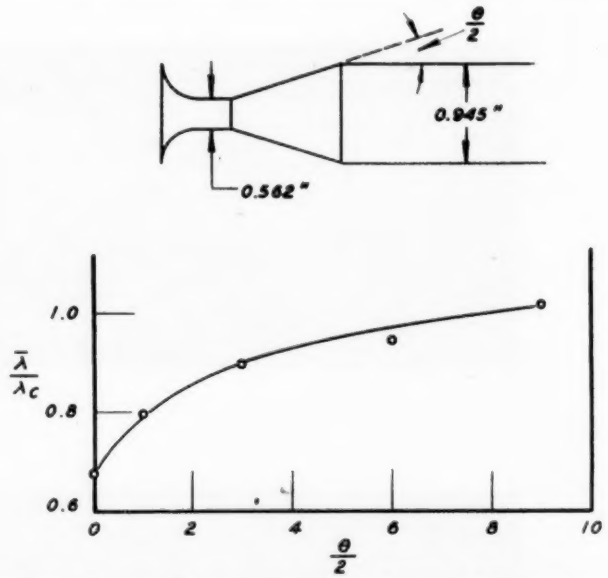

Fig. 13 Ratio of Measured Apparent Friction Coefficient to Friction Coefficient for Incompressible Flow Against Angle of Divergence θ

(The friction coefficient is the mean value of the apparent friction coefficient for the interval of test section from $L/D = 1.59$ to $L/D = 26.98$. The value of λ_c was computed from the von Kármán-Nikuradse relation between Reynolds number and friction coefficient.)

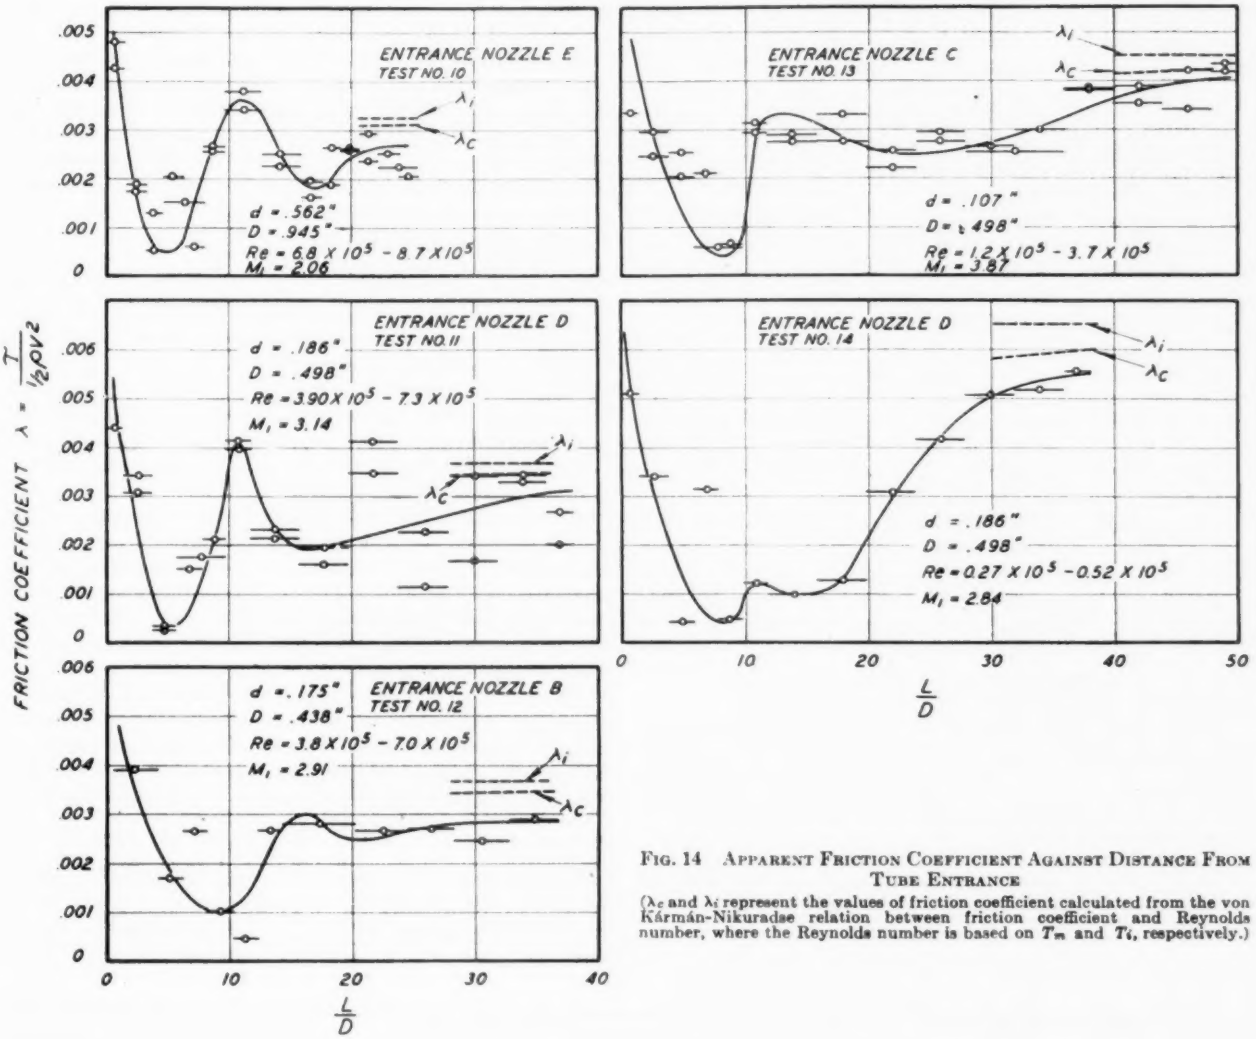

FIG. 14 APPARENT FRICTION COEFFICIENT AGAINST DISTANCE FROM TUBE ENTRANCE

(λ_c and λ_i represent the values of friction coefficient calculated from the von Kármán-Nikuradse relation between friction coefficient and Reynolds number, where the Reynolds number is based on T_m and T_i, respectively.)

According to the data in Fig. 13 the friction coefficient for a given Reynolds number approaches the von Kármán-Nikuradse value for incompressible flow as the angle of divergence increases. Perhaps this is evidence of the increase in thickness of the boundary layer caused by the oblique shock. The von Kármán-Nikuradse value is obtained from flow at large values of L/D where the boundary layer fills the cross section, and turbulence is fully developed. In supersonic flow the presence of an oblique shock may have an effect on the boundary layer similar to the effect of length in incompressible flow.

Apparent Friction Coefficient. The apparent friction coefficient is plotted against distance from the entrance to the test pipe in Fig. 14. The two extremities of the horizontal line which passes through each test point in Fig. 14 show, respectively, the positions at which the two pressures used in calculating the value of the friction coefficient were measured. Thus each point represents a mean value of the apparent friction coefficient over a short interval of length. The pressure difference across this interval was in each instance very small, and any irregularity in the pressure distribution or any error in a pressure measurement had therefore an exaggerated effect on the calculated friction coefficient. For this reason the points in Fig. 14 scatter over a band of considerable width. Nevertheless, a definite pattern is discernible which is common to all five sets of data. Near the entrance to the test pipe the coefficient decreases sharply with increasing distance along the pipe. At a distance of 5 to 10 diam the coefficient passes through a minimum. At greater distances there is evidence of a maximum followed by another minimum.

The data in Fig. 14 are not sufficiently precise to establish the number of maxima and minima or the amplitude of the fluctuations in the value of the coefficient, but an attempt to approximate these is represented by the solid lines in the figure. A somewhat similar variation in friction coefficient near the entrance to a pipe has been shown for flow of an incompressible fluid by Kirsten (11) and by Brooks, Craft, and Montrello (12). It is doubtless a phenomenon relating to the transition from laminar to turbulent flow in the boundary layer. No exact correspondence between pairs of curves in Fig. 14 should be expected because the degree of development of the boundary layer at pipe entrance varied from test to test with the length and other dimensions of the nozzle. The one exception is the pair of curves in the middle of the figure which were obtained with the same nozzle and test pipe.

On each of the charts in Fig. 14 are shown, by dash lines, values of the friction coefficients λ_i and λ_c calculated from the von Kármán-Nikuradse relation for incompressible fluids. The coefficients λ_i and λ_c are calculated using, respectively, the Reynolds numbers corresponding to the viscosity at the temperature before

the inlet nozzle where the velocity is zero and that at the mean stream temperature. In view of the "recovery" of temperature in the boundary layer, some value intermediate between these two would seem to be most appropriate.

For distances from the entrance greater than 20 diam, the trend of the coefficient is definitely upward. The limit of this trend appears to be a horizontal line or a curve with ordinates approximately equal to λ_i or λ_c.

The five charts in Fig. 14 may be roughly grouped into those of high Reynolds number, the left-hand three, and those of low Reynolds number, the right-hand two. The left-hand curves show a distinct similarity in pattern and position, whereas the right-hand group shows in comparison lower values at the minimum point and higher values at large values of L/D.

No analogous trend with Mach number can be discerned. Although the top and middle charts in the left-hand group have Mach numbers at entrance of 2.06 and 3.09, respectively, they differ less than the two middle charts which have Mach numbers of 3.09 and 2.84, respectively. Differences appear to depend on Reynolds number rather than Mach number.

To test whether the changes in characteristics were the result merely of accidental differences between test pipes and entrance nozzles, two tests were run with the same test pipe and nozzle at approximately the same Mach number but with different Reynolds numbers. These are shown by the two middle charts in Fig. 14. The differences between these two charts are consistent with the differences between any other pair of charts for two different Reynolds numbers.

The conclusion seems tenable, therefore, that for values of L/D greater than 50 the apparent coefficient of friction for compressible flow at Mach numbers greater or less than 1 is approximately equal, for equal Reynolds numbers, to the coefficient of friction for incompressible flow.

For Mach numbers greater than 1, however, values of L/D greater than 50 are rarely encountered; and for values less than 50, the apparent coefficient of friction is generally less than that given by the von Kármán-Nikuradse formula for the same Reynolds number. Since the present tests do not exceed a Reynolds number of 8.7×10^5, this last conclusion is open to question if the Reynolds number exceeds 1,000,000.

Because of a slight irregularity at the junction of the nozzle and the test pipe, the data of test 12 at small values of x/D were considered to be less reliable than those of the other tests. The data of test 12 are, nevertheless, in substantial accord with those of the other tests. If they were shown in Fig. 15 they would not alter in any way the conclusions drawn below. The figure is somewhat simplified by omitting them.

Mean Apparent Friction Coefficient. In Fig. 15 the mean apparent friction coefficient between the entrance to the test pipe and any value of L/D is plotted against that value of L/D. This method of plotting has two advantages: (*a*) This mean friction coefficient is more readily applied to design calculations than the more nearly point values in Fig. 14; (*b*) Since it is computed in general from a larger measured pressure difference, the values of the ordinate in Fig. 15 are less affected by small experimental errors and irregularities and therefore yield a smoother curve.

The curves in Fig. 15 consistently with those in Fig. 14 show certain trends with increasing Reynolds number: The point of minimum mean friction coefficient moves to lower values of L/D, and the rate of increase of friction coefficient with L/D at the higher values of L/D decreases. On each curve is given the Reynolds number corresponding to the viscosity at zero velocity (the "complete-recovery" value), and at the right-hand margin is shown the corresponding value of the coefficient of friction for an incompressible fluid at large values of L/D.

The experimental curves are extrapolated in Fig. 15 as they would go if the values for incompressible flow were the asymptotes. The extrapolations cannot, however, extend to the asymptotes. It can be shown from Equation [3] that for a fixed value of the Mach number at entrance, there is a corresponding maximum value of $\lambda \frac{L}{D}$ which will occur when $\mathbf{M}_2 = 1$. That maximum value represents an equilateral hyperbola cutting across Fig. 15. Segments of such hyperbolas are shown for entrance Mach numbers of 1.5, 2, 3, 4, and infinity. For an entrance Mach number of 1 the corresponding hyperbola is

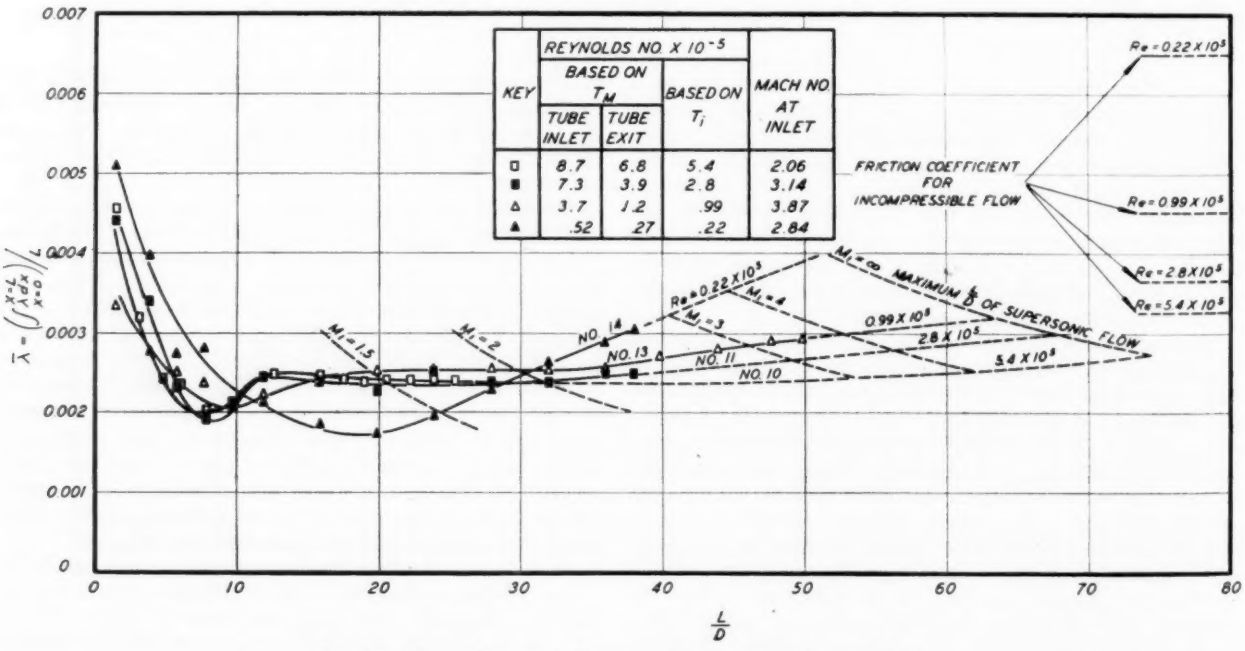

FIG. 15 MEAN APPARENT FRICTION COEFFICIENT AGAINST L/D

formed by the two axes of co-ordinates, and the maximum value of L/D is zero for any finite value of λ.

At the lower values of L/D some variation from the curves in Fig. 15 may be expected if the nozzle design is not identical with the corresponding one employed here. Large departures from these values will result, as indicated in Fig. 13, if oblique shocks are formed at the junction of nozzle and test pipe. But with a carefully designed nozzle and a smooth test pipe the mean apparent friction coefficient should be in close accord with the curves in Fig. 15.

Comparisons

In subsonic flow two previous experimental investigations by Keenan (5) and Frössel (4) indicated that for large values of L/D the apparent friction coefficient is essentially independent of Mach number and is, within experimental error, the same function of Reynolds number as the friction coefficient for incompressible fluids. The present investigation, as shown in Fig. 7, confirms these conclusions.

In supersonic flow the only previous experimental investigation is that of Frössel (4). His conclusion is the same as for subsonic flow, namely, that the apparent friction coefficient at the attainable values of L/D is the same function of Reynolds number as the friction coefficient for incompressible fluids at large values of L/D. The present investigation does not confirm this conclusion. It indicates that the apparent friction coefficient is a function of L/D as well as Reynolds number over the attainable range of L/D, and that the effect of Mach number is to limit the range of values of L/D.

Frössel concludes that his measured friction coefficients are represented within the precision of measurement by the von Kármán-Nikuradse relation. Thus the comparisons of this relation with the present data, as given in Figs. 14 and 15, are in effect comparisons of Frössel's data with the present data. It should be remembered, however, that Frössel's data for supersonic velocities spread over a band with a width of about 20 per cent, and that the method of computing them seems to leave much room for uncertainty.

Frössel offers no discussion of the development of nozzles suitable to his purpose, and the only published illustrations of his nozzles are to such a small scale that little dependable information can be obtained from them. These illustrations, however, are not inconsistent with the assumption that his nozzles were of the conical type with an angle of divergence in the order of 15 deg. The data in Fig. 13 indicate that for angles of this magnitude Frössel's conclusions have been confirmed. For supersonic flow without oblique shocks, however, the conclusions of Frössel have not been confirmed.

For subsonic conditions the minimum exit pressure for a given length of pipe is obtained by lowering the pressure in the exhaust space until the pressure in the exit plane ceases to fall. Then the entrance Mach number corresponding to the exit-plane pressure may be determined by measurements at the inlet. In Fig. 6 the measured pressure from the tap nearest the exit-plane is compared with the calculated minimum pressure (the pressure of maximum entropy). The measured pressure falls slightly below the calculated minimum. This is in accord with similar observations made by Frössel.

In supersonic flow an experimental determination of the maximum pressure is more difficult. The divergence ratio of the nozzle fixes the Mach number at entrance. The maximum pressure will be attained at the exit only if the pipe attached to the nozzle is the longest pipe which will not cause a transverse pressure shock. The maximum pressure cannot be attained, therefore, although it may be approximated closely by a tedious method of trial and error. Where it has been nearly attained in these tests it has always been slightly less than the calculated maximum.

Conclusions

For values of L/D greater than 50 the apparent coefficient of friction for compressible flow at Mach numbers greater or less than 1 is approximately equal, for equal Reynolds numbers, to the coefficient of friction for incompressible flow with completely developed boundary layer.

For Mach numbers greater than 1, however, values of L/D greater than 50 are rarely encountered. For values of L/D less than 50, the coefficient of friction is a function of L/D and Reynolds number. It is generally less than that given by the von Kármán-Nikuradse formula if the Reynolds number is less than 10^6. The effect of Mach number is to limit the range of values of L/D.

For Mach numbers greater than 1, the mean apparent coefficient of friction decreases rapidly from a relatively high value at entrance to a minimum value which it attains within a distance of 20 diam from the entrance. Beyond this minimum point the mean coefficient rises with increasing distance along the tube and appears to approach as a limit the value given by the von Kármán-Nikuradse formula. The point values of the apparent coefficient appear to attain the formula value at a distance of approximately 50 diam from the tube entrance; the mean values of the coefficient would attain the limit at perhaps twice this distance from the entrance.

The variation in coefficient of friction with L/D for supersonic flow is similar to that observed in the flow of incompressible fluids. An adequate comparison cannot be made, however, until more extensive information is available as to the effect of L/D in the flow of incompressible fluids.

The minimum observed pressure in subsonic pipe flow and the maximum observed pressure in supersonic pipe flow are each slightly less than the value calculated on the basis of the assumption that the velocity is uniform across any section.

The apparent coefficient of friction is strongly influenced by the presence of oblique shock waves in the tube.

The junction of the tube with an ordinary conical nozzle causes oblique shock waves, the amplitude of which increases with increasing angle of the cone. The apparent coefficient of friction also increases with increasing angle of the nozzle cone, and appears to attain approximately the von Kármán-Nikuradse value when the angle of the cone is 15 deg or more.

Acknowledgment

A Study of Flow of Plastics Through Pipes

By R. C. BINDER[1] AND J. E. BUSHER[2]

The pipe friction coefficient for true fluids is usually expressed as a function of Reynolds number. This method of organizing data has been extended to tests on the flow of different suspensions which behaved as ideal plastics in the laminar-flow range and as true fluids in the turbulent-flow range. In the laminar-flow range, Reynolds number below about 2100, the denominator in Reynolds number is taken as the apparent viscosity. The apparent viscosity can be determined from the yield value and the coefficient of rigidity. In the turbulent-flow range, the denominator in Reynolds number is an equivalent or turbulent viscosity equal to the dynamic viscosity of a true fluid having the same friction coefficient, velocity, diameter, and density as that of the plastic. The various experimental data on plastics correlate well with this extension of the method for true fluids.

Nomenclature

The following nomenclature is used in the paper:

- D = internal diameter of pipe
- f = pipe friction factor
- g = gravitational acceleration
- h = head loss, unit length of flowing substance
- L = length of pipe
- S = shear stress, force per unit area
- S_0 = yield value or stress of an ideal plastic, force per unit area
- V = average velocity of flowing substance
- ΔP = drop in pressure in the length L
- ρ = density, mass per unit volume, as slugs per cubic foot
- η = coefficient of rigidity
- μ = dynamic viscosity
- μ_a = apparent viscosity of an ideal plastic
- μ_T = turbulent viscosity of an ideal plastic

Introduction

Much experimental data are available on the steady flow of various fluids, as oil, water, and air, through circular pipes. From the point of view of flow characteristics, such fluids may be classified as true or homogeneous fluids. The pipe-flow data for true fluids has been well organized and established in forms convenient for general use. On the other hand, there is a definite lack of organized data on the flow of heterogeneous fluids, suspensions, and plastics through pipes. Different investigators have provided some data on the flow of suspensions through pipes; these suspensions had plastic properties. This paper presents an organization and correlation of the test data of these various investigators and expresses the results in a form which extends the latest organization established for true fluids.

In practice can be found many examples of heterogeneous fluids, in which fine particles, as sand, dust, clay, paper pulp, industrial solids, or sewage sludge, are suspended in water. The problem of the flow of a suspension or plastic is much more complicated than that of a true fluid. Among the problems involved in the transportation of suspensions is that of predicting friction losses, and that of providing suitable pumps and motors for moving the material. The pipe friction loss of a suspension may be considerably higher than that of the fluid carrier alone at the same velocity.

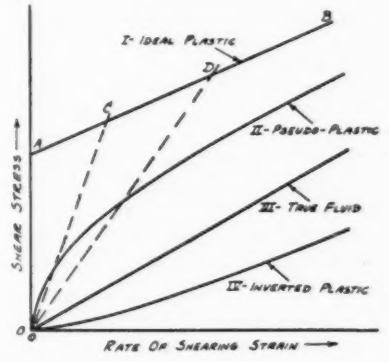

Fig. 1 Stress - Rate of Strain Relations for Different Substances

Fig. 1 shows diagrammatically the relation between shear stress and rate of shearing strain for different substances. Curve III, for a true fluid, shows a linear relation passing through the origin. The slope of curve III, the absolute or dynamic viscosity, is constant. The dynamic viscosity of a true fluid is uniquely determined by the temperature and pressure. It is not generally appreciated that this fact represents a great simplification of many flow problems.

Curve I, for what will be called an "ideal plastic," indicates a relative motion between layers, or deformation, only at a shear stress exceeding a certain minimum, the yield value. The curve AB is linear. The ratio of shear stress to rate of shearing strain or the "apparent viscosity" for a plastic is not constant. The dotted lines CO and DO have different slopes at different velocities; the same substance at different velocities has different apparent viscosities. This variation accounts for one of the main complications found in the flow of plastics.

Consider the flow between two parallel plates a distance x apart. Let S represent the shear stress on each plate, S_0 the yield value of the plastic, and v the velocity of one plate with respect to the other. The coefficient of rigidity η is defined as the ratio

$$\eta = \frac{(S - S_0)x}{v} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

An ideal plastic can be specified by the yield value and the coefficient of rigidity. The coefficient of rigidity has the same dimensions as dynamic viscosity.

Curves II and IV in Fig. 1 indicate other possible relations between shear stress and rate of shear. Curve II might be termed a

"pseudoplastic," and curve IV might be called an "inverted plastic."

Laminar Flow of an Ideal Plastic

The well-known Hagen-Poiseuille law for the laminar flow of a true fluid in a pipe can be expressed in the form

$$\frac{\Delta PD}{4L} = \frac{8V}{D}\mu \quad [2]$$

where ΔP represents the pressure loss in the length L, V the average velocity, D the internal pipe diameter, and μ the absolute or dynamic viscosity of the fluid. It is common practice to express the head loss h in the form

$$h = \frac{fLV^2}{D\,2g} \quad [3]$$

where the dimensionless friction factor f is a function of the dimensionless Reynolds number $N = \rho VD/\mu$. For the laminar flow of a true fluid, the friction factor is given by the simple relation

$$f = \frac{64}{N} \quad [4]$$

Consider next the laminar flow of an ideal plastic through a circular pipe. Imagine a central cylindrical mass of length L and radius y. The velocity at radius y is u. For steady motion there are two resultant forces, a pressure force, and a shear force. The pressure force is $\Delta P\pi y^2$. The shear stress S at y is

$$S = -\eta\frac{du}{dy} + S_0 \quad [5]$$

The first term in Equation [5] is negative because the velocity decreases as the radius increases. The shear force equals the stress S times the area $2\pi yL$. For equilibrium, a balance of forces gives

$$\Delta P\pi y^2 = 2\pi yL\left[-\eta\frac{du}{dy} + S_0\right]$$

$$\eta\frac{du}{dy} = S_0 - \frac{\Delta P}{2L}y \quad [6]$$

Equation [6] is the basic differential equation for the flow of an ideal plastic. The velocity gradient is zero in a central region in which the shear stress is equal to or less than the yield value; that is, there is a central core which moves as a solid plug. After integrating Equation [6] and evaluating the constants from the boundary conditions, the final result can be arranged in the form

$$\frac{\Delta PD}{4L} = \frac{8V}{D}\eta + \frac{4}{3}S_0 \quad [7]$$

A complete discussion of the intermediate steps in deriving Equation [7] can be found in Bingham's book (1),[3] or in a paper by Babbitt and Caldwell (5). A comparison of Equations [2] and [7] is of interest. If the yield value S_0 were zero, then Equation [7] would reduce to Equation [2], and the coefficient of rigidity would approach the dynamic viscosity. Equation [7] can be written as

$$\frac{\Delta PD}{4L} = \frac{8V}{D}\left[\eta + \frac{DS_0}{6V}\right]$$

$$\frac{\Delta PD}{4L} = \frac{8V}{D}\mu_a \quad [8]$$

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

where

$$\mu_a = \eta + \frac{DS_0}{6V} \quad [9]$$

The factor μ_a is an apparent viscosity. Equation [8] is similar in form to the Hagen-Poiseuille law. Thus the friction factor for the laminar flow of an ideal plastic can be expressed as

$$f = \frac{64}{N} \quad [10]$$

if the Reynolds number for the plastic is expressed with the apparent viscosity. Thus for the laminar flow of an ideal plastic, $N = \rho VD/\mu_a$.

The next step is to consider the available experimental data, and their agreement with the analytical relations. Busher (2) made some measurements on the flow of suspensions through copper pipe at various temperatures, velocities, and concentrations. The flowing substance was a heated mixture of grain suspended in water. Fig. 2 shows the head loss as a function of velocity. Note that the head loss for the suspension in some cases is much higher than that for water at the same velocity.

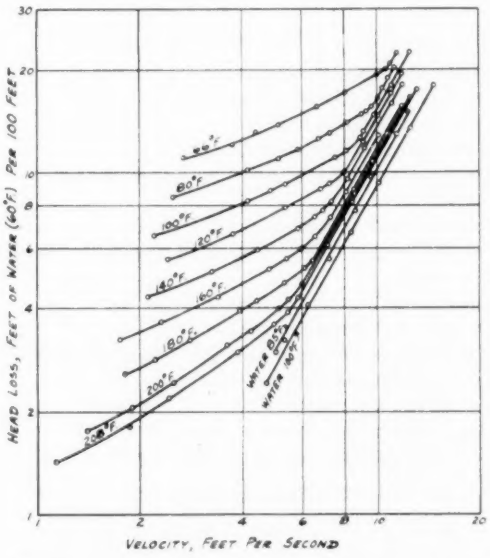

Fig. 2 Friction Loss for Grain Suspensions in 3-In. Copper Pipe

An inspection of Equation [7] shows that if the factor $\Delta PD/4L$ is plotted as a function of $8V/D$, then for an ideal plastic the vertical intercept is $4S_0/3$, and the slope of the curve is the coefficient of rigidity. Busher's data are plotted with these particular co-ordinates in Fig. 3. Many of the experimental points fall on straight lines. In some cases at the high velocities the curve deviates from the straight line as turbulent flow is reached. On the other hand, at velocities lower than those measured, the curves may deviate like a pseudoplastic. But in the laminar-flow range covered by the experimental points, the grain suspensions behaved much as an ideal plastic.

For each temperature, the yield point and the coefficient of rigidity, as determined from Fig. 3, were used to calculate the apparent viscosity and the Reynolds number. Fig. 4 shows the unified correlation of the data at the different temperatures. There is very close agreement between the experimental points and the line $f = 64/N$ in the laminar-flow region through a Reynolds number of 2130.

Gregory (3) made some tests on the flow of clay slurry through a

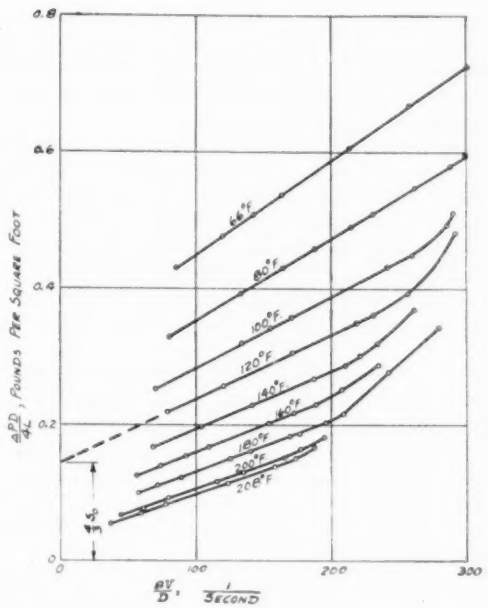

FIG. 3 PRESSURE-VELOCITY RELATIONS FOR GRAIN SUSPENSIONS IN 3-IN. COPPER PIPE

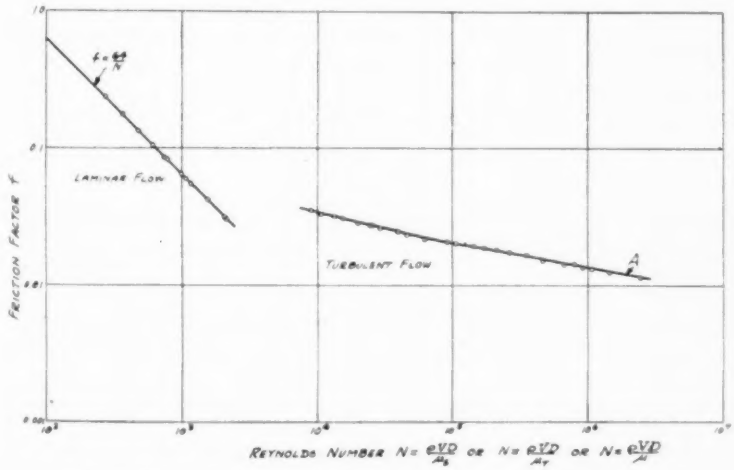

FIG. 4 FRICTION FACTOR VERSUS REYNOLDS NUMBER FOR GRAIN SUSPENSIONS IN 3-IN. COPPER PIPE

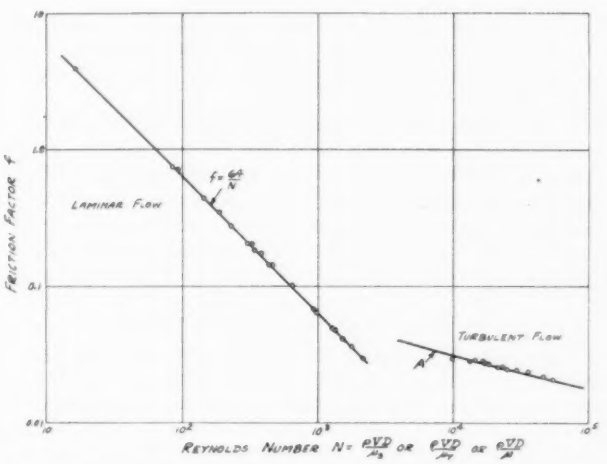

FIG. 6 FRICTION FACTOR VERSUS REYNOLDS NUMBER FOR CEMENT-ROCK SUSPENSIONS IN 3/4-IN. BRASS, 1 1/2-IN. BRASS, AND 3-IN. PIPE

4-in. cast-iron pipe. Some results are given in Fig. 5 and show good agreement with the ideal-plastic relation. Laminar flow was found at a Reynolds number as high as 2070.

Wilhelm, Wroughton, and Loeffel (4) presented the results of an extensive series of tests on suspensions of cement rock in water. Tests were made at different velocities, at different concentrations, and with 3/4-in. brass, 1 1/2-in. brass, and 3-in. wrought-steel pipe. The results are shown in Fig. 6. For laminar flow there is close agreement between the experimental results and the simple analytical relation for an ideal plastic. Laminar flow was realized with a Reynolds number as high as 2150.

Babbitt and Caldwell (5) made a series of tests on the flow of sewage sludge in 1-in., 2-in., and 3-in. pipes. The results for laminar flow are shown in Fig. 7, with the highest Reynolds number at 1850. There is close agreement between the experimental results and the simple analytical relation for an ideal plastic.

Most lubricating oils at ordinary pressures and temperatures act as true fluids. At high pressures, however, some oils exhibit plastic properties. Fig. 8 shows the results of two tests on sperm oil through a capillary tube (internal diameter 0.0456 cm) made by Norton, Knott, and Muenger (6). One test was

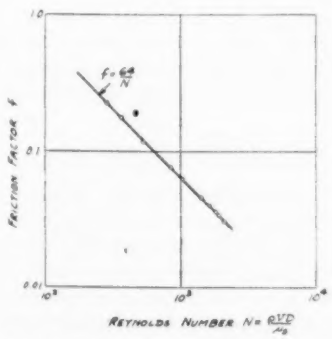

FIG. 5 FRICTION FACTOR VERSUS REYNOLDS NUMBER FOR CLAY SLURRY IN 4-IN. CAST-IRON PIPE

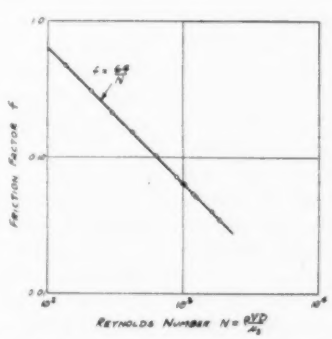

FIG. 7 FRICTION FACTOR VERSUS REYNOLDS NUMBER FOR SEWAGE SLUDGE IN 1-IN., 2-IN., AND 3-IN. PIPES

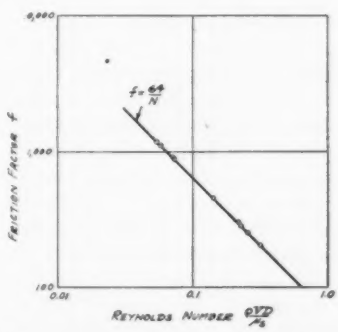

FIG. 8 FRICTION FACTOR VERSUS REYNOLDS NUMBER FOR SPERM OIL THROUGH CAPILLARY
(Oil acted as a plastic because of high pressure.)

at an average pressure of 31,500 psi, and the other at 35,000 psi. At these high pressures the test results fell close to the curve for an ideal plastic. The friction factors are rather high and the Reynolds numbers are rather low.

It is somewhat generally established that the flow of a true fluid is laminar if the Reynolds number is under about 2100. Laminar flow may exist at higher Reynolds numbers, but the flow may be unstable. The data of different investigators indicate that it seems safe to formulate a similar rule for an ideal plastic. The flow of an ideal plastic is laminar if the Reynolds number, based on the apparent viscosity, is under about 2100.

Determination of Apparent Viscosity

The foregoing study of the pertinent data of different investigators yields a simple correlation. There is a practical important question as to the determination of the apparent viscosity or the yield value and the coefficient of rigidity. Babbitt and Caldwell (5) conclude that the yield value and the coefficient of rigidity each is independent of the size and roughness of the pipe. If this conclusion is accepted as satisfactory, then a test with a model pipe could be used to determine the yield value and the coefficient of rigidity for a particular plastic, and predictions could be made for the flow of the same plastic through a prototype pipe. This procedure appears to be good technique, in the same way that the use of a capillary-tube viscometer is considered good technique in measuring the dynamic viscosity of a true fluid. There is some scatter in the data of Babbitt and Caldwell; the yield value from a test on one pipe size may differ from the yield value from a test on another pipe size by as much as 20 per cent. About the same scatter is found in the data on cement-rock suspensions. This scatter may not be too unreasonable if it is noted that the pipe flow data for true fluids may scatter 5 to 10 per cent above and below mean values.

Turbulent Flow

A plastic may behave as a true fluid when the flow is turbulent. Fig. 2 shows some features which are typical of the results of different investigators. The two lines marked "water" are results obtained from actual tests with water in the pipe; the points shown are for turbulent flow. Consider a test of a suspension at a certain temperature. As the velocity increases, the curve changes in slope and approaches a straight line practically parallel to the water curves. These features suggest the possibility of correlating the data on suspensions in a manner similar to that used for water or any other true fluid.

For the turbulent flow of true fluids the friction factor is commonly expressed as a function of Reynolds number at constant roughness values. The main problem for plastic flow is the formulation of a suitable factor to replace the dynamic viscosity in the Reynolds number. Different trials showed that the use of an "equivalent" or "turbulent" viscosity provided a suitable method for organizing results. From one test of a grain suspension is determined a value of the friction factor. This friction factor for the suspension corresponds to a certain Reynolds number for a true fluid flowing through a pipe of the same roughness. For this Reynolds number, and a given density, velocity, and diameter for the suspension, there is thus determined an equivalent or "turbulent" viscosity μ_T for the suspension. The available data show that the turbulent viscosity is practically constant for all rates of shear; it is analogous to a dynamic viscosity.

A complete discussion of Fig. 4 can now be given. In the laminar-flow range only, Reynolds numbers below about 2100, the denominator in the Reynolds number is the apparent viscosity μ_S and can be determined from the yield value and the coefficient of rigidity. Curve A represents the tests with water flowing through the pipe; the denominator in Reynolds number is the dynamic viscosity μ of the true fluid. The experimental points in the turbulent range are for the suspension; the denominator in the Reynolds number is the turbulent viscosity μ_T. The experimental points in the turbulent range follow closely the curve for a true fluid.

A similar discussion applies to the results on cement-rock suspensions shown in Fig. 6. In the laminar-flow range only, the denominator in the Reynolds number is the apparent viscosity μ_s. Curve A is adapted from the data of Stanton and Pannell (7) for smooth drawn pipe; the denominator in the Reynolds number is the dynamic viscosity μ. The experimental points in the turbulent range match fairly well with curve A; the denominator in the Reynolds number for the experimental points is the turbulent viscosity μ_T.

Babbitt and Caldwell (8) made a large series of tests on the turbulent flow of sludges. A number of different clay suspensions and sewage sludge were used, together with different pipe sizes, $^1/_2$ in., 1 in., 2 in., and 3 in. They found that the water suspensions behaved as true fluids in the turbulent range. They concluded that the data correlated well if the denominator in the Reynolds number was taken as the dynamic viscosity of the dispersion medium of the sludge.

In the experiments of Babbitt and Caldwell, apparently the turbulent viscosity did not differ from the dynamic viscosity of the dispersion medium. In other cases, however, there may be a considerable difference between the two viscosities. Fig. 9

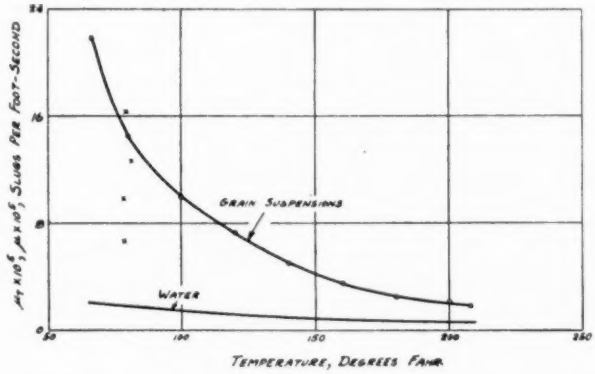

Fig. 9 Turbulent Viscosity and Dynamic Viscosity Versus Temperature

(Crosses refer to cement-rock suspensions.)

shows a plot of turbulent viscosity of the grain suspension and the dynamic viscosity of the dispersion medium water each as a function of temperature. The difference between the two viscosities is large at the low temperatures and decreases as the temperature is increased. The crosses in Fig. 9 are for the different cement-rock suspensions. The turbulent viscosity in each case was greater than the dynamic viscosity of water at the same temperature.

Flow of Pseudoplastics and Inverted Plastics

The foregoing discussion deals with ideal plastics. It would be desirable to have a similar simple organization of data for plastics other than ideal. At the present time there are not sufficient complete published data to draw any reliable general conclusions. For one thing, if the substance is not a true fluid or an ideal plastic, the stress vs. rate-of-strain relation may become very complicated.

One set of test data, however, shows an interesting special case. Wilhelm, Wroughton, and Loeffel made some tests on filter-cel suspensions (4). The results of one test of this suspension in a

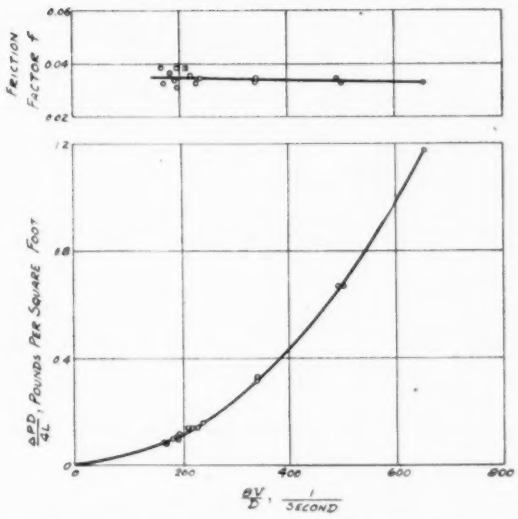

FIG. 10 PRESSURE-VELOCITY RELATION FOR FILTER-CEL SUSPENSION IN 1¼-IN. PIPE

1¼-in. pipe are given in Fig. 10, using the same co-ordinates as in Fig. 3. Fig. 10 shows that the apparent viscosity increases with rate of shear. The relation in a large range of velocities closely approximates a parabola. If the relation is parabolic, then the equation for pressure drop can be written as

$$\frac{\Delta PD}{4L} = C\left(\frac{8V}{D}\right)^2$$

$$\Delta P = \frac{C256LV^2}{D^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

where C is a constant. For a given suspension, pipe diameter, and length, the pressure drop is solely a function of the square of the velocity. In other words, the friction factor f is constant. The test data show an almost constant friction factor over a wide variation of velocity. A constant friction factor means a constant Reynolds number. For a given diameter and density, a constant Reynolds number means a constant ratio between the velocity V and the apparent viscosity μ_a.

CONCLUSION

A number of different investigators have provided data on the flow of suspensions. Different substances were tested, different pipe sizes were used, and different ranges of flow were covered. These substances behaved as ideal plastics in the laminar-flow range and as true fluids in the turbulent-flow range. These test data have been organized in a form which extends the conventional plot of friction factor versus Reynolds number for true fluids. In the laminar-flow range, Reynolds numbers below about 2100, the denominator in Reynolds number is taken as the apparent viscosity of the plastic. This apparent viscosity can be determined from the yield value and coefficient of rigidity. In the turbulent-flow range, the denominator in the Reynolds number is taken as an equivalent or "turbulent" viscosity. This turbulent viscosity is the viscosity a true fluid would have for the same friction factor as the plastic. The turbulent viscosity of a suspension may be much higher than the dynamic viscosity of the dispersion medium of the suspension.

Action of Forces and Moments Symmetrically Distributed Along a Generatrix of a Thin Cylindrical Shell

By F. K. G. ODQVIST,[1] STOCKHOLM, SWEDEN

Applications of the present subject theory have been made to monolithic structures by certain Scandinavian engineers who have treated the subject and related problems in a series of papers. The author has confined his studies to more slender structures, such as welded and riveted plate containers, ship hulls, and similar applications, to which a simplified form of the theory may be applied. For an isotropic shell with no stiffeners, explicit formulas are developed in important cases, where the external load is applied to a cylindrical shell, distributed along a generatrix.

THE present subject and related problems have been treated in a series of papers by Scandinavian engineers (1–5).[2] Having in mind applications to monolithic concrete structures, reinforced by stiffeners, for roofs, container walls, and the like, some of these writers have taken the more complete equations of cylindrical shells as a point of departure for their investigations. For the application to more slender structures such as welded and riveted plate containers, steam boilers, ship hulls, or even monocoque structures, the author (3) has confined his work to the simplified form of the theory, laid down by H. Schorer (6). Thus for an isotropic shell with no

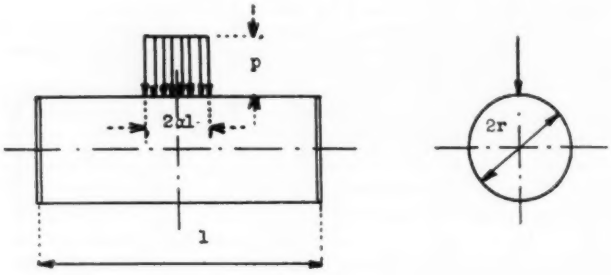

FIG. 1

stiffeners, it has been possible to develop explicit formulas in a series of important cases, where the external load is applied to a cylindrical shell, distributed along a generatrix, Figs. 1 to 3, inclusive.

The treatment has therefore been confined to forces and moments, symmetrically distributed and constant along the part $2\alpha l$ around the middle of a generatrix of a cylinder of length l with its ends linked to stiff circular plates. With the notations

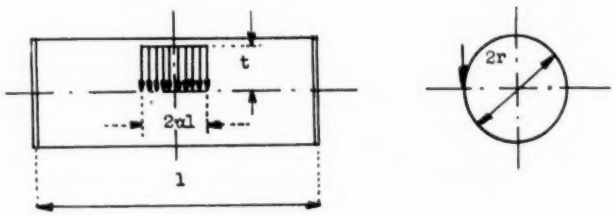

FIG. 2

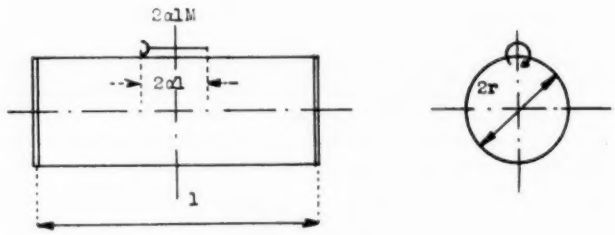

FIG. 3

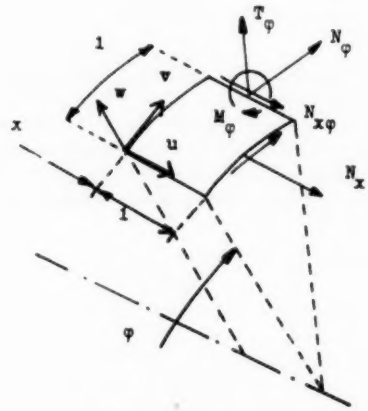

FIG. 4

in Fig. 4, Schorer's theory may be presented in the following form:

$$\frac{\delta^8 M_\varphi}{\delta\varphi^8} + \frac{12(1-\beta^2)r^8}{h^2}\frac{\delta^4 M_\varphi}{\delta x^4} = 0 \quad \ldots\ldots\ldots\ldots [1]$$

$$M_\varphi = \sum_n \Big[e^{-m_1\sqrt{n}\varphi}\,(C_{1n}\sin m_2\sqrt{n}\varphi + C_{2n}\cos m_2\sqrt{n}\varphi) + e^{-m_2\sqrt{n}\varphi}\,(D_{1n}\sin m_1\sqrt{n}\varphi + D_{2n}\cos m_1\sqrt{n}\varphi)\Big]\cos n\pi x/l \quad [2]$$

where $C_{1n} \ldots D_{2n}$ are constants to be determined by the conditions at the loaded generatrix. The thickness of the shell is h; x is counted positive from the middle of the generatrix. With the notation (β = Poisson ratio)

$$m = [12(1-\beta^2)]^{1/8}\,(r/h)^{1/4}\,(\pi r/l)^{1/2} \cong 2.39(r/h)^{1/4}\,(r/l)^{1/2} \quad [3]$$

---

[1] Professor of Strength of Materials, Royal Institute of Technology.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

we have

$$\left.\begin{aligned} m_1 &= m\cos\pi/8 = 0.92388\,m \\ m_2 &= m\sin\pi/8 = 0.38268\,m \end{aligned}\right\} \quad \ldots\ldots [4]$$

The sums are to be extended over all positive odd integers n.

Essential for the validity of the theory is that m shall be comparatively large, say, greater than 5. With $M\varphi$ being known, the following quantities may be obtained by recurrence, using new series of constants

rT_φ	$C_{1n}^{(1)}$	$C_{2n}^{(1)}$	$D_{1n}^{(1)}$	$D_{2n}^{(1)}$	..... [5]
rN_φ	$C_{1n}^{(2)}$	*	*	*	..... [6]
$-\pi r^2 N_{x\varphi}/l$	$C_{1n}^{(3)}/n$	*	*	*	..... [7]
$-\pi^2 r^3 N_x/l^2$	$C_{1n}^{(4)}/n^2$	*	*	*	..... [8]
$-\pi^3 r^3 Ehu/l^3$	$C_{1n}^{(4)}/n^3$	*	*	*	..... [9]
$-\pi^4 r^4 Ehv/l^4$	$C_{1n}^{(5)}/n^4$	*	*	*	..... [10]
$\pi^4 r^4 Ehw/l^4$	$C_{1n}^{(6)}/n^4$	*	*	*	..... [11]
$\pi^4 r^4 Eh\dfrac{\delta w}{\delta\varphi}/l^4$	$C_{1n}^{(7)}/n^4$	*	*	*	..... [12]

derived successively by means of the formulas

$$\left.\begin{aligned} C_{1n}^{(i+1)} &= \sqrt{n}\,[-m_1 C_{1n}^{(i)} - m_2 C_{2n}^{(i)}] \\ C_{2n}^{(i+1)} &= \sqrt{n}\,[m_2 C_{1n}^{(i)} - m_1 C_{2n}^{(i)}] \\ D_{1n}^{(i+1)} &= \sqrt{n}\,[-m_2 D_{1n}^{(i)} - m_1 D_{2n}^{(i)}] \\ D_{2n}^{(i+1)} &= \sqrt{n}\,[m_1 D_{1n}^{(i)} - m_2 D_{2n}^{(i)}] \end{aligned}\right\} \quad [i = 0 \ldots 6] \ldots\ldots [13]$$

where $C_{1n}^{(0)} \ldots D_{2n}^{(0)}$ are the same as $C_{1n} \ldots D_{2n}$. To obtain a quantity of the left column in expressions [5] to [12], one has to introduce the corresponding set of constants in Equation [2], but for the quantities $N_{x\varphi}$ and u, where $\sin n\pi x/l$ is to be substituted for $\cos n\pi x/l$.

The external loads per unit of length of the generatrix should be developed in Fourier's series, that is, according to Figs. 1 to 3.

$$\left.\begin{matrix} p(x) \\ t(x) \\ M(x) \end{matrix}\right\} = \sum_n \left\{ \begin{matrix} p_n \\ t_n \\ M_n \end{matrix} \right\} \cos n\pi x/l, \quad \begin{matrix} p_n \\ t_n \\ M_n \end{matrix} = \frac{4}{\pi n} \sin n\pi\alpha \begin{Bmatrix} p \\ t \\ M \end{Bmatrix} \quad \ldots\ldots [14]$$

The conditions at the loaded generatrix are for $\varphi = 0$:

(*a*) the case of Fig. 1

$$2T_x = p(x), \quad N_{x\varphi} = 0, \quad v = 0, \quad \frac{\delta w}{\delta\varphi} = 0 \ldots\ldots [15]$$

(*b*) the case of Fig. 2

$$2N_\varphi = t(x), \quad M_\varphi = 0, \quad u = 0, \quad w = 0 \ldots\ldots [16]$$

(*c*) the case of Fig. 3

$$2M_\varphi = M(x), \quad N_\varphi = 0, u = 0 \quad w = 0 \ldots\ldots [17]$$

Using the foregoing expressions, we obtain

$$\left.\begin{aligned} &(a)\ C_{1n} = -(\sqrt{2}-1)C_{2n} = (\sqrt{2}-1)D_{1n} = -D_{2n} = \frac{pr\sqrt{2-\sqrt{2}}}{2\pi mn\sqrt{n}} \sin n\pi\alpha \\ &(b)\ C_{1n} = -C_{2n} = D_{1n} = D_{2n} = -\frac{tr}{\pi\sqrt{2}m^2n^2} \sin n\pi\alpha \\ &(c)\ C_{1n} = D_{1n} = 0, \quad C_{2n} = D_{2n} = \frac{M}{\pi n} \sin n\pi\alpha \ldots\ldots \end{aligned}\right\} \ldots [18]$$

Equations [18] together with [5] to [13] contain the solution of our three problems. For the deflections $w(x, 0)$ and $v(x, 0)$ in radial and circumferential direction, respectively, we get, along the loaded generatrix, the following

Case (*a*)

$$w(x, 0) = -\frac{\sqrt{2-\sqrt{2}}\,[12(1-\beta^2)]^{5/8} l^{3/2} r^{3/4}\, p}{\sqrt{2}\,\pi^{5/2} E h^{5/4}} \sum_n \frac{\sin n\pi\alpha \cos n\pi x/l}{n^2\sqrt{n}} \ldots\ldots [19]$$

Case (*b*)

$$v(x, 0) = -\frac{\sqrt{2-\sqrt{2}}\,[12(1-\beta^2)]^{3/8} l^{5/2}\, t}{\sqrt{2}\,\pi^{7/2} r^{3/4} h^{7/4} E} \sum_n \frac{\sin n\pi\alpha \cos n\pi x/l}{n^3\sqrt{n}} \ldots [20]$$

$$\frac{\delta w}{r\delta\varphi}(x, 0) = -\frac{\sqrt{2-\sqrt{2}}\,[12(1-\beta^2)]^{5/8} l^{3/2}\, t}{\sqrt{2}\,\pi^{5/2} r^{1/4} h^{9/4} E} \sum_n \frac{\sin n\pi\alpha \cos n\pi x/l}{n^2\sqrt{n}} \ldots\ldots [21]$$

Case (*c*)

$$\frac{\delta w}{r\delta\varphi}(x, 0) = \frac{[12(1-\beta^2)]^{7/8} r^{1/4} l^{1/2} M}{\pi^{3/2}\sqrt{2-\sqrt{2}}\, h^{11/4} E} \sum_n \frac{\sin n\pi\alpha \cos n\pi x/l}{n\sqrt{n}} \ldots\ldots [22]$$

Equations [19] to [22] may be combined to solve statically indeterminate problems in connection with the supports of cylindrical containers such as marine steam boilers.

To investigate the action of a single concentrated radial force P in the middle of a generatrix, we may put $2\alpha lp = P$ and let α tend to zero. The passage to the limit may be carried out in Equation [19], term by term. The result is

$$\lim_{\alpha = 0} = \frac{1}{\pi\alpha} \sum_n \frac{\sin n\pi\alpha}{n^2\sqrt{n}} = \sum_n \frac{1}{n\sqrt{n}} = 1.689$$

In such case we get for the deflection

$$w(0, 0) = -1.689 \frac{\sqrt{2-\sqrt{2}}\,[12(1-\beta^2)]^{3/8} r^{3/4} l^{1/2}\, P}{\sqrt{2\pi}\, 2\pi h^{5/4} E} \ldots [23]$$

In this case the quantity N_φ will become infinite at the origin. The effect of a concentrated transverse force $T = 2\alpha lt$ may be similarly investigated.

In case (*c*) the sum in Equations [22], though convergent, does not permit of a passage to the limit $\alpha = 0$, in which case it becomes divergent. Moreover some of the series corresponding to expressions [5] to [12] will show extremely slow convergence in all cases (*a*) to (*c*), a thing already noticed by Aas-Jakobsen in attacking the equations of the general theory, where in some cases he has been compelled to use up to 49 terms of his expansions in order to obtain acceptable numerical results. As a means of improving the convergence of such series, the author suggests using Kummers' transformation, which in this case may be utilized in the following form, valid for α less than $1/2$

$$\left.\begin{aligned} \sum_n \frac{\sin n\pi\alpha}{\sqrt{n}} &= \frac{1}{2\sqrt{2\alpha}} + \frac{\alpha}{2} + \sum_n s_n \sin n\pi\alpha \ldots\ldots \\ \sum_n \frac{\sin n\pi\alpha}{n\sqrt{n}} &= \pi\sqrt{\alpha/2} - \pi\alpha/2 + \sum_n c_n \sin n\pi\alpha \end{aligned}\right\} \ldots [24]$$

where

$$\left.\begin{aligned} s_n &= 1/\sqrt{n} - 2S(n\pi/2)/\sqrt{n} - 2\sin n\pi/2/\pi^2 n^2 \\ c_n &= 1/n\sqrt{n} - 2C(n\pi/2)/n\sqrt{n} + 2\sin n\pi/2/\pi n^2 \end{aligned}\right\} \quad \ldots [25]$$

and $S(z)$, $C(z)$ are Fresnel's integrals of the argument $z = n\pi/2$, tabulated for instance in (7). The sums to the right in Equation [24] converge much more rapidly than those to the left and may be used for the calculation of the stresses in the neighborhood of the points of application of the load.

Experiments in support of the foregoing theory have been carried out with a carefully produced steel cylinder at the Royal Technical Institute, Stockholm. Equation [23] was found to fit experimental data for a cylinder with $m = 5.09$ within experimental errors, which were of the order of 1 per cent. The order of magnitude of the stresses also fitted the corresponding formulas.

The theory permits of generalization, e.g., to the case of longitudinal stiffeners (3). In the case of transverse stiffeners it is generally more convenient to use a simple approximate theory, considering the stiffener as a curved beam supported on the shell as an elastic foundation with a spring constant determined from conditions of axial symmetry. Also this simple theory has been confirmed by experiments. A somewhat more elaborate theory taking account of the general theory of cylindrical shells (nonsymmetrically loaded) has been worked out by Lundgren (4), and Aas-Jakobsen (5).

Equivalent Circuits for the Numerical Solution of the Critical Speeds of Flexible Shafts

By GABRIEL KRON,[1] SCHENECTADY, N. Y.

A special type of equivalent circuit is developed that is particularly suited for the numerical calculation of the critical speeds of uniformly rotating shafts. The shaft may consist of several spans rotating in flexible bearings supported by a flexible foundation. Either the various spans may be asymmetrical along two principal axes or the bearings may have asymmetrical flexibilities. The same circuits are, of course, valid also for the study of the natural frequency of vibration of a skewed asymmetrical beam held by flexible supports at several points, such as a turbine bucket. The circuits may be solved by slide rule, by punch-card methods, or by a "network analyzer." The procedure is self-checking as the correctness of the numbers may be checked at any stage of the calculations. For the symmetrical case, the results are identical with those found by the method of Prohl (1)[2] or Myklestad (2), even though the circuit method requires fewer calculations. In general, the equivalent circuits for the various spans, bearings, overhung loads, and foundations are independent and are interchangeable for different combinations of shaft structure. Also, any variation in a component part leaves the circuits of the other parts unchanged. A punch-card study of a turbine generator shaft with fixed bearings carrying a high-pressure turbine, a low-pressure turbine, and a generator is given in a companion paper by A. W. Rankin (3).

Introduction

DURING the last few years many papers have appeared, both in this country and abroad, calling renewed attention to the analogy existing between simple mechanical structures and electrical circuits, a relation well known but little used for over a century. In this analogy, mass and inductance, spring and capacitance, play identical roles; similarly current takes the place of force, and voltage that of displacement. (The dual analogy, with an interchange of mass and spring, force and displacement, is also frequently employed.) Apparently both electrical and mechanical engineers find this interplay of concepts useful and of benefit in their respective fields. The arrival of the a-c network analyzer, on which the electrical circuits may be quickly solved, accelerated the diffusion of these parallel ideas.

In all such studies each component unit of the mechanical system has one degree of freedom. For instance, each mass and spring have a linear displacement in the x direction only, or each mass and spring rotate around the x-axis only. However, for the greatest number of cases, each mechanical unit has two or more degrees of freedom and, in the most general case, it has six; in particular, three translations along the x-, y-, z-axes and three rotations around them.

Electrical analogs of planar and spatial elastic structures built up from units with two to six degrees of freedom are developed in references (4, 6), and network-analyzer results are shown in references (5, 7). In problems of the critical speeds of large flexible shafts, such as those of turbogenerator sets, it has been found that no presently available network analyzer is equipped with units sufficiently flexible to cover the very large range of values required by the shaft constants. Hence the need arose to solve the electrical networks numerically either by hand or by punch-card machines.

During the calculations it was discovered that the electrical network could be transformed into a new form that required far fewer numerical steps. These transformations are intimately connected with the properties of electrical networks, and apparently no mechanical analog of them exists. These new equations and networks are developed in Appendix 1 while the body of the paper limits itself to the description and development of a routine procedure of calculation.

It is felt that the use of the electrical network has facilitated the introduction of the following features:

1 The number of additions and multiplications required for the calculation of a single beam section is less than the number of operations used in similar problems employing purely mechanical concepts (references 1 and 2).

2 The electric circuit has enabled the development of a method of check that can be used at any particular stage during the calculation. It is believed that one not already acquainted with general circuit parameters in a matrix form, concepts known to (some) electrical engineers, would have had difficulty in discovering these formulas.

3 The fact that each degree of freedom has an identical electrical network (see Fig. 3) greatly reduces the number of operations necessary to route the punched cards through the machines.

Because of the employment of an electrical network in preference to a mechanical network or to a set of algebraic equations, certain simplifications have become almost obvious. For instance, in Appendix 1 of this paper a complicated set of beam equations is reduced to a simplified set by first establishing an equivalent circuit for the former, simplifying the electrical network, then writing the resultant simple equations by an inspection of the network. The same procedure is performed by algebraic manipulations in Appendix 1 of the companion paper by Rankin. There seems to be no mechanical analog of the procedure, and the algebraic manipulations must follow willy-nilly the electric-circuit manipulations.

SYMMETRICAL SHAFT AND BEARING

Equivalent Circuit of a Section

The equivalent circuit of a constant-diameter section of a symmetrical rotating shaft—to be used in numerical calculations—is given in Fig. 1. The voltages D to ground at both ends

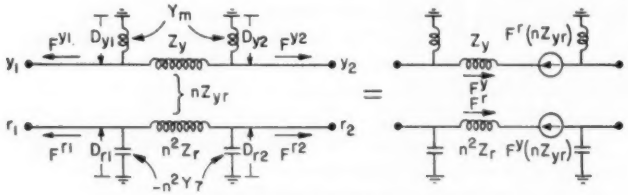

FIG. 1 EQUIVALENT CIRCUIT OF A SECTION

of the section represent:

1 Linear displacement along y.
2 Angular displacement along r.

The currents F at both ends represent:

1 Shear along y.
2 Moment along r.

The values of the constants taken from reference (4) are given in Table 1. The Z's represent impedances, the Y's admittances. The transformation ratio n in Fig. 1 may be selected for any convenient scale. The mass of the section is divided into two equal parts placed at the two ends of the section. The moment of inertia and gyroscopic force of the section are only cursorily treated. Their consideration only changes the value of the ground capacitors as shown in Figs. 14–16, inclusive.

TABLE 1 CALCULATIONS OF CONSTANTS

Section inertia, in.^{4} $= I$
Section length, in. $= L$
Section weight, lb $= W$
N = number of 1000 rpm
$B = EI$

$$M = \frac{W/2}{386.4} \quad \omega^2 = \left(\frac{1000 \times 2\pi}{60}\right)^2 = 10{,}965$$

The admittances are

$$Y_2 = \frac{12B}{L^3} \quad Y_6 = \frac{6B}{L^2} \quad Y_7 = \frac{2B}{L} \quad Y_m = (M\omega^2)\,N^2$$

The circuit constants are

$$Z_y = \frac{2}{Y_2} \quad Z_r = \frac{2}{Y_7} \quad Z_{yr} = \frac{3}{Y_6}$$

$$Y_y = Y_{mi} + Y_{mj} \quad | \quad Y_r = -Y_{7i} - Y_{7j}$$

where i and j indicate adjacent sections

Equivalent Circuit of a Span

When several sections form a span between two bearings, the resultant circuit is shown in Fig. 2. It should be noted:

1 That the mutual inductance of every other section is reversed. (This is shown in Appendix 1.)

2 That the two admittances in parallel existing at the interconnections may be combined into one, giving the final circuit in Fig. 3.

When several spans exist, the alteration in the signs of Z_{yr} should be continued without interruption so that some spans may start with a negative Z_{yr}. (The alternation in the sign of Z_{yr} is not due to any assumed sign convention. It was introduced to simplify the electric circuit of each span.

Schedule of Calculations

Let a single section on the resultant span network in Fig. 3 be considered. (This network section is not identical with a beam section as the ground coils of two neighboring beam sections in Fig. 2 have been combined.) By an inspection of Fig. 3 the following set of equations may be written expressing the unknown right-hand quantities (primed) in terms of known left-hand quantities (unprimed) as

$$\left.\begin{aligned} D_y' &= D_y - Z_y F^y - Z_{ry} F^r \\ D_r' &= D_r - Z_r F^r - Z_{ry} F^y \\ F^{y\prime} &= F^y - Y_y D_y' \\ F^{r\prime} &= F^r - Y_r D_r' \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [1]$$

Here D and D' are identical with D_1 and D_2 of a beam section, but F and F' are not the same as F^1 and F^2, that is, F and F' do not represent actual shears and moments in the beam. They have a physical meaning only in the electrical network and have no mechanical equivalent.

Calculations of Spans Between Flexible Bearings

When the bearings are flexible at both ends of a span, the basic calculation consists of impressing a unit voltage D_1 or current F^1 at the left (the other three quantities remaining zero) and calculating by the previous equations the four voltages and currents appearing at the other end. The following two cases are possible:

1 The whole shaft is calculated through without dividing the shaft into spans.

In that case only any two of the four possible unit quantities are impressed on the left end of the shaft. However, every time a bearing flexibility is changed the whole calculation has to be repeated for all spans and for all speeds.

2 Each span is calculated separately, irrespective of the presence of bearings.

In that case all four of the possible unit quantities are impressed at the left end of each span in succession. Once the span has been calculated at a particular speed, the same calculations are used for all variations in bearing flexibilities.

Impressing two unit voltages and two unit currents, the four separate calculations give sixteen different constants in the form of four equations, shown schematically in Table 2.

TABLE 2 RESULTS OF NUMERICAL CALCULATIONS ON A SPAN

		Impressed unit quantities at left end of span			
		D_{y1}	D_{r1}	F^{y1}	F^{r1}
Calculated quantities at right end of span	$D_{y2} =$	a	b	i	j
	$D_{r2} =$	c	d	k	l
	$F^{y2} =$	e	f	m	n
	$F^{r2} =$	g	h	o	p

Also for every given speed N, a new set of sixteen numbers has to be calculated.

Instead of assuming a single unit D or F at a time, it is possible to assume four unknowns simultaneously, namely, D_{y1}, D_{r1}, F^{y1}, and F^{r1}, so that at each step four constants are calculated instead of one. The number of resultant operations does not

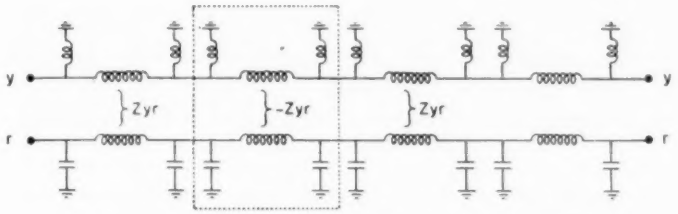

FIG. 2 INTERCONNECTION OF SECTIONS INTO A SPAN

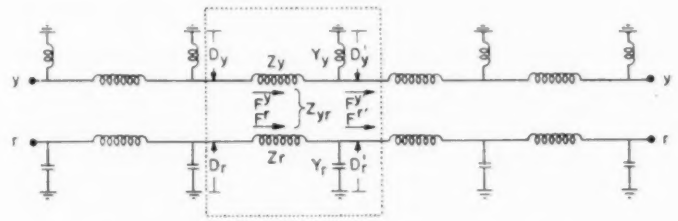

FIG. 3 RESULTANT EQUIVALENT CIRCUIT OF A SPAN

change; on the other hand, the circuit constants Z_y, Z_r, etc., have to be looked up only once instead of four times.

CHECK ON CALCULATION

In order to check the correctness of the four numbers derived at any part of the span, say one third or halfway along the span, it is necessary that two columns be calculated simultaneously, in particular either F^{y1} and F^{r1} or D_{y1} and D_{r1}. The two sets of calculations may be done by two separate calculators proceeding with a different column and checking their results at any part of the circuit. If at some point of the circuit one of the calculators has column F^{r1} (namely, j, l, n, and p), the other has column F^{y1} (namely, i, k, m, and o), then their numbers are correct if (using Equation [29] of Appendix 2)

$$ol + mj = in + kp \quad \ldots\ldots [2]$$

For the two other columns D_{y1} and D_{r1}, the numbers are correct if

$$ch + af = eb + dg \quad \ldots\ldots [3]$$

CALCULATION OF SPAN EQUIVALENT CIRCUIT

If the circuits are solved on a network analyzer, it is necessary to set up an equivalent circuit representing the results of Table 2. Those not interested in such a solution may leave this section out and may represent the span network by a blank rectangle, as in Fig. 5.

The sixteen numbers found for a particular speed do not yet represent the self and mutual admittances of the equivalent circuit. The latter are also sixteen in number, forming a symmetrical set as shown in Equation [4]. They are found by the formulas shown in Table 3. There are also two checks (Y_e and Y_f) on the correctness of calculations

$$\begin{array}{c|c|c|c|c} & D_{y1} & D_{r1} & D_{y2} & D_{r2} \\ \hline F^{y1} = & Y_a & Y_e & Y_f & Y_g \\ \hline F^{r1} = & Y_e & Y_b & Y_h & Y_i \\ \hline F^{y2} = & Y_f & Y_h & Y_e & Y_j \\ \hline F^{r2} = & Y_g & Y_i & Y_j & Y_d \end{array} \qquad \bar{I} = \bar{Y}\,\bar{E} \quad \ldots\ldots [4]$$

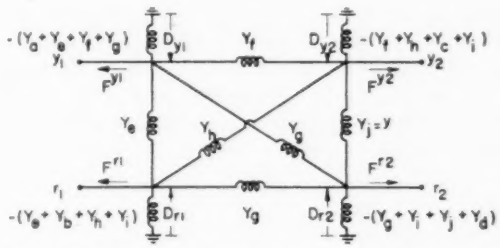

FIG. 4 EQUIVALENT CIRCUIT OF A SPAN BETWEEN TWO BEARINGS

TABLE 3 CALCULATION OF SELF AND MUTUAL ADMITTANCES

Find $D = il - kj$

$$Y_f = \frac{l}{D} \quad Y_g = -\frac{j}{D} \quad Y_h = -\frac{k}{D} \quad Y_i = \frac{i}{D}$$

$$Y_a = -(Y_g c + Y_f a) \quad Y_b = -(Y_h b + Y_i d)$$

$$Y_e = -(Y_g d + Y_f b) = -(Y_h a + Y_i c)$$

$$Y_c = Y_f m + Y_h n \quad Y_d = Y_i p + Y_g o$$

$$Y_j = Y_i n + Y_g m = Y_f o + Y_h p$$

The equivalent circuit in Fig. 4 is formed as follows:

1 The mutual admittances of Equation [4] also represent the mutual coils between corresponding junctions. For instance, Y_h in row r_1 and column y_2 is the coil lying between junctions r_1 and y_2.

2 The coils to ground are found by adding up the four admittances in the respective columns and changing the sign. For instance, the admittance of the coil from junction y_1 to ground is

$$Y_{ga} = -(Y_a + Y_e + Y_f + Y_g) \quad \ldots\ldots [5]$$

INTERCONNECTION OF SPANS, BEARINGS, AND FOUNDATIONS

The spans are interconnected in series as shown in Fig. 5, while the bearing flexibilities along y are shown as shunts to grounds between spans. (Of course coils in parallel may be replaced by a single coil.)

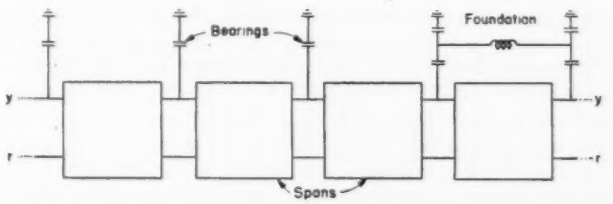

FIG. 5 INTERCONNECTED SPANS, BEARINGS, AND FOUNDATIONS

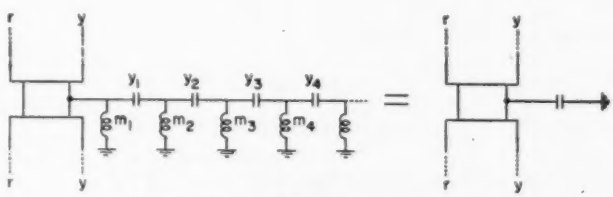

FIG. 6 BEARING EQUIVALENT CIRCUIT

Each bearing admittance may itself be the resultant of a more complex circuit. For instance, in Fig. 6 is shown a generator bearing circuit in detail. The bearing circuits themselves may be interconnected by circuit elements representing the nature of the foundation.

When the bearing and foundation motions are all assumed to exist only along a single linear direction y, their equivalent circuit is the conventional circuit of masses and springs connected in shunt or series. However, the bearing may have a tilting motion along the axis r, to be taken care of by an appropriate shunt admittance along r.

Reduction of Overhung Sections

If, beyond the last bearing, an overhung section exists as shown in Fig. 7(a), the axes y_2 and r_2 may be eliminated and the circuit replaced by three coils as shown in Fig. 7(b). These coils may be combined with parallel coils already existing to the left of the bearing so that the representation of the overhung section requires no extra coils.

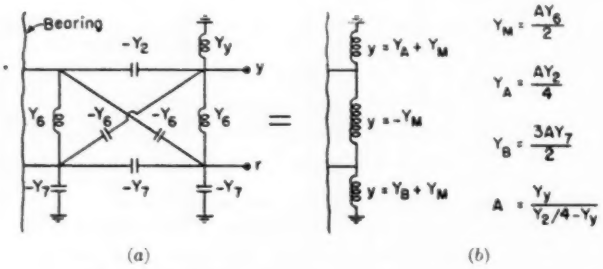

Fig. 7 Reduced Equivalent Circuit of Overhung Section

When the overhung section exists ahead of the first bearing, then the axes Y_1 and r_1 are eliminated, resulting again in the foregoing circuit but with the sign of Y_6 reversed.

The two cases cited assumed that the overhung section had a positive Y_6. With a negative Y_6, the signs change correspondingly.

The resultant equivalent circuit of several spans with bearing flexibilities, overhung sections, and foundations is shown in Fig. 8.

Numerical Calculation of Critical Speeds

The natural frequencies are calculated in two steps, as follows:

1 Assume unit voltage D_{y1} impressed on the left-hand side of the shaft, Fig. 8, with the other voltage D_{r1}, and the two currents F^{y1} and F^{r1} being zero. Calculate the two voltages and two currents D_{y2}', $F^{y2}{}'$, D_{r2}', and $F^{r2}{}'$ appearing on the right-hand side of the shaft, as shown in Fig. 8.

2 Assume unit voltage E_{r1} impressed on the left-hand side, with the other three quantities zero, and calculate the four right-hand quantities D_{y2}'', $F^{y2}{}''$, D_{r2}'', and $F^{r2}{}''$.

Both currents on the left-hand side of the shaft are zero. One of the resultant currents on the right-hand side, say, $F^{y2} = F^{y2}{}' + F^{y2}{}''$, may also be made equal to zero by changing the unit voltage D_{r1} to xD_{r1} so that

$$F^{y2} = F^{y2}{}' + xF^{y2}{}'' = 0$$

from which $x = -F^{y2}{}'/F^{y2}{}''$. With xD_{r1} impressed, the other right-hand current F^{r2} becomes

$$F^{r2} = F^{r2}{}' - \left(\frac{F^{y2}{}'}{F^{y2}{}''}\right) F^{r2}{}'' \quad \ldots\ldots\ldots\ldots\ldots [6]$$

representing the "excess moment." Now at those speeds N at which the excess moment F^{r2} becomes zero, all four currents are zero and the speed is a critical speed. By assuming a variable speed N, the values of F^{r2} may be plotted against N. The calculations may be checked again at any desired point by Equation [2].

When the presence of the foundation is considered under one or more spans, Fig. 8, an unknown potential D is introduced at junction A. If the unknown D is carried along to junction B, it is possible to solve for it, since the outgoing horizontal current at junction B is zero. More complicated mesh circuits may also be solved in an analogous manner by carrying along two or more unknown voltages simultaneously with the unit voltage until they can be determined.

Instead of assuming first a unit voltage D_{y1} impressed, then another unit voltage D_{r1}, it is possible to impress two voltages simultaneously, namely, 1 along D_{y1} and x along D_{r1}, and carry through the network two sets of currents and voltages. The number of numerical operations to be performed is the same in either case.

Calculation of Spans Between Rigid Bearings

When all bearings are rigid, the deflections D_y at the bearings are zero. In that case it is sufficient to impress two unit quantities on each span instead of four. Several possibilities of calculations are open. In one method F^{r1} and xF^{y1} are assumed (F^{r1} and F^{y1} are both unity, while x is unknown.) The two sets of calculations are now performed simultaneously. The resultant four equations of Table 2 become

		$x F^{y1}$	F^{r1}
$D_{y2} = i\,x F^{y1} + j F^{r1}$	=	i	j
$D_{r2} = k\,x F^{y1} + l F^{r1}$	=	k	l
$F^{y2} = m\,x F^{y1} + m F^{r1}$	=	m	n
$F^{r2} = o x F^{y1} + p F^{r1}$	=	o	p

$\ldots\ldots [7]$

At the end of each span D_{y2} is equated to zero, thereby allowing the determination of the unknown x.

ASYMMETRICAL SHAFT OR BEARINGS

Asymmetrical Shaft

One or more of the spans may have different elastic constants

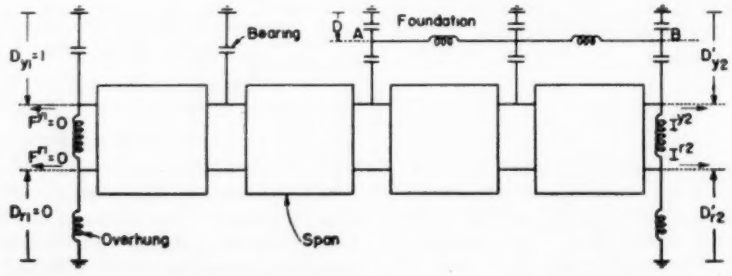

Fig. 8 Resultant Equivalent Circuit of a Shaft

along two principal axes at right angles. For instance, in a turbine shaft the generator span is asymmetrical due to the presence of slots. In such cases it will be assumed that the bearings and foundations are symmetrical.

When the principal axes in each of the asymmetrical spans are parallel, then each principal axis is treated independently of the other with the method of the previous section of the paper. Two sets of critical speeds have to be calculated for the two axes independently.

When the principal axes in each of the asymmetrical sections are not parallel but are at a constant angle (different between different sections), then, at least for one section, the two circuits along the two sets of axes y, r and z, q are not independent but are interconnected. The detailed equivalent circuit of a section to be put on the analyzer is given in Fig. 10 and Table 5 of reference (4). For numerical calculations the circuit may be simplified by multiplying the rows and columns of r_2 and q_2 by -1. Then four mutual admittances appear, as shown in Fig. 9, in a manner analogous to Fig. 1. The four ground admittances are

$$\left.\begin{array}{l|l} Y_{r1} = -(Y_5+Y_{12}+Y_{23}+Y_{27}) & Y_{q1} = -(Y_6+Y_{12}+Y_{24}+Y_{27}) \\ Y_{r2} = -(Y_5-Y_{12}+Y_{23}+Y_{27}) & Y_{q2} = -(Y_6-Y_{12}+Y_{24}+Y_{27}) \end{array}\right\} \quad \ldots [8]$$

$$\bar{Y} = \begin{array}{c|cccc} & \bar{y} & \bar{r} & \bar{z} & \bar{q} \\ \hline \bar{y} & -Y_{12} & Y_{15} & Y_9 & Y_{20} \\ \bar{r} & Y_{15} & Y_{24} & Y_{21} & -Y_{27} \\ \bar{z} & Y_9 & Y_{21} & -Y_3 & Y_{18} \\ \bar{q} & Y_{20} & -Y_{27} & Y_{18} & Y_{23} \end{array} \quad \ldots [9]$$

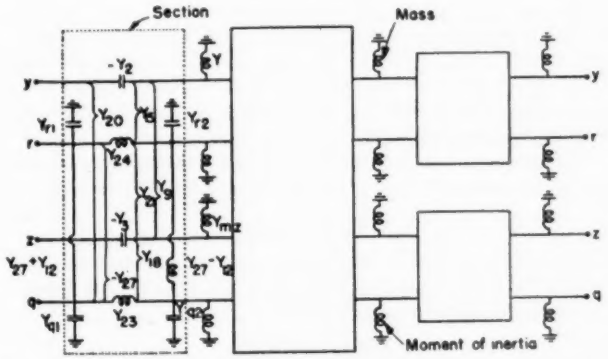

FIG. 9 EQUIVALENT CIRCUIT OF SHAFT WITH ASYMMETRICAL, TWISTED SECTION

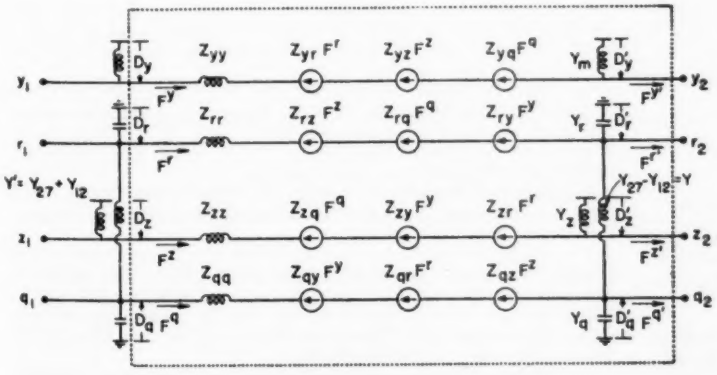

FIG. 10 EQUIVALENT CIRCUIT OF ASYMMETRICAL, TWISTED SECTION

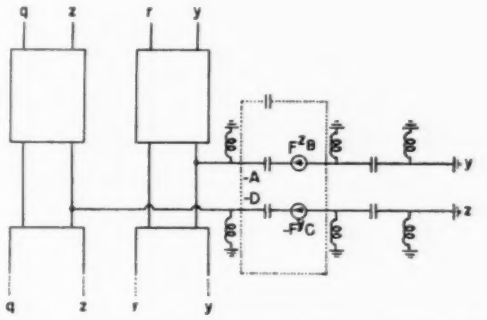

FIG. 11 EQUIVALENT CIRCUIT OF ASYMMETRICAL BEARING

Its inverse has to be calculated to find the self and mutual impedances $\bar{Z}$ needed for the numerical calculations, Fig. 11.

$$\bar{Z} = \begin{array}{c|cccc} & \bar{y} & \bar{r} & \bar{z} & \bar{q} \\ \hline \bar{y} & Z_{yy} & Z_{yr} & Z_{yz} & Z_{yq} \\ \bar{r} & Z_{ry} & Z_{rr} & Z_{rz} & Z_{rq} \\ \bar{z} & Z_{zy} & Z_{zr} & Z_{zz} & Z_{zq} \\ \bar{q} & Z_{qy} & Z_{qr} & Z_{qz} & Z_{qq} \end{array} \quad \ldots [10]$$

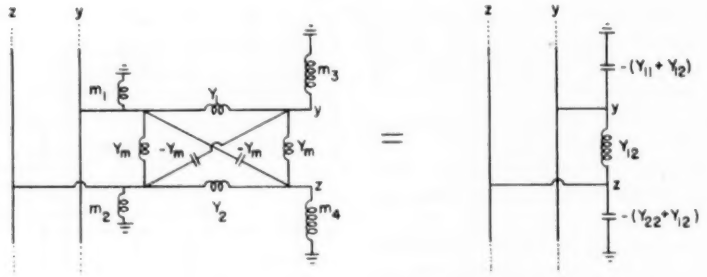
The equivalent circuit to be used for this numerical procedure is shown in Fig. 10 in which the induced voltages due to mutual inductances are shown by generators. By inspection of Fig. 10 the following set of eight equations may be written for the asymmetrical shaft in analogy to the set of Equations [1]

$$\left.\begin{array}{l} D_y' = D_y - Z_{yy}F^y - Z_{yr}F^r - Z_{yz}F^z - Z_{yq}F^q \\ D_r' = D_r - Z_{rr}F^r - Z_{rz}F^z - Z_{rq}F^q - Z_{ry}F^y \\ D_z' = D_z - Z_{zz}F^z - Z_{zq}F^q - Z_{zy}F^y - Z_{zr}F^r \\ D_q' = D_q - Z_{qq}F^q - Z_{qy}F^y - Z_{qr}F^r - Z_{qz}F^z \\ F^{y\prime} = F^y - Y_y D_y' \\ F^{r\prime} = F^r - Y_r D_r' - Y(D_r' - D_q') \\ F^{z\prime} = F^z - Y_z D_z' \\ F^{q\prime} = F^q - Y_q D_q' - Y(D_q' - D_r') \end{array}\right\} \quad \ldots [11]$$

Here again the equations do not represent a beam section. They correspond to a section of the electrical network on.

ASYMMETRICAL BEARING

If an asymmetrical coupling between the bearing flexibilities along the y and z directions is assumed, the form of this coupling is



$$\bar{Y} = \begin{array}{c|cc} & \bar{y} & \bar{z} \\ \hline \bar{y} & -A & B \\ \bar{z} & -C & -D \end{array} \quad \ldots [12]$$

where C is different from B (say, $B = KC$) and has usually opposite sign.

For numerical calculations, such an asymmetrical coupling may be represented by generators, as shown in Fig. 11.

REDUCTION OF BEARING CIRCUIT

Each of the bearing circuits may be replaced by an equivalent delta (employing only three coils) by the following steps:

(a) (b)

FIG. 12 STEPS IN THE REDUCTION OF AN ASYMMETRICAL BEARING CIRCUIT

1 The simple series-shunt circuits along y and z may be replaced by an equivalent coil m so that the bearing circuit becomes that in Fig. 12(a).

2 The latter circuit is reduced to three coils, Fig. 12(b), by the following formulas

$$Y_{11} = -m_1 + \frac{m_3[Y_m^2 - Y_1(Y_2 + m_4)]}{(Y_1 + m_3)(Y_2 + m_4) - Y_m^2} \quad \ldots\ldots [13]$$

$$Y_{22} = -m_2 + \frac{m_4[Y_m^2 - Y_2(Y_1 + m_3)]}{(Y_1 + m_3)(Y_2 + m_4) - Y_m^2} \quad \ldots\ldots [14]$$

$$Y_{12} = \frac{m_3 m_4 Y_m}{(Y_1 + m_3)(Y_2 + m_4) - Y_m^2} \quad \ldots\ldots [15]$$

The resultant simplified circuit of the shaft system to be put on the network analyzer or to be solved numerically is shown in Fig. 13.

NUMERICAL CALCULATION OF CRITICAL SPEEDS

The critical speeds are calculated in a manner analogous to that shown under the same heading of the first section of the paper. However, now four different unit voltages and currents are impressed on the left-hand side in succession, instead of two, and eight different quantities are calculated on the right-hand side instead of four.

To determine the "excess moment" along, say, r, three of the resultant right-hand currents are to be made equal to zero instead of one. Changing three of the impressed voltages by x, y, and z, respectively, the "excess moment" is

$$\left.\begin{aligned} F^{r2} = F^{r2'} &+ \left[\frac{a(kh - gl) + e(fl - jh) + i(jg - fk)}{Det}\right] F^{r2''} \\ &+ \left[\frac{a(cl - kd) + e(jd - bl) + i(bk - jc)}{Det}\right] F^{r2'''} \\ &+ \left[\frac{a(gd - ch) + e(bh - fd) + i(fc - bg)}{Det}\right] F^{r2''''} \end{aligned}\right\} \quad \ldots\ldots [16]$$

where the right-hand currents are denoted by letters according to the scheme

$$\begin{vmatrix} F^{x2'} & F^{x2''} & F^{x2'''} & F^{x2''''} \\ F^{y2'} & F^{y2''} & F^{y2'''} & F^{y2''''} \\ F^{q2'} & F^{q2''} & F^{q2'''} & F^{q2''''} \end{vmatrix} = \begin{vmatrix} a & b & c & d \\ e & f & g & h \\ i & j & k & l \end{vmatrix} \quad [17]$$

When the presence of a foundation introduces extra meshes, they are again taken care of by extra variables as in the first section with the same heading.

Instead of assuming one impressed unit voltage at a time, it is possible to introduce two impressed voltages, say, 1 along axis y_1 and x along r_1, and carry two sets of numbers. Afterward a unit voltage may be impressed along axis z_1 and x along q_1. Or it is even possible to introduce four voltages simultaneously, say, 1 along axis y_1, x along r_1, y along z_1, and z along q_1, and carry four sets of numbers simultaneously throughout the network. Again the number of operations is not decreased with either method, but the procedure may be speeded up.

It is possible to check the correctness of the numbers at any particular bearing by the use of Equation [29], Appendix 2.

Appendix 1

Simplified Equivalent Circuits of a Beam

The admittance matrix and equivalent circuit of a beam with mass Y_m and moment of inertia Y_I are given in Equation [18] and in Fig. 14, reproduced from reference (4).

$$\bar{Y} = \begin{array}{c|cccc} & \bar{y}_1 & \bar{r}_1 & \bar{y}_2 & \bar{r}_2 \\ \hline \bar{y}_1 & Y_2 - Y_m & Y_6 & -Y_2 & Y_6 \\ \bar{r}_1 & Y_6 & 2Y_7 - Y_I & -Y_6 & Y_7 \\ \bar{y}_2 & -Y_2 & -Y_6 & Y_2 - Y_m & -Y_6 \\ \bar{r}_2 & Y_6 & Y_7 & -Y_6 & 2Y_7 - Y_I \end{array} \qquad \left.\begin{array}{l} \bar{I} = \bar{Y}\,\bar{E} \\ \bar{F} = \bar{Y}\,\bar{D} \end{array}\right\} \quad \ldots\ldots\ldots [18]$$

The constants are shown in Table 1. With this sign convention, the equivalent circuits of beams may be interconnected in shunt and in series in arbitrary manner, the same way as the beams are.

This circuit is not in a form to be used for numerical calculations, hence let the directions of D_{r2} and F^{r2} on the beam be changed by multiplying the row and column of r_2 by —1.

$$\bar{Y} = \begin{array}{c|cccc} & \bar{y}_1 & \bar{r}_1 & \bar{y}_2 & \bar{r}_2 \\ \hline \bar{y}_1 & Y_2 - Y_m & Y_6 & -Y_2 & -Y_6 \\ \bar{r}_1 & Y_6 & 2Y_7 - Y_I & -Y_6 & -Y_7 \\ \bar{y}_2 & -Y_2 & -Y_6 & Y_2 - Y_m & Y_6 \\ \bar{r}_2 & -Y_6 & -Y_7 & Y_6 & 2Y_7 - Y_I \end{array} \quad \ldots [19]$$

Then, provided the signs on the circuit remain unchanged, all mutual admittances at junction r_2 also change signs, while all ground coils assume different values as shown in Equation [19] and Fig. 15. In particular, there is no coil in parallel with the mass.

With this new sign convention, the circuits cannot be interconnected in arbitrary manner, only in series and then even with certain precautions only, as will be presently shown.

The four Equations [19] $\bar{F} = \bar{Y}\,\bar{D}$ may be rewritten as

$$\left.\begin{array}{rl} F^{y1} + Y_m D_{y1} &= Y_2 (D_{y1} - D_{y2}) + Y_6 (D_{r1} - D_{r2}) \\ F^{r1} + (Y_1 - Y_7)\, D_{r1} &= Y_6 (D_{y1} - D_{y2}) + Y_7 (D_{r1} - D_{r2}) \\ F^{y2} + Y_m\, D_{y2} &= -(F^{y1} + Y_m\, D_{y1}) \\ F^{r2} + (Y_I - Y_7)\, D_{r2} &= -[F^{r1} + (Y_I - Y_7)\, D_{r1}] \end{array}\right\} \quad \ldots [20]$$

These equations may be simplified by a simplification of its electrical equivalent circuit shown in Fig. 15. It may be noted in the latter that part of the circuit without the grounds represents a transformer shown in Fig. 16 (because of the presence of four identical cross-coils Y_6, two of them plus, the other two minus). The admittance matrix of the transformer is

$$\bar{Y} = \begin{array}{c|cc} & & \\ \hline & -Y_2 & Y_6 \\ & Y_6 & -Y_7 \end{array} \quad \ldots\ldots\ldots [21]$$

Its impedance matrix is

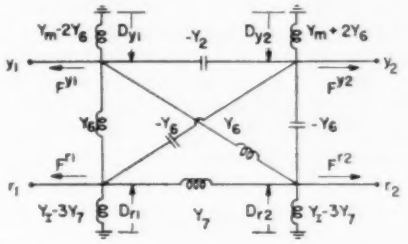

Fig. 14 Original Equivalent Circuit of a Beam Section

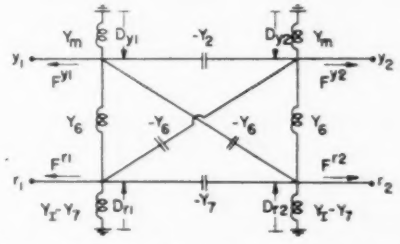

Fig. 15 Simplified Equivalent Circuit of a Section

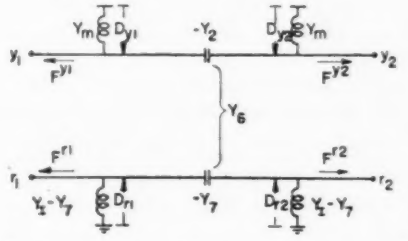

Fig. 16 Transformer Representation of a Section

$$\bar{Z} = \begin{array}{|c|c|} \hline Z_y & Z_{yr} \\ \hline Z_{yr} & Z_r \\ \hline \end{array} = \begin{array}{|c|c|} \hline \dfrac{2}{Y_2} & \dfrac{3}{Y_6} \\ \hline \dfrac{3}{Y_6} & \dfrac{2}{Y_7} \\ \hline \end{array} = \begin{array}{|c|c|} \hline \dfrac{L^3}{6B} & \dfrac{L^2}{2B} \\ \hline \dfrac{L^2}{2B} & \dfrac{L}{B} \\ \hline \end{array} \quad \ldots [22]$$

so that the final equivalent circuit is that shown in Fig. 1.

When the equivalent circuits of two neighboring sections are placed side by side as in Fig. 2, it can be noted that the two shunt impedances along each axis may be combined into one coil, as shown in Fig. 3. The equations of one repetitive section in Fig. 3 may now be written down by simple inspection as

$$\left.\begin{array}{rl} D_y' &= D_y - Z_y F^y - Z_{ry} F^r \\ D_r' &= D_r - Z_r F^r - Z_{ry} F^y \\ F^{y\prime} &= F^y - Y_y\, D_y' \\ F^{r\prime} &= F^r - Y_r\, D_r' \end{array}\right\} \quad \ldots\ldots\ldots [23]$$

The step from Equation [19] (or [18]) to Equation [23] used in the numerical work has been accomplished by purely electrical considerations. The same steps are retraced algebraically in Appendix 1 of the companion paper by Rankin (3) by following closely the electrical manipulations.

Because of the change in sign of the axis r_2 the beam sections can now be interconnected in series only with the precaution that the second beam section has opposite signs along r_1 instead of along r_2. This is equivalent to changing the signs of Y_6 in the

matrix of Equation [19] and in the circuit, Fig. 2; leaving the signs of currents and voltages unchanged.

Because of the alternation of Y_6, the absolute potentials on the lower lines, namely, the angles, also alternate in sign, forming a zigzag curve. In the original network in Fig. 14 the angles form a smooth curve; on the other hand, the coils representing masses contain another coil in parallel.

Appendix 2

General Circuit Parameters

The numerical method of starting with known D's and F's at one end and finding the D's and F's at the other end is equivalent to calculating the general circuit parameters $\bar{A}$, $\bar{B}$, $\bar{C}$, and $\bar{D}$ of the system

$$\begin{array}{|c|c|c|c|}\hline D_{y1} & D_{x1} & F^{y1} & F^{x1} \\ \hline \end{array}$$

$$\begin{array}{|c|c|}\hline D_{y2} \\ \hline D_{x2} \\ \hline F^{y2} \\ \hline F^{x2} \\ \hline \end{array} = \begin{array}{|c|c|c|c|}\hline a & b & i & j \\ \hline c & d & k & l \\ \hline e & f & m & n \\ \hline g & h & o & p \\ \hline \end{array} = \begin{array}{|c|c|}\hline \bar{A} & \bar{B} \\ \hline \bar{C} & \bar{D} \\ \hline \end{array} \quad \ldots [24]$$

However, each parameter now consists of a matrix instead of a number. The self and mutual admittances may be found as follows

$$\left.\begin{aligned} \bar{D}_2 &= \bar{A}\,\bar{D}_1 + \bar{B}\,\bar{F}_1 \\ \bar{F}_2 &= \bar{C}\,\bar{D}_1 + \bar{D}\,\bar{F} \end{aligned}\right\} \ldots\ldots\ldots\ldots [25]$$

From the first equation of Equation [25]

$$\bar{F}_1 = \bar{B}^{-1}\,\bar{D}_2 - \bar{B}^{-1}\,\bar{A}\,\bar{D}_1 \ldots\ldots\ldots\ldots [26]$$

Substituting into the second equations

$$\left.\begin{aligned} \bar{F}_1 &= (-\bar{B}^{-1}\,\bar{A})\,\bar{D}_1 + (\bar{B}^{-1})\,\bar{D}_2 = \bar{Y}^{11}\,\bar{D}_1 + \bar{Y}^{12}\,\bar{D}_2 \\ \bar{F}_2 &= (\bar{C} - \bar{D}\,\bar{B}^{-1}\,\bar{A})\,\bar{D}_1 + (\bar{D}\,\bar{B}^{-1})\,\bar{D}_2 = \bar{Y}^{21}\,\bar{D}_1 + \bar{Y}^{22}\,\bar{D}_2 \end{aligned}\right\} [27]$$

Or, from the second equation

$$\bar{D}_1 = \bar{C}^{-1}\,\bar{F}_2 - \bar{C}^{-1}\,\bar{D}\,\bar{F}_1$$

Substituting into the first equations

$$\left.\begin{aligned} \bar{D}_1 &= (-\bar{C}^{-1}\,\bar{D})\,\bar{F}_1 + (\bar{C}^{-1})\,\bar{F}_2 = \bar{Z}_{11}\,\bar{F}_1 + \bar{Z}_{12}\,\bar{F}_2 \\ \bar{D}_2 &= (\bar{B} - \bar{A}\,\bar{C}^{-1}\,\bar{D})\,\bar{F}_1 + (\bar{A}\,\bar{C}^{-1})\,\bar{F}_2 = \bar{Z}_{21}\,\bar{F}_1 + \bar{Z}_{22}\,\bar{F}_2 \end{aligned}\right\} \ldots [28]$$

Because of the symmetry of $\bar{Y}^{11}$, $\bar{Y}^{22}$ and $\bar{Z}_{11}$, $\bar{Z}_{22}$, four relations follow

$$\left.\begin{aligned} 1 \quad -\bar{B}^{-1}\,\bar{A} &= (-\bar{B}^{-1}\,\bar{A})_t \\ 2 \quad \bar{D}\,\bar{B}^{-1} &= (\bar{D}\,\bar{B}^{-1})_t \end{aligned}\right| \left.\begin{aligned} 3 \quad -\bar{C}^{-1}\,\bar{D} &= (-\bar{C}^{-1}\,\bar{D})_t \\ 4 \quad \bar{A}\,\bar{C}^{-1} &= (\bar{A}\,\bar{C}^{-1})_t \end{aligned}\right\} [29]$$

The second and fourth relations give the two checks used in the numerical calculations. An additional set of checks follows from the symmetry of $\bar{Y}^{12}$ with $\bar{Y}^{21}$ and $\bar{Z}_{12}$ with $\bar{Z}_{21}$

$$\bar{B}\,\bar{C}_t - \bar{A}\,\bar{D}_t = \bar{1} \quad \text{or} \quad \bar{C}\,\bar{B}_t - \bar{D}\,\bar{A}_t = \bar{1} \ldots\ldots [30]$$

$$\left.\begin{aligned} (ie + jf) - (am + bn) &= 1 \\ (kg + lh) - (co + dp) &= 1 \end{aligned}\right| \left.\begin{aligned} (ig + jh) - (ao + bp) &= 0 \\ (ke + lf) - (cm + dn) &= 0 \end{aligned}\right\} [31]$$

The self and mutual admittances of the equivalent circuit are from Equations [27]

$$\bar{Y}^{12} = \bar{B}^{-1} \mid \bar{Y}^{11} = -\bar{B}^{-1}\,\bar{A} \mid \bar{Y}^{22} = \bar{D}\,\bar{B}^{-1} \ldots\ldots [32]$$

and are given in detail in Table 3.

Calculation of the Multiple-Span Critical Speeds of Flexible Shafts by Means of Punched-Card Machines

By A. W. RANKIN,[1] SCHENECTADY, N. Y.

In turbine design, the critical speeds must be adequately spaced from the normal running speed to assure a smoothly operating unit. It is essential therefore that these critical speeds be predicted early in the design. To overcome general methods of calculating multiple-span critical speeds of irregular shafts, the author has devised a method employing standard punched-card business machines to avoid the prohibitive manual calculations hitherto involved in such work.

Nomenclature

THE following nomenclature is used in the paper:

In addition to the specific subscripts of the quantities given below, the auxiliary subscripts 0, 1, 2 are used to indicate initial values on the left overhang and first and second bearings, respectively.

Unprimed letters refer to the left-hand quantities on any incremental mesh circuit in Fig. 4, or incremental shaft section in Figs. 14 and 15; primed letters refer to the corresponding right-hand quantities.

A, B, C, D = general factors used only for description of multiplier operations [5]

d_{y11}, d_{y2} = calculated values of D_y, based upon assumed initial conditions, Equations [2a, b], respectively

d_r, d_{r2} = calculated values of D_r, based upon assumed initial conditions Equations [2a, b], respectively

D_y, D_r = shaft deflection and slope, respectively

E = Young's modulus

f_{y1}, f_{y2} = calculated values of F_y, based upon assumed initial conditions, Equations [2a, b], respectively

f_{r1}, f_{r2} = calculated values of F_r, based upon assumed initial conditions, Equations [2a, b], respectively

F_y, F_r = shaft shear and moment, respectively (see discussion at close of Appendix 1)

g = gravity acceleration = 386

i, j = adjacent shaft sections; Appendix 1

I = effective inertia of each incremental shaft length

l = length of each incremental shaft length

M = moment on end of each incremental shaft length; Appendix 1

N = Speed in thousands of rpm

P = acceleration forces = $\frac{1}{2}\frac{W}{g}\omega^2 y$

s = shear force on end of incremental shaft length Appendix 1

$S = s + P$

W = weight of each incremental shaft length

y = shaft deflection; Appendix 1

Y_7, Y_m = admittances to ground in Fig. 2; defined in Table 1

Y_r = sum of adjacent Y_7 values

Y_y = sum of adjacent Y_m values

Z_r, Z_{ry}, Z_y = line impedances as shown in Figs. 2, 3, and 4; defined in Table 1. (Note that Z_{ry} alternates in sign in progressing through successive sections as shown in Figs. 2 and 3.)

α, β = co-ordinate systems; defined in Fig. 2(a)

θ = shaft slope; Appendix 1

ω = speed, radians per sec

General

THE important role in turbine design played by the critical speeds of multiple-span flexible shafts is too well known to require more than a superficial introduction. It is sufficient to note that to guarantee a smooth-running unit the critical speeds must be adequately spaced from the normal running speed. It is therefore essential that these disturbing critical speeds be accurately predicted during the design stage. A practicable, quick method of calculating multiple-span critical speeds accurately would accordingly be of not inconsiderable benefit in practical design.

Several accurate and general methods of calculating multiple-span critical speeds of irregular shafts are available in the technical literature, but in the author's experience these methods, while completely competent in a technical sense, are not satisfactory for routine design or development because of the discouraging number of calculations which must be made. This criticism becomes more specific when one realizes that it is not possible to calculate critical speeds directly; it is necessary to start at a speed less than the first important critical speed and repeat the calculation for successively higher speeds until the practical range is covered. The critical speeds are then those speeds for which all the boundary conditions are satisfied; for speeds other than the critical speeds it will be found that one boundary condition remains unsatisfied. The number of assumed speeds for a typical four-bearing shaft, for instance, can be realized by noting that the lowest critical speed may be down to 1000 rpm while the highest of practical interest may be around 5000 rpm. In order to determine accurately all the critical speeds and modes of vibration, it is necessary to use 200-rpm increments or smaller.

In addition to the large number of assumed speeds, it is necessary to divide an irregular shaft into a number of incremental lengths. For a typical four-bearing turbine-generator set, about thirty such incremental lengths are necessary. The calculation sequence must be repeated for each incremental length for each assumed speed. It is accordingly evident why numerical investigations of critical speeds of multiple-bearing sets have heretofore been limited strictly to the most important cases.

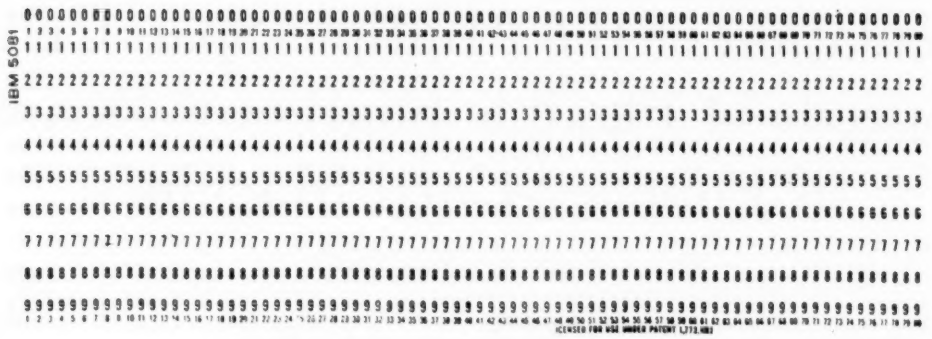

FIG. 1 STANDARD I.B.M. CARD; TYPE 5081

It is the purpose of this paper to show how standard punched-card machines[2] can be employed to eliminate the prohibitive manual calculations just discussed.

Punched-card machines are standard machines now in relatively wide use in machine accounting. The data under study are fed into these machines by means of cards of the type shown in Fig. 1. These cards are punched in accordance with the known data, and the machines are actuated by contacts through the punched holes. The results of the operations performed by the machines are punched automatically on cards in a similar fashion. Such machines have already been discussed to some extent in the technical literature. Eckert (1)[3] has described their application to astronomical calculations; McPherson (2) has described the various machines, and the mathematical operations which they can perform; Kormes (3, 4) has discussed the solution of both differential equations and field problems; Critchlow (5) has already pointed out that these machines can be "successfully and economically" used in aircraft flutter studies; and there are several other publications on their application to technical problems.

Although punched-card machines could undoubtedly be applied to the methods of calculating critical speeds already available in the technical literature, for instance, the methods of Myklestad (6) or of Prohl (7), the studies of the author have been confined principally to the equivalent-circuit analogies of Kron (8), and his relations and equations will be used in this paper. It will be necessary, therefore, to digress somewhat and summarize Kron's equations for calculating critical speeds. This summary is given in the following section. The reader is referred to the companion paper by Kron[4] for the original derivation of these equations, although a derivation without the use of the equivalent-circuit analogue is given in Appendix 1 of this paper. Kron's relations appear to be particularly well suited to punched-card methods of solution because of their highly repetitive nature.

It should be noted that although the method of calculation as presented in this paper is based upon the equivalent electric circuit, yet the a-c network analyzers (9) now in fairly wide use on various technical problems do not have sufficient range for this application. It has been found by trial that the number of digits needed in the calculation of multiple-span critical speeds is too great for the network analyzers now available. Satisfactory results have been obtained for many mechanical vibration problems by means of network analyzers but for long shafts on several bearings, it is necessary to resort to calculating machines using a large number of digits.

Basic Analytical Relations

In the equivalent-circuit analogy, the shaft deflection and slope, D_y and D_r, respectively, are represented by voltages to ground, while the shear and moment, F_y and F_r, respectively, are represented by line currents. The shaft is first divided into an adequate number of incremental lengths, and the basic equivalent circuit in Fig. 2 is constructed. Note that Z_{ry} is a mutual impedance between the upper and lower circuits. The impedances Z and admittances Y are given in Table 1. Note that the coordinate systems alternate at the extremities of each beam increment, as indicated by the α and β designations.

TABLE 1 IMPEDANCES Z AND ADMITTANCES Y

$$Y_{ri} = -\frac{2EI_i}{l_i} \qquad Y_r = Y_{ri} + Y_{rj}$$

$$Y_{mi} = .5\,\frac{W_i}{g}\,\omega^2 \qquad Y_y = Y_{mi} + Y_{mj}$$

$$Z_r = \frac{l}{EI} \qquad Z_{ry} = \pm\frac{l^2}{2EI} \qquad Z_y = \frac{l^3}{6EI}$$

The circuit in Fig. 2 is known as the basic equivalent circuit because each circuit section is a complete representation of the corresponding beam section. The shear and moment acting on each section are obtained by direct measurement of the current in the upper and lower horizontal branches, respectively, *at the circuit sectioning points marked by the dashed lines.* This basic circuit can be reduced to the less complex circuit in Fig. 3, the condensed basic equivalent circuit, by adding the adjacent Y_r and Y_m values. This condensed circuit has fewer meshes and is accordingly easier to handle in numerical calculations, but it should be noted that the terminal points of each section (the dashed lines in Fig. 2) are no longer directly available since they were submerged when the adjacent Y_r and Y_m values were added.

The condensed circuit in Fig. 3 is used for the calculation of all parts of the shaft except the boundary points, such as shaft ends or rigid[5] bearings, at which points auxiliary stations are set up by means of which the true terminal points are obtained without disturbing the symmetry of the basic equations given in the following paragraph.

A representative mesh circuit for an incremental length of the condensed circuit in Fig. 3 is shown in Fig. 4. From this circuit

[2] The machines used for the study presented in this paper were manufactured by the International Business Machines Corporation, The experience of the author is limited to these machines.

[3] Numbers in parentheses refer to Bibliography at end of paper.

[4] "The Equivalent Circuits for the Numerical Solution of the Critical Speeds of Flexible Shafts," by Gabriel Kron, also presented at the 1945 Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[5] In this paper, the term "rigid bearings" signifies bearings with no flexibility in the vertical or horizontal directions. All bearings are assumed of a ball-seat type equivalent to a pin through a beam, and the term "rigid" refers only to flexibility in the journal supports.

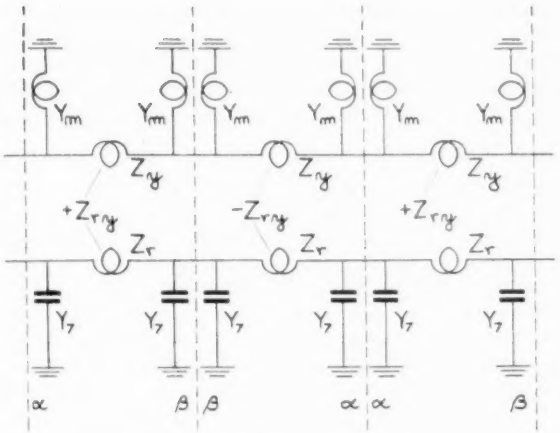

FIG. 2 BASIC EQUIVALENT CIRCUIT

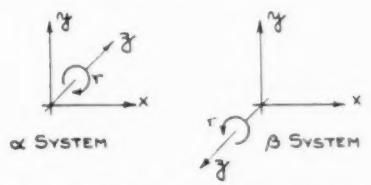

FIG. 2(a) CO-ORDINATE SYSTEMS FOR FIG. 2

it is evident that the right-hand currents and voltages are related to the corresponding left-hand quantities by the Equations [1a, b, c, d]

$$D_y' = D_y - F_y Z_y - F_r Z_{ry} \quad [1a]$$

$$D_r' = D_r - F_r Z_r - F_y Z_{ry} \quad [1b]$$

$$F_y' = F_y - D_y' Y_y \quad [1c]$$

$$F_r' = F_r - D_r' Y_r \quad [1d]$$

The foregoing are the basic analytical equations for the calculation of critical speeds. The method of obtaining a numerical solution of these equations is essentially as described by Prohl. Beginning at the free end of the shaft, the initial conditions, defined by Equations [2a] and [2b], are separately employed, and two independent solutions are thereby obtained.

$$D_{y0} = 1,\ D_{r0} = F_{y0} = F_{r0} = 0 \quad [2a]$$

$$D_{r0} = 1,\ D_{y0} = F_{r0} = F_{y0} = 0 \quad [2b]$$

If the shaft ends are in bearings rather than free as assumed in this paper, the initial conditions are as already discussed by Myklestad or by Prohl. The method of calculating past a rigid bearing has been previously described by Prohl, but for completeness this method is also given in Appendix 2 of this paper. In either case, the numerical solution will continue as described in the following paragraph.

Beginning with the initial conditions Equations [2a, b], and applying Equations [1a, b, c, d] as often as is necessary, the deflection, slope, shear, and moment at any point along the shaft can be written as in Equations [3a, b, c, d], respectively.

$$D_y = d_{y1} D_{y0} + d_{y2} D_{r0} \quad [3a]$$

$$D_r = d_{r1} D_{y0} + d_{r2} D_{r0} \quad [3b]$$

$$F_y = f_{y1} D_{y0} + f_{y2} D_{r0} \quad [3c]$$

$$F_r = f_{r1} D_{y0} + f_{r2} D_{r0} \quad [3d]$$

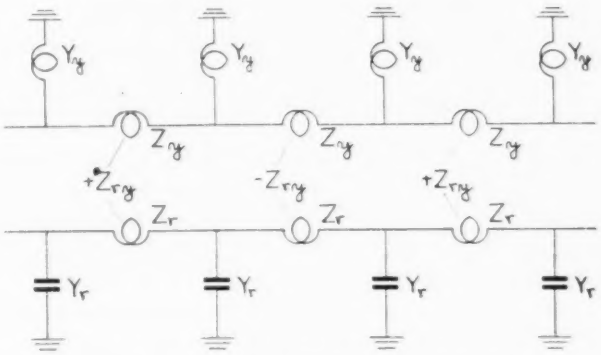

FIG. 3 CONDENSED BASIC EQUIVALENT CIRCUIT

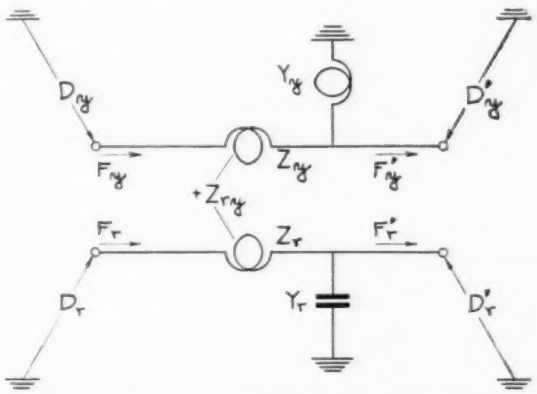

FIG. 4 REPRESENTATIVE MESH SECTION FROM CONDENSED BASIC EQUIVALENT CIRCUIT

By means of Equations [3a, b, c, d], one of the two remaining known boundary conditions is applied. The critical speeds are then those speeds for which the remaining boundary condition is automatically fulfilled; for speeds other than critical speeds it will be found that the last boundary condition cannot be fulfilled. For instance, if the shaft ends on a free overhang, there must be zero shear and zero moment at the end. Setting Equation [3c] equal to zero and substituting into Equation [3d] gives Equation [4a] for the moment at the end of the shaft

$$F_r = \left(f_{r2} - \frac{f_{r1} f_{y2}}{f_{y1}} \right) D_{r0} \quad [4a]$$

The critical speeds are those speeds for which Equation [4a] equals zero. These critical speeds can best be determined by plotting F_r, the "excess moment," against the assumed speed.

As a second example, if the shaft ends at a rigid bearing, there must be zero deflection and zero moment. Making Equation [3a] equal to zero and substituting into Equation [3d] gives Equation [4b] for the moment at the end of the shaft. As in the foregoing, the critical speeds are then those speeds for which the excess moment, Equation [4b], is equal to zero

$$F_r = \left(f_{r2} - \frac{f_{r1} d_{y2}}{d_{y1}} \right) D_{r0} \quad [4b]$$

The foregoing completes the summary of Kron's equations for the determination of critical speeds. The solution of these equations by means of punched-card machines is described in the next section.

Application of Punched-Card Machines

The machines used in the study presented in this paper are as follows:

1 A key-punch machine for punching the original data manually.

2 An interpreter for typing automatically the identifying data on each card.

3 A multiplier for performing the necessary multiplications.

4 A reproducer for transcribing automatically selected data from a given position on one set of cards to the same or a different position on another set of cards.

5 A duplicator for duplicating cards automatically when necessary.

6 A numeric listing machine for reading selected data from a set of cards and listing them as directed.

7 A sorting machine for necessary card sorting.

With the exception of the multiplier, all are standard machines available in accounting departments geared to general machine accounting. The multiplier is itself a standard multiplying punch with the addition of a standard device called an "algebraic sign control." By means of the latter, the multiplier can be plugged to perform either of the following operations, with due regard for the algebraic signs of all components

$$A \pm (B \times C) = D \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

A, B, and C are automatically read from a card, the selected operation [5] is performed, and the result D with its algebraic sign is automatically punched into a designated position on the same card.

To obtain a solution of the critical-speed problem, standard I.B.M. cards, type 5081, Fig. 1, were divided into fields[6] and the two types of cards shown in Fig. 5 were printed. Type 1 cards are used for calculating D_y' and F_y', and type 2 cards are used for calculating D_r' and F_r'. Two cards are needed of each type for each incremental shaft length for each assumed speed; one card is used for the application of the initial conditions, Equations [2a], and the second for the initial conditions, Equations [2b]. Four cards are thus needed for each station for each assumed speed as follows:

Type 11: Initial conditions [2a]; calculation of D_y' and F_y'
12: Initial conditions [2a]; calculation of D_r' and F_r'
21: Initial conditions [2b]; calculation of D_y' and F_y'
22: Initial conditions [2b]; calculation of D_r' and F_r'

The shaft weight and stiffness values Z_y, Z_r, Z_{ry}, Y_y, and Y_r are punched into fields, 7, 8, and 9, and the type, station, and assumed speeds are simultaneously punched into fields 1, 2, and 3. Note that Z_y, Z_r, Z_{ry}, Y_r, and the type and station need be hand-punched into only one card for each station; as these data do not change with speed, the remaining cards for each station can be punched automatically on the reproducer. Only Y_y and the assumed speed need be hand-punched on each card, and even the assumed speed can be punched automatically on the reproducer by first making master cards to cover the desired speed range. In addition, note that types 21 and 22 can be completely punched automatically from types 11 and 12, respectively.

The assumed initial conditions, Equations [2a, b], are hand-punched into fields 4, 5, and 6 of the cards for the first station, and all the necessary preliminary punching is then completed.

The calculations of Equations [1a, b] must be performed in two steps since, as shown in operations [5], the multiplier can perform only $A \pm (B \times C) = D$. The cards with the initial conditions are placed in the multiplier with the latter plugged to read fields 4, 5, and 7, calculate $4 - (5 \times 7)$, and punch the result into field 10. With this operation, the quantity [6a] has been calculated and punched into the cards of types 11 and 21, and the quantity [6b] has been calculated and punched into the cards of types 12 and 22.

$$D_y - F_y Z_y \quad \ldots\ldots\ldots\ldots\ldots\ldots [6a]$$

$$D_r - F_r Z_r \quad \ldots\ldots\ldots\ldots\ldots\ldots [6b]$$

Upon completion of this operation for all cards, the multiplier is replugged to read fields 10, 6, and 8, calculate $10 - (6 \times 8)$, and punch the result into field 11, and the cards are sent through the multiplier again. Upon completion of this second operation, and the punching of the result into field 11, the last product on the right-hand side of Equations [1a, b] have been calculated and subtracted from the quantities defined in [6a, b]. D_y' has thus been calculated and punched in cards of types 11 and 21, and D_r' has been calculated and punched in cards of types 12 and 22.

The replugging of the multiplier, as mentioned in the foregoing paragraph, takes practically no time as the plugging is done on detachable plugboards, and the necessary number of these are plugged for the required operations before the first run is made. Replugging the multiplier accordingly requires only the removal of one plugboard and the insertion of another, and this is a matter of a few seconds. A new "skip" bar, which positions the field in which the punching is to be done, must also be changed with each plugging change, but this is also a matter of seconds.

By means of a third plugboard, the multiplier is now plugged to read fields 5, 9, and 11, calculate $5 - (9 \times 11)$, and punch the result in field 12, and the cards are run through a third time. With the completion of this operation, F_y' has been calculated and punched on cards of types 11 and 21, and F_r' has been calculated and punched on cards of types 12 and 22, in accordance with Equations [1c, d]. The calculations are thus completed for the first incremental shaft length.

The primed quantities, calculated and punched on the first set of cards in accordance with Equations [1a, b, c, d], now become the unprimed quantities for the next incremental shaft length, and accordingly must be transferred to the cards for the next incremental shaft length. The cards for the first incremental shaft length are accordingly fed into a reproducer plugged to read fields 11 and 12, as calculated in the foregoing paragraphs, and these calculated data are punched into fields 4 and 5 of the cards for the second incremental shaft length.

With the foregoing operation, D_y and F_y have been punched into cards of types 11 and 21, and D_r and F_r into cards of types 12 and 22. To punch F_r and F_y into field 6, the cards for this second incremental shaft length are divided into two groups; types 11 and 21 in one group and 12 and 22 in the second group. These two groups are sent through the reproducer with the latter plugged to read field 5 in one group of cards and punched into field 6 of the other group of cards. Two runs are needed to punch field 6 in both groups of cards. By these two runs, F_r has been punched into the cards of types 11 and 21 for the second incremental shaft length, and F_y into the cards of types 12 and 22. As with the multiplier, the replugging of the reproducer for these transcribing operations takes little time as detachable plugboards are preplugged for the necessary operations.

The foregoing completes the punching of the cards for the second incremental shaft length. These are then placed in the multiplier, and the operations described in the foregoing paragraphs are repeated until the end of the shaft is reached. At this point, the final cards are placed in a numeric listing machine plugged to read and list fields 11 and 12 (D_y' and F_y', and D_r' and F_r'), and the excess moment is obtained from the listed data by manual calculations.

[6] A field is merely a group of columns in which data of a particular nature will always appear. The cards of Fig. 5 have twelve such fields each.

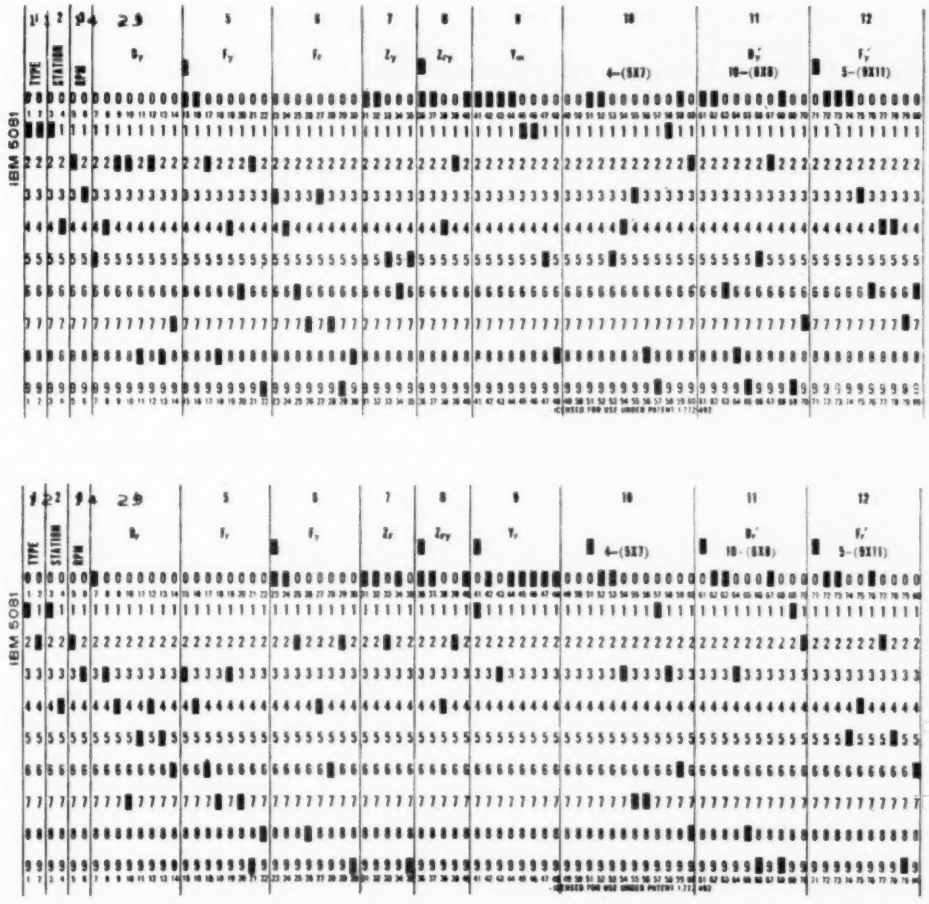

FIG. 5 TWO TYPES OF CARDS USED FOR CALCULATION OF CRITICAL SPEEDS BY MEANS OF PUNCHED-CARD MACHINES
(Upper type 1; lower type 2. The Y_m on the type 1 cards should be Y_y.)

Another method of obtaining the excess-moment curve is to place the final cards in a reproducer plugged to transfer fields 11 and 12 into new cards, and the excess moment can then be obtained by the multiplying machine. The cards containing the calculation of the excess moment are then placed in the numeric listing machine plugged to read and list the calculated excess moment, and the critical speeds are then obtained by plotting the listed data.

The modes of vibration are obtained by means of Equation [3*a*]. The final boundary conditions will give D_{r0} in terms of D_{y0} and will give the critical speeds. The type 11 and 21 cards are placed in a sorter, and all the speeds closest to the calculated critical speeds are picked out. The d_{y1} values from the type 11 cards are punched automatically by means of the reproducer into field 5 of a new set of cards. The d_{y2} values from the type 21 cards are similarly punched into field 11 of the new set of cards, and D_{r0} in terms of D_{y0}, as obtained from the calculation of the excess moment, is gang-punched into field 9. These new cards are then placed in the multiplier, and with the plugboard plugged to calculate $5 + (9 \times 11)$, the result is punched in field 12, the quantity thus punched in field 12 being the amplitude of vibration. These cards are then placed in the listing machine plugged to read and list field 12. A plot of the listed data will then give the mode of vibration.

NUMBER OF DIGITS

It is recognized that in any calculation of critical speeds, a relatively large number of digits is required as the excess moment is normally the difference between two large numbers. The multiplying machine used in the study presented in this paper can handle eight digits in the multiplier and eight digits in the multiplicand and can punch ten digits in the operation given by [5]. These two extra digits are used in permitting the growth of the calculated data, and in determining when to shift decimals in the various plugboards. Of the ten digits in field 12, for instance, the first (column 71) is used to record the sign, while the second (column 72) is punched zero so long as there are only eight digits in the calculated quantities, these eight digits being punched in columns 73 to 80, inclusive. By passing a needle through the zero of column 72, it is a simple matter to determine when the calculated quantity has increased from eight to nine digits since the (ninth) digit punched in column 72 will no longer be zero. It is then necessary to shift the decimal on the plugboard. In this way the requisite accuracy can be easily maintained throughout the entire calculation. The growth of fields 10 and 11 is handled in the same way.

NUMERICAL EXAMPLE

As an example of the methods described in the foregoing paragraphs, numerical calculations were made on the four-bearing stationary turbine-generator model shown in Fig. 6. Considerable test data were available on this model, and calculations for the case of rigid bearings were accordingly made to test both the

correctness of Kron's equivalent-circuit analogies as well as the efficacy of the punched-card method of solution.

The model was divided into twenty-six incremental lengths which when added to the auxiliary stations at the rigid bearings gave a total of thirty stations. The speed range under study was from 1500 rpm to 4500 rpm in 200-rpm increments, thereby giving a total of $30 \times 16 \times 4 = 1920$ cards.

One day was required for the calculation of the shaft stiffness and weight constants, and another day was required to punch these data into the cards. Complete calculations for three stations could be made in 1 hr, thus requiring 10 hr for the shaft calculations, exclusive of the auxiliary calculations at the rigid bearings. The latter calculations required about 6 hr total, so about 4 days were required for the entire study. It should be noted, however, that a complete set of punched cards is now available for this model, and if any design changes are suggested, only the cards applying to the particular part of the shaft which is changed will require any appreciable time for repunching, since all the other cards can be quickly punched automatically on the reproducer.

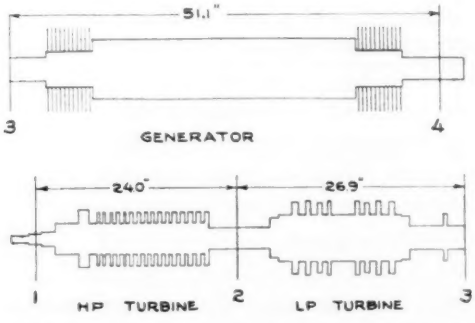

FIG. 6 STATIONARY TURBINE-GENERATOR MODEL USED FOR NUMERICAL EXAMPLE, SHOWING LOCATION OF BEARINGS 1, 2, 3, AND 4 (Vertical scale on this drawing is 5 times the horizontal scale. In order to conserve space, this drawing shows the model parted at the No. 3 bearing; actually, the turbines are rigidly connected to the generator and form a single-shaft unit on four bearings.)

Calculations were first made to determine the single-span critical speeds of the three elements. The results of these calculations together with corresponding values determined by test are given in Table 2.

TABLE 2 SINGLE-SPAN CRITICAL SPEEDS

	Calculated, rpm	Test, rpm
High-pressure turbine and turbine overhang	3900	3900
Low-pressure turbine	4095	4165
Generator and generator overhang	1865	1840

The calculations for the complete four-bearing set, in Fig. 6, were begun at the free end of the high-pressure turbine overhang. The curve of excess moment obtained at bearing No. 2 is shown in Fig. 7. The calculated first critical of the high-pressure turbine and its overhang is 3900 rpm, and the test value was likewise 3900 rpm.

The curve of excess moment obtained at bearing No. 3 is shown in Fig. 8. The calculated first critical speed of the assembly of high-pressure and low-pressure turbine and turbine overhang is 3995 rpm, while the test value was 3980 rpm.

The curve of excess moment obtained at the free end of the generator-shaft overhang is shown in Fig. 9. The calculated first-critical speed of the complete four-bearing model was 2025 rpm, while the results of two tests were 2120 rpm and 2050 rpm. The calculated second critical of the complete four-bearing model was 4180 rpm, while the results of two tests were 4165 rpm and 4205 rpm.

The foregoing checks between calculated and test values are remarkably close, especially in view of the difficulty of determining the correct effective inertias, as well as the known variations in Young's modulus.

The modes of vibration for the first and second critical speeds are shown in Fig. 10. These modes actually were plotted for 1900 rpm and 4100 rpm, respectively, rather than for the exact critical speeds, but they are in good agreement with the known modes of the first and second criticals.

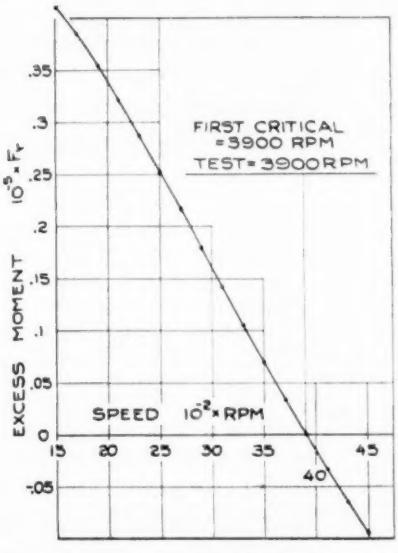

FIG. 7 EXCESS-MOMENT CURVE FOR HIGH-PRESSURE TURBINE AND TURBINE OVERHANG OF FIG. 6

In a preceding paragraph it was pointed out that to investigate any proposed design change, only the cards applying to the particular part of the shaft being changed need be repunched manually. As an example of the time required to determine the effect of any design change, the low-pressure element of the model shown in Fig. 6 was stiffened in order to increase its single-span first critical speed. The total time required to make this change and determine the new four-bearing critical speeds was less than 1 day. The excess-moment curve for this modified set, employing the low-pressure element with the high single-span critical speed, is shown in Fig. 11. Note that the four-bearing criticals have been changed only to a minor degree. Fig. 11 illustrates one of the most important advantages of the punched-card method of solution, i.e., the rapidity with which the effect of changes can be obtained means that contemplated design changes can be thoroughly studied during the preliminary layout stages.

Fig. 12 illustrates the manner in which data are obtained from the numeric listing machine. This specific illustration shows the listed deflections from which was plotted the mode of vibration for the second critical speed shown in Fig. 10. Similar listings were obtained to plot all the curves in Figs. 7, 8, 9, 10, and 11, as well as those curves from which Table 2 was obtained. It is important to note that it is unnecessary ever to read any data, calculated or otherwise, directly from the punched cards. These data are either automatically transcribed to new cards for further calculations, or they are listed in the manner shown in Fig. 12.

ACKNOWLEDGMENT

The author takes great pleasure in acknowledging the cooperation of his associates in the General Electric Company in the study presented in this paper. Thanks are extended to L. H.

Appendix 1

DERIVATION OF SHAFT EQUATIONS

The fundamental shaft equations given by Equations [1*a*, *b*, *c*, *d*] will be derived in this appendix without recourse to the elec-

| | | |

With the chosen co-ordinate systems, the relations, Equations [11*a*, *b*] are physically self-evident.

$$y_j = y_i' \quad [11a]$$

$$\theta_j = \theta_i' \quad [11b]$$

Equating the shear forces, as in Equation [12*a*], gives S_j in terms of S_i, as in Equation [12*c*].

$$s_i' + s_j = 0 \quad [12a]$$

$$s_j = s_i + \frac{1}{2}\frac{W_i}{g}\omega^2 y_i + \frac{1}{2}\frac{W_i}{g}\omega^2 y_i' + \frac{1}{2}\frac{W_j}{g}\omega^2 y_j - \frac{1}{2}\frac{W_j}{g}\omega^2 y_j \quad [12b]$$

$$S_j = S_i + \left(\frac{1}{2}\frac{W_i}{g}\omega^2 + \frac{1}{2}\frac{W_j}{g}\omega^2\right) y_j \quad [12c]$$

Equating the moments, as in Equation [13*a*], gives M_j in terms of M_i, as in Equation [13*c*].

$$M_i' + M_j = 0 \quad [13a]$$

$$M_j = M_i - \frac{2EI_i}{l_i}\theta_i - \frac{2EI_i}{l_i}\theta_i' - \frac{2EI_j}{l_j}\theta_j + \frac{2EI_j}{l_j}\theta_j \quad [13b]$$

$$\left(M_j - \frac{2EI_j}{l_j}\theta_j\right) = \left(M_i - \frac{2EI_i}{l_i}\theta_i\right) - \left(\frac{2EI_i}{l_i} + \frac{2EI_j}{l_j}\right)\theta_j \quad [13c]$$

The shaft Equations [1*a*, *b*, *c*, *d*] of the electrical analogue can be obtained from the foregoing by means of the following substitutions

$$\left.\begin{aligned} Y_{\gamma i} &= -\frac{2EI_i}{l_i} & Y_r &= Y_{\gamma i} + Y_{\gamma j} \\ Y_{mi} &= \frac{1}{2}\frac{W_i}{g}\omega^2 & Y_y &= Y_{mi} + Y_{mj} \end{aligned}\right\} \quad [14]$$

$$Z_r = \frac{l}{EI} \qquad Z_{ry} = \frac{l^2}{2EI} \qquad Z_y = \frac{l^3}{6EI}$$

$$\left.\begin{aligned} y_i &= D_y & y_i' &= y_j = D_y' \\ \theta_i &= D_r & \theta_i' &= \theta_j = D_r' \\ S_i &= -F_y & S_j &= -F_y' \\ M_i - \frac{2EI_i}{l_i}\theta_i &= M_i + Y_{\gamma i}\theta_i = -F_r \\ M_j - \frac{2EI_j}{l_j}\theta_j &= M_j + Y_{\gamma j}\theta_j = -F_r' \end{aligned}\right\} \quad [15]$$

Substituting Equations [14] and [15] into Equations [9*a*], [9*b*], [12*c*], and [13*c*], gives the basic shaft Equations [16*a*, *b*, *c*, *d*]. Note that these equations are identical with Equations [1*a*, *b*, *c*, *d*], which were obtained by the electrical analogue.

$$D_y' = D_y - Z_y F_y - Z_{ry} F_r \quad [16a]$$

$$D_r' = D_r - Z_r F_r - Z_{ry} F_y \quad [16b]$$

$$F_y' = F_y - Y_y D_y' \quad [16c]$$

$$F_r' = F_r - Y_r D_r' \quad [16d]$$

Note that Z_{ry} alternates in sign in progressing through the successive shaft sections.

It is evident from the last two expressions in Equations [15], that in general F_r and F_r' are not true moments because of the presence of the $\frac{2EI}{l}\theta$ factors. They are called moments in this paper, and used as such, because their numerical values are of importance only at boundary points, such as rigid bearings or shaft ends, at which points they do become true moments. At these boundary points, the $\frac{2EI_j}{l_j}\theta_j$ term becomes zero, either because the shaft ends at the ith section, or because the rigid bearing appears between the ith and jth sections. In either case, F_r' becomes numerically equal to $-M_j$ and is a true moment. In a similar manner, the $\frac{2EI_i}{l_i}\theta_i$ term is dropped at the initial boundaries, and F_r is then a true moment.

It is also evident that in general F_y and F_y' are not true shear forces but differ from the latter by the terms $\frac{1}{2}\frac{W}{g}\omega^2 y$. Like the foregoing F_r and F_r', however, the numerical values of F_y and F_y' are of importance only at boundary points, and at these points they become true shear forces by simply dropping the offending $\frac{1}{2}\frac{W}{g}\omega^2 y$ terms.

It is emphasized that F_r, F_r', F_y, and F_y', which in general are not true moments or shears, are merely convenient variables which greatly simplify and shorten the numerical solutions of critical-speed problems. At boundary points these variables must be properly handled in order to force them to reduce to true moments and shears. In the electrical circuit, the boundary values are applied at the shaft-sectioning points, marked by the dashed lines in Fig. 2. This was mentioned in the discussion of the equivalent electrical circuits, at which it was pointed out that the adjacent Y_m and Y_γ values should not be added together at the boundary points. The method of modifying the corresponding mechanical equations at the boundary points, as was described in the foregoing paragraphs, can be most easily visualized by a study of the equivalent electrical circuit.

Appendix 2

Rigid Bearings

The method of carrying the calculations past a rigid bearing will be given in this appendix. Consider the simple two-bearing

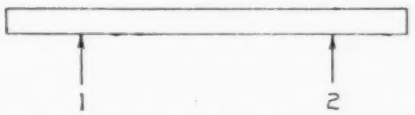

Fig. 15 Two-Bearing Shaft for Appendix 2

shaft of Fig. 15. Let the initial conditions at the left end be as given in Equations [2*a*, *b*]. The variables F_r, F_y, etc., must be modified at the known boundary points, as described in Appendix 1, so that at these points true moments and shears will be obtained.

Using Equations [3*a*, *b*, *c*, *d*], let the calculated values at the first bearing be

$$D_{y1} = d_{y11}D_{y0} + d_{y21}D_{r0} \quad [17a]$$

$$D_{r1} = d_{r11}D_{y0} + d_{r21}D_{r0} \quad [17b]$$

$$F_{y1} = f_{y11}D_{y0} + f_{y21}D_{r0} \quad [17c]$$

$$F_{r1} = f_{r11}D_{y0} + f_{r21}D_{r0} \quad [17d]$$

Setting D_{y1} equal to zero eliminates D_{y0}. Substituting into Equations [17*b*, *d*] gives D_{r1} and F_{r1}

$$D_{r1} = \left(- \frac{d_{y21} d_{r11}}{d_{y11}} + d_{r21} \right) D_{r0} \quad [18a]$$

$$F_{r1} = \left(- \frac{d_{y21} f_{r11}}{d_{y11}} + f_{r21} \right) D_{r0} \quad [18b]$$

Setting D_{y1} equal to zero fixes the deflection at zero corresponding to a rigid bearing, and also eliminates one variable, D_{y0}. The bearing reaction at the first bearing is unknown, however, and it is accordingly necessary to introduce a new shear variable corresponding to the unknown bearing reaction. The calculations immediately to the right of the first bearing are accordingly started with the two initial conditions defined by

$$D_{r1} = D_{r1},\ F_{r1} = F_{r1},\ D_{y1} = F_{y1} = 0 \quad [19a]$$

$$F_{y1} = 1,\ D_{y1} = D_{r1} = F_{r1} = 0 \quad [19b]$$

At the second bearing, equations analogous to Equations [17*a*, *b*, *c*, *d*] are obtained, except that D_{y0} is replaced by F_{y1}. The unknown D_{r0} is still present since the quantities defined by conditions [19*a*] are directly proportional to D_{r0}. Specifying zero deflection ($D_{y2} = 0$), corresponding to a rigid bearing, will give the unknown shear F_{y1} in terms of D_{r0}, and eliminates one unknown. A second unknown shear must be introduced, however, corresponding to the unknown bearing reaction at No. 2 bearing, and the calculations immediately to the right of No. 2 bearing are started with the two initial conditions defined by

$$D_{r2} = D_{r2},\ F_{r2} = F_{r2},\ D_{y2} = F_{y2} = 0 \quad [20a]$$

$$F_{y2} = 1,\ D_{y2} = D_{r2} = F_{r2} = 0 \quad [20b]$$

At the free end to the right in Fig. 15, equations for the shear and moment are obtained analogous to Equations [17*c*, *d*], except that D_{y0} is now replaced by F_{y2}. The known boundary condition of zero shear at the free end will give F_{y2} in terms of D_{r0}. Substituting into the moment equation will give the expression for "excess moment" in terms of D_{r0}. Those speeds for which the excess moment is zero, independent of the value of D_{r0}, are then the critical speeds.

Design and Application of Rail-Transportation Gearing

By D. R. MEIER[1] and J. C. RHOADS,[2] ERIE, PA.

The special requirements of rail-transportation gears are described in this paper together with a description of various types of gear failures. The major design considerations are discussed and methods given for the calculation of gear-tooth stresses. Several charts used in making design calculations are included.

Nomenclature

The following nomenclature is used in the paper:

A, B, A', B' = constants
DP = diametral pitch
F = face width
H_B = Brinell hardness
M = pinion torque
P_1 = load per inch of face per inch of pinion pitch diameter
N = number of teeth in pinion
N_A = number of teeth in action
W = tangential tooth load
d_p = pinion pitch diameter
p = circular pitch
S_b = bending stress
S_c = compressive stress
S_f = endurance-limit value of compressive stress
ϕ = pressure angle
y = Lewis tooth form factor
R = gear ratio

Introduction

Gears have greatly influenced the development of electric drive for rail-transportation vehicles. A summary of various aspects of the design and application of such gearing is presented in this paper, in a form suitable for direct application in design work.

Historical Review

Although some of the early electric motors were gearless with the motor armature directly on the axle, the industry did not progress rapidly until motors were geared to the axle. The early gears were cast and relatively soft, but their quality steadily improved and greater loads were carried as design knowledge was acquired. Gear development has kept pace with motor development, so that as motor constants permitted higher armature speeds, gears were available to utilize these speeds. The progress in traction-motor design in the last 35 years is shown in Fig. 1,

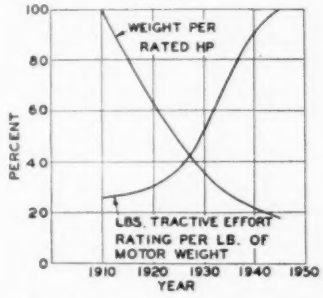

Fig. 1 Progress in Motor Design; Single-Reduction Gearing

prepared from data on motors in service. All of these motors are geared to the axle through single-reduction gearing. The gearing has had a greater effect on the increase in tractive effort per pound weight than on the decrease in weight per horsepower. Tractive effort is a torque function and is therefore directly dependent on gear ratio, whereas increased horsepower per unit weight must be accompanied by fundamental motor-design changes in addition to speed increase.

Application

General Requirements

The requirements for railway gearing are quite different from those of other types of gearing.

Life. The life should be many times that of automotive gearing. Fig. 2 is a view of a pinion taken after 1,500,000 miles

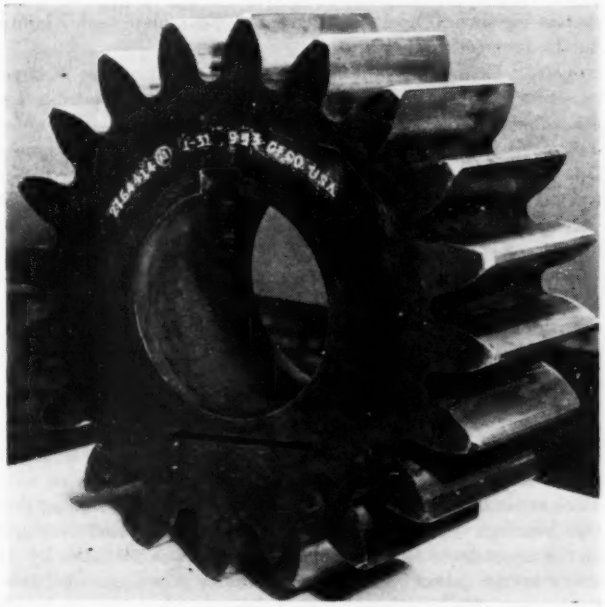

Fig. 2 Condition of Railway Motor Pinion After 1,500,000 Miles of Locomotive Operation

[1] Design Engineer, Mechanical Design Section, Transportation Motor Division, General Electric Co.

[2] Head of Mechanical Design Section, Transportation Motor Division, General Electric Co.

Contributed by the Railroad and Applied Mechanics Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

service, showing negligible wear. The amount of wear depends to a great extent on the maintenance and the type of service. The life of switching-locomotive gears should be measured in hours rather than in miles because of the large amount of low-speed high-torque operation. In most cases automotive gearing can be designed for a finite number of load cycles, below the endurance limit. Railway gearing on the other hand must usually be designed for 10,000,000 or more cycles of load application, which is practically equivalent to designing for the endurance limit.

Loading. The load on railway gears varies from extremely high load at low speeds to a relatively light load at high speeds. There are two general types of duty curves which the motor follows. Fig. 3 shows a comparison of the characteristic curves

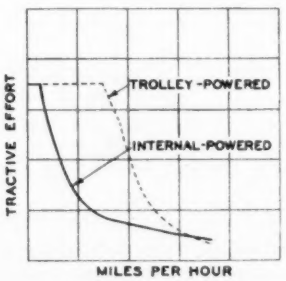

FIG. 3 CHARACTERISTIC CURVES FOR INTERNAL-POWERED AND TROLLEY-POWERED LOCOMOTIVES

for internal-powered locomotives, and trolley locomotives. Because of limited power the internal-powered locomotive develops maximum tractive effort only to a relatively low speed, and as the speed increases the tractive effort decreases, following a constant horsepower curve. The trolley locomotive, with much less of a power limitation, can for a short period develop maximum tractive effort up to several times the speed of the internal-powered locomotive.

Capacity. The gears must have enough capacity to run under adverse conditions of wear and lubrication without complete failure. A gear failure on a locomotive may tie up the whole system for several hours or may cause a complete motor failure due to overspeeding.

Noise. Gear noise is relatively unimportant except in street cars or subways, since the noise of the wheels on the rails and other background noise tends to subordinate the gear noise. This situation will change as reductions are made in other noises. But with operators and passengers relatively far removed from the gears, noise will always be of less consequence on vehicles of this type than on applications where the operating personnel must be very close to the gears.

Backlash. Railway gears are made to operate with backlash that may be considered excessive for some types of gears. It has been found from experience that far less trouble is encountered with excessive backlash than with insufficient backlash, since involute-gear action is independent of backlash.

TYPICAL APPLICATION

Fig. 4 shows a typical axle-hung railway motor. Fig. 5 is a sketch showing the load reactions of such a motor on an axle. The gear-center distance is held by the armature and axle suspension bearings. The motor-armature pinion is carried overhung on the armature shaft. The gear-load reactions are taken by the axle suspension bearings and by the motor nose suspended from the truck. The locating thrust of the motor is taken by flanges on the axle suspension bearings. At maximum gear loads for the direction of rotation of the motor shown in Fig. 5, the reaction

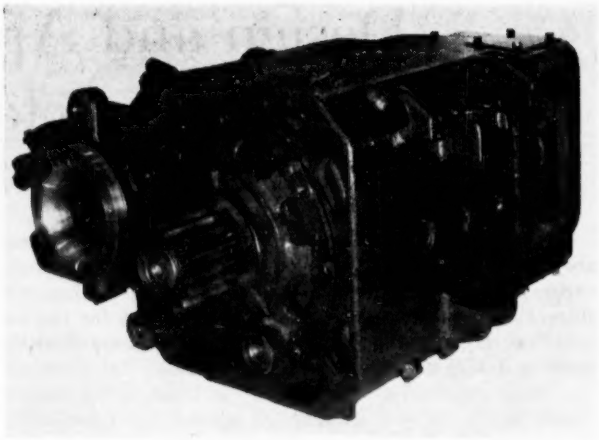

FIG. 4 TYPICAL AXLE-HUNG RAILWAY MOTOR

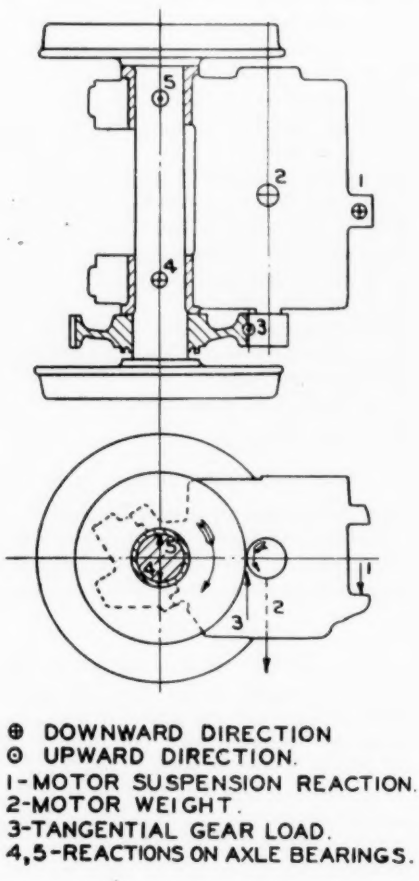

FIG. 5 SKETCH OF RAILWAY MOTOR SHOWING LOAD REACTIONS ON MOTOR PARTS

on the axle bearing adjacent to the gear is down, whereas the reaction on the opposite bearing is up. This results in a misalignment of the gear mesh equal to the bearing clearance divided by the length between bearings.

Gear cases are usually made in two halves with the split on a horizontal plane through the gear centers, to provide easy removal for maintenance and inspection. Considerable clearance is provided in the gear-case fit around the axle to take care of axle-lining wear. Gaskets are not used at the joints. For these rea-

sons lubricants of very high viscosity must be used to keep leakage to a minimum.

In general it is necessary to have motors interchange on axles, although experience is dictating the need for keeping gears and pinions together. Some railroads are removing pinions when a motor is removed. The pinion is then wired to the axle until such time as a new motor is applied, when the proper pinion is mounted on the new motor shaft. Gears that are worn together maintain conjugate tooth action, but a pinion worn with one gear and mated with another will generally have excessively rough tooth action, which may cause loose armature punchings, insulation failures, broken shafts, failed bearings, and actual gear failures.

Typical Failures

There are five general types of failures encountered on railway-type gearing.

Tooth Breakage. Tooth breakage is usually caused by fatigue and occurs rather infrequently in railway applications. Fig. 6

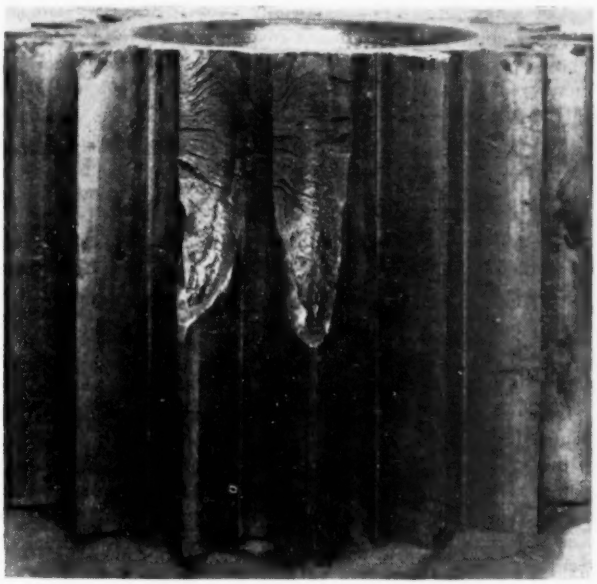

Fig. 6 Fatigue Failure on Railway-Motor Pinion

shows a typical breakage failure. It should be noted that the start of the fatigue crack is usually located some distance in from the more heavily loaded end of the tooth. This may be due to a tendency to shift the load inboard because of local deflections at the end of the tooth. Such a failure necessitates replacement of the broken element, and generally also of the mating member since it is common for a tooth to get caught in the mesh when it breaks out. It is also possible for the armature shaft to be bent when such a failure occurs.

Pitting. Pitting of gearing is a rather common failure caused by too high a compressive stress for the material used (1, 3, 4).[3] It is thought that pitting failures are caused by high subsurface shear stresses, which cause fatigue cracks to form and progress to the tooth surface. It is also thought that the lubricant enters these cracks under high pressure as the tooth undergoes load and causes the crack to progress still further. Finally a small piece of the material breaks out, leaving a craterlike cavity. Quite generally these pits occur near or slightly below the pitch line. In many cases pitting shows up early in the life of a set of gears. Fig. 7 shows pitting on a railway pinion of about 450 Bhn, which has been operated on test at a load exceeding its design limit. A certain amount of pitting does not necessarily mean that gearing must be removed from service, as it is not uncommon for very heavily loaded gears to pit when new, and for the pitting to stop as the gears wear to more nearly full-face contact.

Spalling. Spalling is a type of failure (sometimes termed shelling or flaking) wherein large pieces of the tooth surface may come out almost anywhere on the profile from the root to the tip of the tooth. Fig. 8 shows a spalled motor pinion. This type of failure is generally attributed to improper material, heat-treatment, or processing. Such a failure is far more serious than pitting, because a considerably higher percentage of the surface is removed.

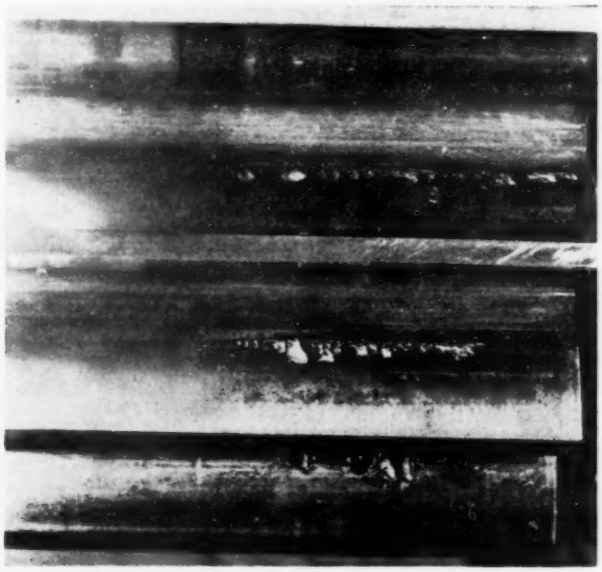

Fig. 7 Pitting of Tooth Surface Due to Excessive Load

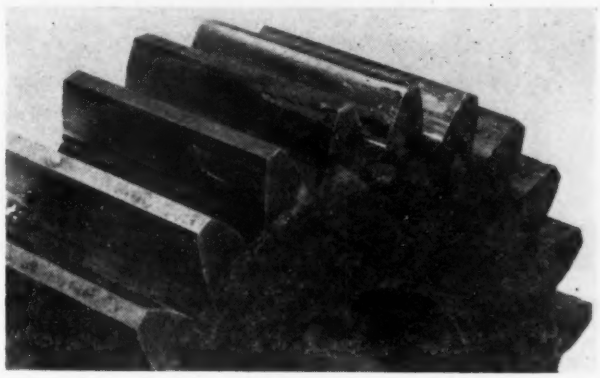

Fig. 8 Spalling of Tooth Surface

Scuffing. Scuffing is caused by metal-to-metal contact between a mating gear and pinion, due either to improper lubricant or to improper lubrication. This phenomenon has been well described in the literature (5). In most railway-gear applications, scuffing is due to lack of lubrication and not to excessive loads or speeds. In some instances, gears that are very heavily loaded at high speeds will scuff even with the proper amount of

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

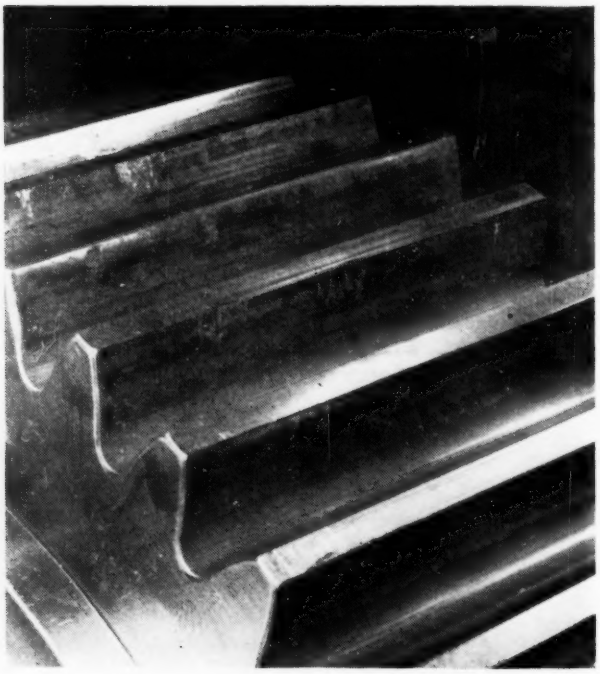

FIG. 9 SCUFFING CAUSED BY IMPROPER LUBRICATION

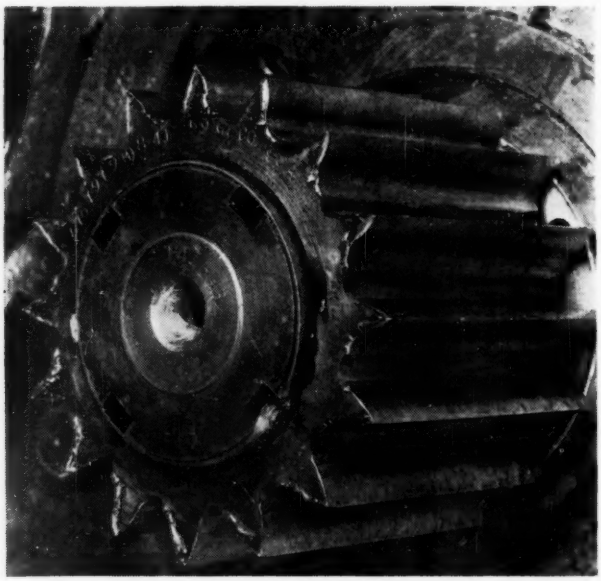

FIG. 10 EXCESSIVE WEAR CAUSED BY INSUFFICIENT LUBRICATION

lubricant, and in such cases extreme-pressure lubricants are indicated. Fig. 9 shows a gear in the early stages of scuffing. It should be noted that the scuffing takes place only where sliding occurs. There is no evidence of scuffing near the pitch line, since in this region little or no sliding takes place. This view also shows fine pitting of a different nature from that shown in Fig. 7. This difference is thought to be due to difference in materials.

Wear. Excessive wear may be caused by insufficient or improper lubrication. Fig. 10 shows what may happen when gears are run without lubricant. Another cause for excessive wear is abrasive material in the lubricant, which acts as a lapping compound and can cause a great amount of wear. Such wear is characterized by a lapped appearance varying from a highly polished to a deeply scratched surface, depending on the size of foreign particles in the lubricant. The scratches are radial from root to tip on the profile.

Experience has shown that where it is possible to provide oil-tight gear cases which will retain lubricants of reasonable viscosity, and which will keep foreign material out of the lubricant, gear wear is negligible.

TYPE OF GEARING USED

Spur gears are used in the majority of railway applications because (*a*) they create no end thrust; (*b*) they are simple in design and easy to manufacture; (*c*) they are interchangeable; (*d*) they are not critical with respect to center distances; (*e*) they have good efficiency.

Other types of gearing such as helical, spiral-bevel, and hypoid are used on special applications where noise, geometry, or other considerations dictate their use.

Axle-hung railway motors usually have antifriction armature bearings, but sleeve-type axle suspension bearings. The axle bearings may operate with relatively large diametral clearance, therefore it is important that the gears used be able to accommodate themselves to the spread in centers which occurs with wear.

DESIGN

MAJOR CONSIDERATIONS

The major considerations in the design of railway gears are as follows:

1 Tooth strength in bending.
2 Tooth surface durability.
3 Tooth proportions.
4 Number of teeth in action.

By far the most important of these is tooth strength. A failure due to tooth breakage may seriously damage the motor or break the mating gear member. Even if no damage results, expensive equipment must be taken out of service to make repairs. Adequate strength for wear must be provided, but excessive wear is not as serious as tooth breakage because replacements can usually be made before complete failure occurs.

Since the traction-motor size and weight are so closely dependent on gear ratio, there is always the incentive to get as much gear reduction as possible on new designs. This applies especially to high-tractive-effort, slow-speed, switching locomotives. The gear diameter is determined by the wheel diameter and the clearance to be provided between the gear case and the rail; therefore the pinion must be reduced in size if higher reductions are to be obtained.

It has been shown, Fig. 3, that the maximum load on the gearing occurs at the lowest speed on the characteristic curve. The pitch-line velocity at this point may be from 200 fpm on internal-powered switching locomotives to 2000 fpm on trolley locomotives. In the case of internal-powered locomotives, on maximum reduction the pitch-line speed is so low as to make dynamic loading negligible; therefore static-stress calculations are used directly. In the case of locomotives where greater pitch-line speeds are used, the calculations are also made on a static-stress basis, but the values of allowable stress are decreased, based on service and test data to allow for increased dynamic loading.

For all stress calculations it will be assumed that the load is uniformly distributed along the face of the tooth. It is realized that this condition cannot be obtained in practice, because of

slight misalignment due to machining errors, bearing wear, and deflection of loaded parts, including the shaft, bearings, pinion, and gear teeth. Therefore, in using the equations of elasticity to calculate stresses, it will be recognized that the assumption of uniform distribution of load is not valid. However, this need not detract seriously from the value of the calculations as long as conventional design proportions, for which service data are available, are used.

Bending Stress

It has been found satisfactory to use the Lewis formula (Appendix 2) for the calculation of bending stress. This is more conservative than methods which involve the number of teeth in action, or methods which are based on applying the load at the highest point on the tooth at which one tooth carries all of the load. However, in a field of service where interchanging of gears and pinions is freely practiced, with the probable result that worn (nonconjugate) profiles will be run together and where operation under adverse conditions occurs frequently, conservatism must be practiced.

It is usually desirable to provide 10 to 15 per cent greater strength in the pinion tooth than in the gear tooth, because of the greater number of revolutions of the pinion with attendant greater wear.

The problem of obtaining sufficient strength in the pinion tooth tends to limit the design, because strengthening the tooth requires coarsening the pitch, which works to the detriment of good tooth action. Stubbing the teeth has the same effect, though in some cases it may be preferable to using a coarser pitch.

In using the Lewis equation for bending, it has been found convenient to express the tooth form factor y, in the form

$$y = \frac{N}{A'N + B'} \quad [1]$$

where A' and B' are arbitrary constants. As is shown in Appendix 2, this equation may be combined with the Lewis equation

$$S_b = \frac{W}{pFy} \quad [2]$$

to give the equation

$$S_b = P_1(AN + B) \quad [3]$$

where P_1 is the pounds per inch of face per inch of pinion pitch diameter.[4]

For three systems of gearing examined by this method, it developed that the constants A and B could be made integral numbers and still have the expression accurate within a few per cent for numbers of teeth between 15 and 35. This satisfactorily covers the range of pinion-tooth numbers normally used. It is not necessary that this expression apply to the gear, since the gear-tooth strength is not limiting.

Equation [3] is convenient for calculating bending stresses because it eliminates the necessity for consulting a table of y factors. Also it utilizes the independent variable P_1 as it is used later in the compressive-stress equation. If the value of P_1 is substituted in Equation [3], together with the value of permissible bending stress, the minimum number of teeth for satisfactory strength may be calculated. If this number turns out to be prohibitively low, an increase in pinion volume will be required, as will be evident from reference to Equation [6].

It will be noted that the foregoing relations do not take stress concentration due to tooth-fillet radii into account. Since practically all of the gearing used on railway motors has continuous-radius fillets, in which the ratio of fillet size to tooth size is approximately a constant, it is assumed that the stress-concentration factor is the same for all teeth.

It is recognized that any method of calculation of tooth bending stress is approximate unless sufficient test data are available to permit the development of empirical relations for correlating bending stress with fatigue life. Such data are obtained from testing machines and actual service.

Compressive Stress

The load is transmitted from pinion to gear through a relatively narrow contact band formed by the elastic deformation of the contacting surfaces. The compressive stress at the contacting surfaces depends on the unit load, the radii of curvature of the surfaces, and the modulus of elasticity. It has been shown that the compressive stress is the criterion for pitting of gear teeth and rollers. The compressive stress also influences the rate of wear of gear teeth when they are loaded below the pitting limit. The equations for calculating the compressive stress between curved surfaces are well known (2). The equation for cylindrical surfaces in contact is easily modified to give the following equation for surface-contact stress at the pitch line of steel gears and pinions[5]

$$S_c = 3240 \sqrt{\frac{P_1(1 + 1/R)}{\sin \phi \cos \phi}} \quad [4]$$

For 20-deg pressure-angle gearing, this reduces to

$$S_c = 5710 \sqrt{P_1(1 + 1/R)} \quad [5]$$

Equation [4] shows that the effect of increasing the pressure angle is to lower the compressive stress. It also shows that the compressive stress is independent of the number of teeth for a given diameter and ratio. The criterion for severity of loading is the variable P_1, the pounds per inch of face, per inch of pinion-pitch diameter. It has already been shown that this variable can conveniently be used to calculate bending stress.

To facilitate the calculation of compressive stress, the curves shown in Fig. 11 are used. These curves show the compressive stress as a function of the unit loading P_1, for the various gear ratios and pressure angles. They serve equally well for calculating the stress on existing gear sets or for designing new gear sets.

By combining the tangential-load equation $W = 2M/d_p$ with $P_1 = W/d_pF$, the relationship

$$d_p^2F = \frac{2M}{P_1} \quad [6]$$

is obtained. This equation shows that the pinion volume is proportional to the torque and inversely proportional to P_1. The value of P_1 may be established by choosing the value of compressive stress and referring to the curves of Fig. 11. The same result may be obtained by combining Equations [4] and [6] to give

$$d_p^2F = \frac{2M\ (1 + 1/R)}{\left(\frac{S_c}{3240}\right)^2 \sin \phi \cos \phi} \quad [7]$$

This relationship shows that the volume of the pinion-pitch cylinder is inversely proportional to the square of the compressive stress. Where weight and space are important the use of high compressive stresses is therefore necessary.

[4] This method applied to the 20-deg full-depth system, for which y factors are given in reference (1), leads to the equation $S_b = P_1(2N + 22)$. This equation has an error of less than 2 per cent between 15 and 35 teeth.

[5] For internal gears the $1/R$ term has a minus sign.

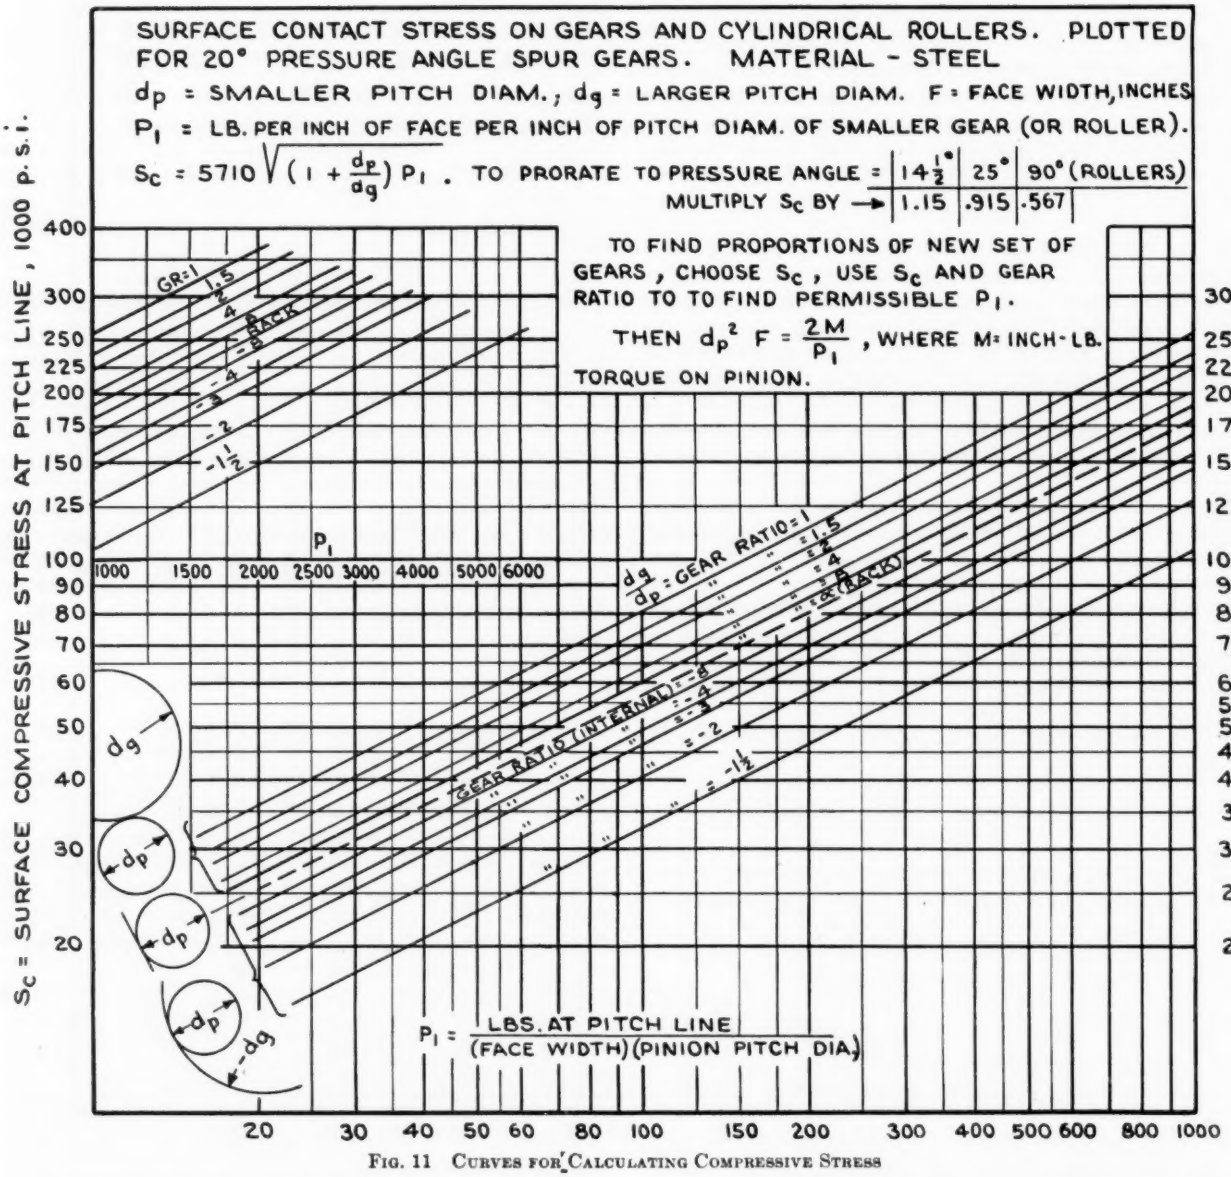

FIG. 11 CURVES FOR CALCULATING COMPRESSIVE STRESS

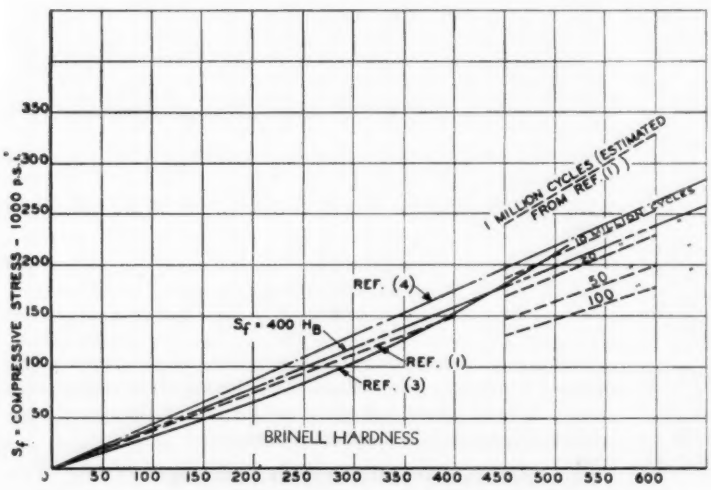

FIG. 12 SURFACE ENDURANCE LIMIT FOR STEEL

The magnitude of the compressive stress which will give satisfactory life may be judged by the designer from experience. Data from various tests are also available. Data from the tests of Way (3), and Niemann (4) and also the data given by Buckingham (1) are plotted in Fig. 12. These curves show that the endurance limit of steel in surface compression is approximately

$$S_f = 400(H_B) \quad [8]$$

Since the tensile strength is about 500 times the Brinell hardness number, the endurance limit for surface compression is roughly 80 per cent of the tensile strength.

The applicability of roll-test data to gear design may be questioned but it has been the authors' experience that gears will operate successfully at stresses approaching the value of 400 times the Brinell hardness. This experience covers quite a wide variety of designs, including different types of materials, heat-treatments, and

manufacturing methods, together with various designs of gear elements and mountings. Just how close to this value the gears may be stressed depends on (*a*) how much dynamic load will be superimposed on the static load (a function of the pitch-line speed, the mass and stiffness of the connected parts, and the errors in various parts, particularly the gears); (*b*) how well the load will be distributed over the tooth length; (*c*) the life expected in the gearing, (*d*) other factors such as surface finish, etc.

Fig. 13 has been plotted from Equations [7] and [8] to show the relationship between pinion-torque capacity per unit volume and material hardness.

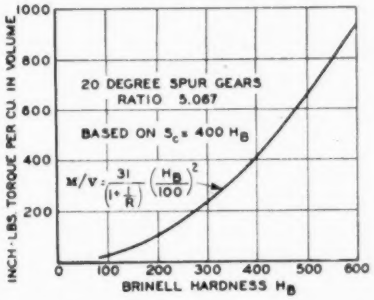

FIG. 13 RELATION OF PINION-TORQUE CAPACITY TO MATERIAL HARDNESS

The ratio of bending stress to tensile strength tends to be higher for hard materials than for soft materials, assuming that in each case the material is loaded to its compressive-stress endurance limit. This is illustrated in Table 1. This table shows that as advantage is taken of harder materials for carrying higher loads, bending failures are more likely to occur than pitting failures.

TABLE 1 15-TOOTH, 2½ DIAMETRAL-PITCH PINION, 76/15 RATIO, 20-DEG-PRESSURE-ANGLE FULL-DEPTH INVOLUTE

Brinell hardness, Bhn	300	600

$S_b = P_l\ (2N + 22)$	22900	91600
Ratio (S_b/ultimate strength)	0.153	0.306

PROPORTIONS

There are many different systems of spur gearing in use, involving different pressure angles and tooth proportions. Fig. 14 shows a comparison between four different designs of the same ratio. The 14½-deg and 20-deg-pressure-angle designs with standard proportions are well known. The 20-deg and 25-deg long- and short-addendum designs are growing in popularity.

Gearing of higher pressure angles operates at lower compressive stress for the same unit loading. The relative magnitudes of compressive stress at the pitch line on 14½-deg, 20-deg, and 25-deg pressure-angle gearing are 100 per cent, 87 per cent, and 79.5 per cent, respectively. Also the higher-pressure-angle systems have teeth of superior strength in bending.

When the number of teeth in the pinion is small it may be necessary to undercut the tooth to provide clearance for the tip of the gear tooth as it goes through action. For full-depth involute systems, this occurs when the number of teeth is 32 or less on 14½-deg pressure angle, and 18 or less on 20-deg pressure angle.

Fig. 14 shows the amount of undercut present in each design. There is no undercut present in the 20-deg and 25-deg long- and short-addendum designs. Undercutting weakens the tooth and decreases the number of teeth in action. It will be noted that the 14½-deg design is so badly undercut as to make it undesirable for use on power-transmission systems, because there are only 1.049 teeth in action. This does not provide sufficient overlap in

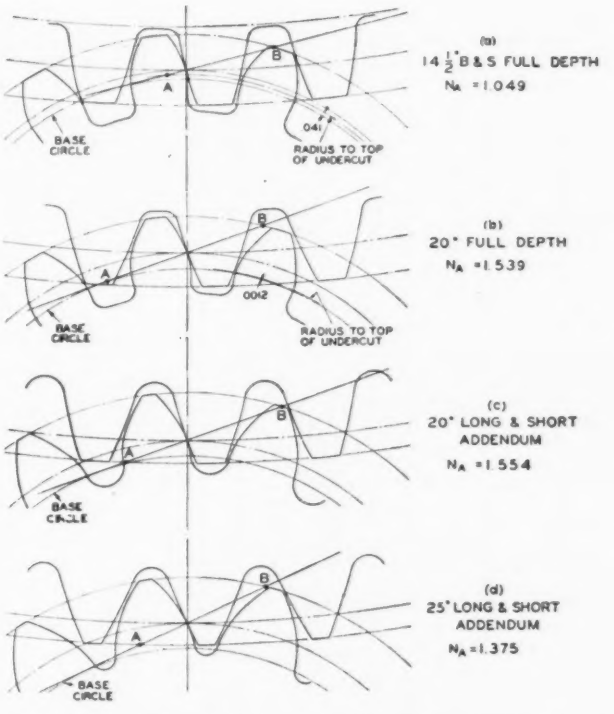

FIG. 14 GEAR-TOOTH ACTION; COMPARISON OF INVOLUTE-TOOTH FORMS

(Ratio 76/15. Duration of contact points *A* to *B*.)

tooth action between adjacent teeth to transmit the load smoothly.

Since there is frequent use of pinions of as few as 15 teeth in railway-motor design, it is not desirable to use a design of gearing in which the pinion must be undercut. It has been found advantageous to use 20-deg-pressure-angle long- and short-addendum gearing. The combination most often used is one in which the pinion addendum is approximately 35 per cent longer, and the addendum of the gear 35 per cent shorter than the standard proportions of $1/DP$. When these addenda are used, the pinion tooth is made thicker than standard to balance the strength between the gear and the pinion.

Fig. 15 shows a 20-deg-pressure-angle tooth laid out to these proportions, together with some other tooth designs for comparison. The heavy lines on the tooth surfaces show the portions of

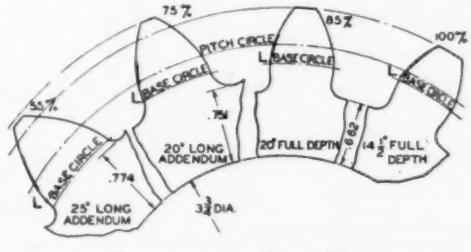

FIG. 15 COMPARISON OF TOOTH PROPORTIONS

the profiles on which full load is taken by one tooth. The percentage figures represent comparative bending stresses for equal loading. The dots on the tooth surfaces marked "L" are located at the lowest points of contact. The 25-deg tooth has the same width of top land as the 20-deg long-addendum tooth. Both are proportioned so that the pinions and their mating gears may be

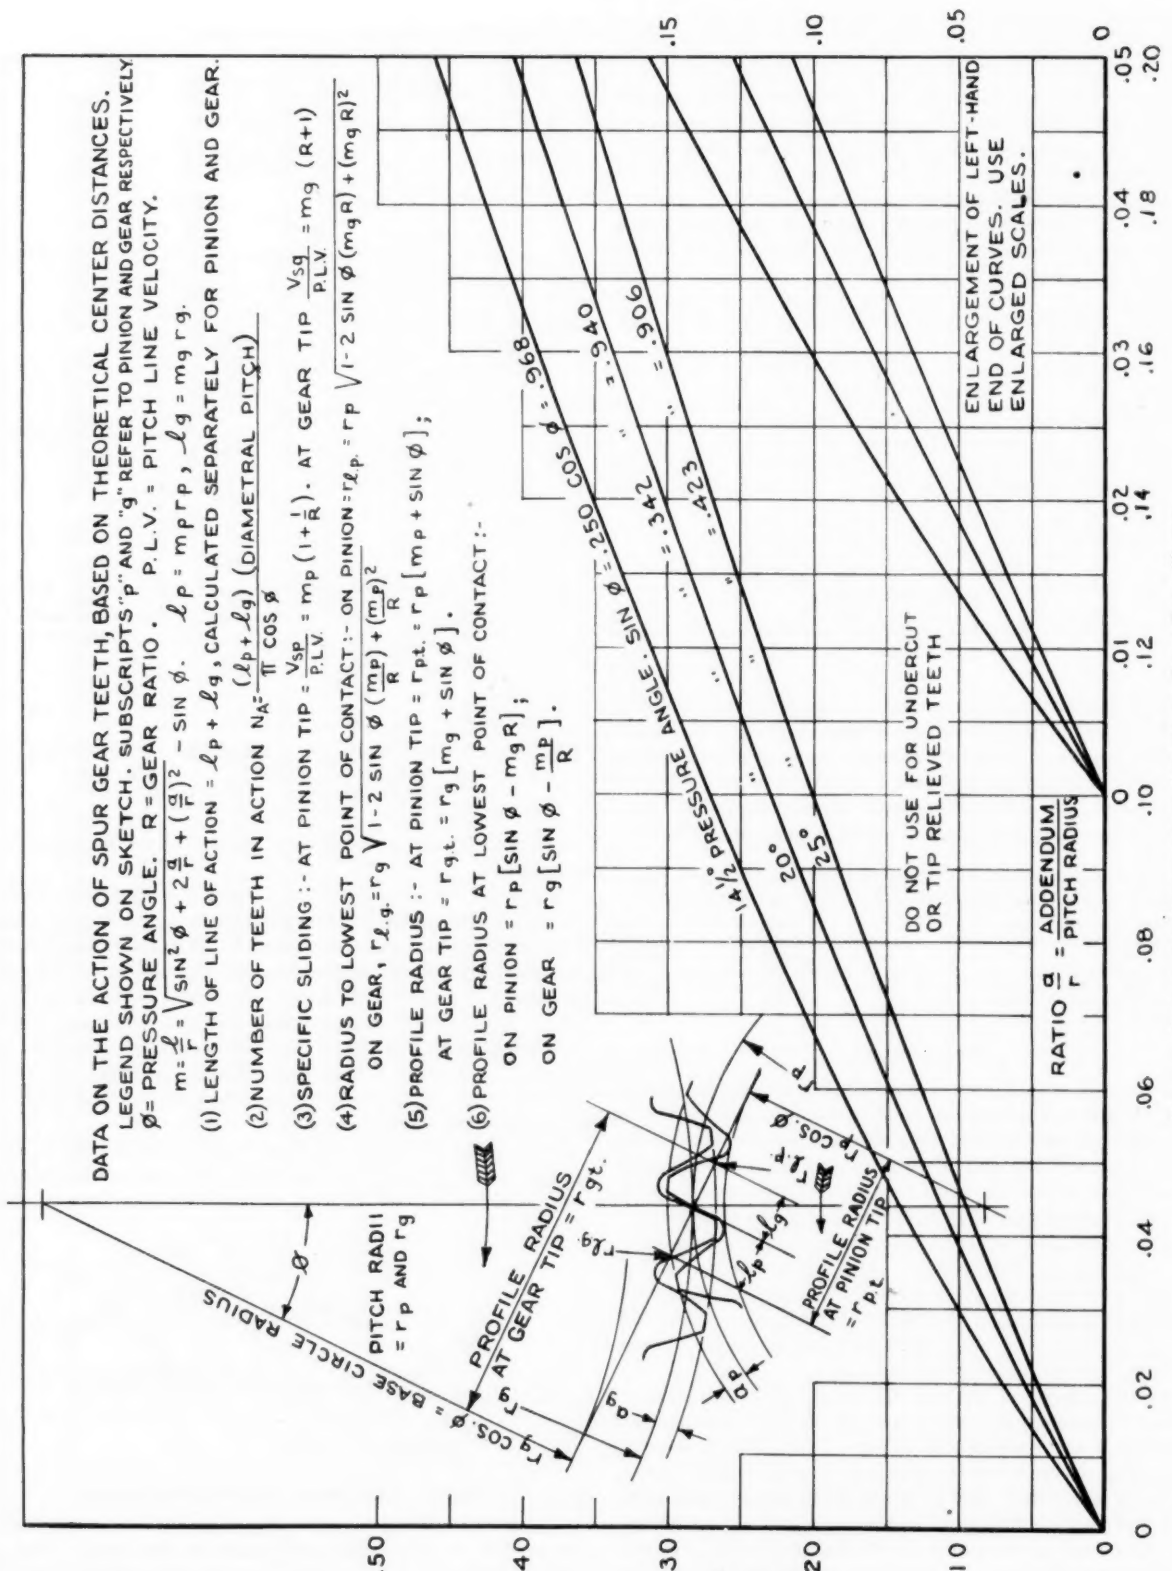

FIG. 16 CHART FOR CALCULATING ACTION OF SPUR-GEAR TEETH

cut with the same hob. This results in slightly less addendum on the 25-deg tooth design.

The principal advantages of the 20-deg and 25-deg long-addendum designs are as follows:

1 There is no undercutting of the tooth, even on a 15-tooth pinion.

2 Greater tooth strength is provided.

3 The root diameter is larger. This permits the use of a larger shaft for the same metal section between tooth root and bore, or a thicker metal section for the same shaft size. The 25-deg tooth has the disadvantage that the number of teeth in action is relatively low, Fig. 14.

The design of the root fillet radius was never given serious attention until it was discovered that the fatigue life in bending was greatly influenced by the stress concentration at the fillet. The development of the continuous-radius fillet began about 1930. It is now widely used for all heavily loaded gearing where tooth breakage is a problem. The continuous-radius fillet is formed by a cutting tool having a round-nosed tip. When the tool is used to cut the particular number of teeth for which it was designed, the fillet radius will be a portion of the arc of a circle, tangent to the tooth profile at a point just below the lowest point of contact. When a different number of teeth is cut, the fillet radius is a compound radius still tangent to the profile. In the case of form-ground teeth the fillet radius may always be an arc of a single radius.

The continuous-radius-fillet design reduces the stress-concentration factor in bending to a minimum, because it gives the maximum fillet radius possible for a given design.

Number of Teeth in Action

The tooth proportions normally used result in a number of teeth in action between 1 and 2. There is usually no attempt to obtain a minimum of two teeth in action.

During the first phase of contact on a particular tooth, two teeth work together to carry the load. In the next phase, one tooth carries the load alone, and in the final phase two teeth share the load. The average number of teeth in contact varies from 1.5 to 1.7 for most designs. This number may be permitted to go considerably lower, possibly to 1.35, without disturbing seriously the smoothness of action. However, the calculation of compressive stress at the pitch line only may not be adequate for such a case, because, at the beginning of the period when the total load is carried by one tooth, contact will take place considerably below the pitch line where the radius of curvature of the pinion-tooth profile is appreciably less than at the pitch line, with correspondingly higher compressive stress. This is illustrated in Fig. 15. A comparison of the 20-deg long- and short-addendum design with the 20-deg full-depth design shows that the former has an advantage in this respect.

Figs. 14 (*c*) and (*d*) show that contact between the pinion and the gear begins at point A, where the outside diameter of the gear intersects the line of action (pinion driving). Contact ends at point B, where the outside diameter of the pinion cuts the line of action. At any instant the number of teeth in action is an integral number, usually 1 or 2. The average number of teeth in action is found by dividing the length of the line of action AB by the base pitch. The base pitch is the distance between adjacent teeth measured along the line of action and is equal to $\frac{\pi}{DP}\cos\phi$.

It will be noted that contact does not begin as described in the preceding paragraph for the designs in Fig. 14 (*a*) and (*b*), because the pinion teeth are undercut to obtain clearance for the tip of the gear tooth. Contact begins at the intersection of the line of action with the circle formed by the radius to the top of the undercut. It will be noted in Fig. 14 (*b*), that even a very slight undercut shortens the line of action considerably.

The calculation of the number of teeth in action is facilitated by the use of the chart, Fig. 16.

This chart also shows a method for calculating some other items of interest in design. While this chart is marked for use only when the gears being studied are to be operated on theoretical centers, it may be used for nonstandard centers provided that the operating addenda, pitch radii, and pressure angles are used.

Appendix 1

Gear-Tooth Action

The transfer of power from one involute gear to another may be compared to the action of a crossed belt, Fig. 17. Since the base circles bear the same relation in diameter to each other as do the pitch circles, there will be rolling contact at the pitch point (provided there is no belt slippage) just as in mating involute gears. The "line of action" will be represented by the tight or driving side of the belt.

The tooth profile is generated in a manner geometrically equivalent to tracing a line with a pencil attached to a string as it is unwound from the base circle, as shown in Fig. 18. The string is analogous to the line of action of Fig. 17. It is evident that the involute curve is everywhere normal to the string used for its construction. Likewise, in involute gears the tooth profiles are always normal to the line of action.

Rolling contact exists in involute gears only at the pitch point. On either side of this point the tooth surfaces slide relative to

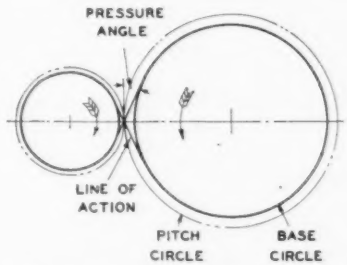

Fig. 17 Crossed-Belt Analogy

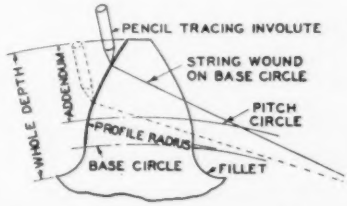

Fig. 18 Tooth Cross Section, Showing Method of Tracing Involute

each other, the sliding increasing in magnitude with increasing distance from the pitch point. For the 20-deg long- and short-addendum design, maximum sliding velocity occurs at the tip of the pinion tooth. Specific sliding is defined as the ratio of the sliding velocity to the pitch-line velocity. Fig. 16 shows a method of calculating the specific sliding at the tooth tips.

Appendix 2

The value of the tooth form factor y may be expressed as

$$y = \frac{N}{A'N + B'} \quad [9]$$

where A' and B' are arbitrary constants.

This expression for y is substituted in the Lewis equation

$$S_b = \frac{W}{pFy} \text{ to give } S_b = \frac{W(A'N + B')}{pFN} \quad [10]$$

Since the circular pitch

$$p = \frac{\pi}{DP} \quad [11]$$

then

$$pN = \frac{\pi}{DP}(N) = \pi d_p \quad [12]$$

Substituting this in Equation [10]

$$S_b = \frac{W}{\pi d_p F}(A'N + B') = \left(\frac{W}{d_p F}\right)(AN + B) \quad [13]$$

By definition

$$P_1 = \frac{W}{d_p F} \quad [14]$$

therefore

$$S_b = P_1(AN + B) \quad [15]$$

Local Stress Distribution in Cylindrical Shells

By LEON BESKIN,[1] DOWNEY, CALIF.

The stress distribution in cylindrical shells with light frames is very different from the conventional beam distribution in the neighborhood of the applied loads. The problem is examined hereafter for circular cylinders with circular frames of constant section. The case of an indefinite shell with one loaded frame is examined in detail, and diagrams are given for the following unit conditions: Concentrated radial force, tangential force, couple.

Nomenclature

The following nomenclature is used in the paper:

A, a = total frame-section area and equivalent area for shear

B, b_k = applied local couple and coefficient of trigonometric development (in a frame)

C = structure constant (Equations [34])

D = rigidity factor (Equation [30]): $\frac{1}{D_{k,j}} = \frac{1-\eta_j}{R^2}\left[\frac{\mu_{k,j}^2}{I_j} + \frac{\varphi_k^2}{A_j} + \frac{E}{G}\frac{\sigma_k^2}{a_j}\right]$

e = eccentricity

E, G = moduli of the material

F = axial force in frame

h = effective thickness of skin (stringers included)

H = load constant (Equations [35])

I = moment of inertia of frame

j = reference number of frame

k = reference number of harmonic

K = constants (Table 3)

L = distance between frames

M = moment in frame

M_x, M_y, M_z = external moments on structure

m, n = constants (Equation [39])

N = normal flow in beam

P, p_k = applied radial load and coefficient (in frame)

Q, q_k = applied shear flow (in frame)

R = radius of shell

S = shearing force in frame

t = effective thickness in shear

T = shear flow in beam

V = load constant (Equations [31])

W = strain energy

X, Y, Z = external loads on structure

x, y, z = axes of reference (z along the axis of beam)

α, β = constants (Table 1)

γ, δ, δ' = constants (Equations [38]): $\delta_k = \frac{ED_kL}{Gtk^2}$; $\delta'_k = \frac{D_kL^3}{hR^2}$

Γ_0 = concentrated load (Equation [62])

Δ = constants (Equations [66])

ϵ' = constant (Equation [40])

λ = constant (Equation [41])

μ = constant (Equation [26])

$$\mu_{k,j} = \frac{R^2}{k^2}\left(\frac{1}{k_2 - 1} - \eta_j\right); \quad \bar{\mu}_{k,j} = -\mu_{k,j}$$

$\eta = e/R$

ξ = constant (Equation [38])

φ = constant (Equation [26])

$$\varphi_k = -\frac{R^2}{k^2 - 1}; \quad \bar{\varphi}_k = -\varphi_k$$

ψ = constant (Equation [37])

σ = constant (Equation [26])

$$\sigma_k = -\frac{R^2}{k(k^2 - 1)}; \quad \bar{\sigma}_k = \sigma_k$$

ρ = constant (Equation [47])

θ = angle (Fig. 2)

Ω = constant (Equation [19])

$$\Omega_{k,j} = \frac{N_{k,j+1} - N_{k,j}}{L_{j+1}} + \frac{N_{k,j-1} - N_{k,j}}{L_j}$$

Introduction

It is well known that the actual stress distribution in beams constituted by a thin skin with light frames is very different from the distribution given by the conventional beam theory. Especially, when one frame only is loaded, the conventional methods lead to excessive bending moments in the loaded frame, and zero bending in the adjacent frames. Actually, the total moment calculated by conventional methods is distributed between the loaded frame and the adjacent frames, and the shear distribution in the beam near the loaded frame does not coincide with the conventional distribution. However, the conventional distribution is reached at some distance from the loaded frame, and this distance defines the region in which all the frames are subjected to bending.

The object of this paper is the analysis of the stress in the neighborhood of a load acting on a thin circular beam with light frames. The analysis applies to circular beams with a skin of uniform thickness and equally spaced equal stiffeners, and with frames of constant section.

The method of analysis applied in this paper has been used under restrictive conditions by N. J. Hoff,[2] this author having neglected the influence of the eccentricity of the frames and of the axial and shearing deformations. In the case of light frames and concentrated loads, the two first factors given cannot be neglected, and the diagrams which follow show that their con-

sideration may lead to double the moments obtained by the approximate theory.

These results apply only for light frames, because cylindrical shells with a circular section and a skin of constant thickness do not warp under the action of a shear distributed according to the beam theory. Thus, if the frames do not deflect under the applied loads, the deflected sections of the beam remain plane under the action of the shear strain, and the conventional beam distribution can be applied. The lateral extension due to Poisson's ratio effect is neglected hereafter, because the corresponding skin deformations are incompatible with the frame deformation. This effect is negligible in the case of a thin skin, a narrow strip of which follows the frame deformations without appreciably modifying the general equilibrium. This strip must be included in the frame section properties. It is assumed that only the frames have a bending rigidity, and that the stiffeners are submitted to axial loads only.

The general method is developed in part 1. Trigonometric developments are used to represent stresses, loads, and deflections. Each harmonic corresponds to a problem which is the mathematical analogue of the problem of a beam with elastic supports which coincide with the frames of the actual beam. In part 2, the general method is applied to the determination of the stress distribution in a loaded frame of an indefinite shell, in the two cases, intermediate frame, end frame. Diagrams are given for three unit loadings of an intermediate frame (concentrated loads): (1) Radial force; (2) tangential force; (3) couple (axis parallel to the center line).

PART 1 GENERAL METHOD OF ANALYSIS

Equilibrium of Shell

All the applied loads are concentrated at the frames, so that there is no hoop tension, and the state of stress is defined by the following:

N = normal stress flow in skin in direction of generators
T = shear flow in skin in direction of generators and perpendicular direction

Because there are no surface loads, the shear flow T is constant along a generator between two consecutive frames.

The relation of equilibrium between N and T is

$$\frac{\partial N}{\partial z} + \frac{1}{R}\frac{\partial T}{\partial \theta} = 0 \qquad [1]$$

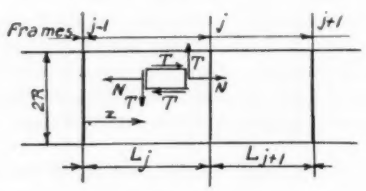

Fig. 1

in which (Fig. 1)

z = distance along center line of shell
θ, R = angle defining point of circumference and radius of shell

Since T is a function of θ only, N is a linear function of the abscissa x between two consecutive frames.

Let

L_j = distance between consecutive frames numbered $j-1, j$
$N_j(\theta)$ = value of N along frame j
$T_j(\theta)$ = value of T in span j

In a span j, by application of Equation [1], it is found

$$T = T_j(\theta) = -\int \frac{\partial N}{\partial z} R d\theta = -\int \frac{R}{L_j} [N_j(\theta) - N_{j-1}(\theta)] d\theta. \qquad [2]$$

$N_j(\theta)$ can be represented by a trigonometric series

$$N_j(\theta) = N_{0,j} + N_{1,j}\cos\theta + \overline{N}_{1,j}\sin\theta + \ldots\ldots + N_{k,j}\cos k\theta + \overline{N}_{k,j}\sin k\theta + \ldots \qquad [3]$$

By substitution of Expression [3] in Equation [2], it is found

$$T_j(\theta) = T_{0,j} + \frac{R}{L_j}\sum_{K=1}^{\infty}\frac{1}{k}[(\overline{N}_{k,j} - \overline{N}_{k,j-1})\cos k\theta - (N_{k,j} - N_{k,j-1})\sin k\theta] \ldots\ldots [4]$$

The terms $N_{0,j}$ disappear from Equation [4] because they have the same value at both ends of each span, since they correspond to a constant axial load.

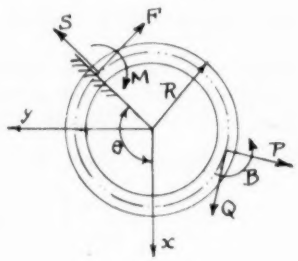

Fig. 2

Equilibrium of Frames

Let (Fig. 2)

$M_j(\theta)$; $S_j(\theta)$; $F_j(\theta)$ = bending moment, shearing force, axial force, respectively, in a frame numbered j
$P_j(\theta)$; $Q_j(\theta)$; $B_j(\theta)$ = radial loads, tangential loads, distributed couples, respectively, acting on a frame on a unit length of circumference

These loads are composed of external forces which are designated by P^*, Q^*, B^*, respectively, and of differences between shear flows T acting on the two sides of a frame, which give tangential loads Q and couples B in the frames, due to the frame eccentricity.

Term e_j being the distance between the shell and the neutral line of the frame (eccentricity of the frame), the couples B due to the shears are equal to $Q\eta_j R$, in which $\eta_j = e_j/R$.

The resulting loads on a frame due to the external loads and the differences of shear flows from the shell are developed in trigonometric series, in which, for simplicity, index j is omitted.

Normal loads

$$P = p_0 + \sum_k p_k \cos k\theta + \sum_k \bar{p}_k \sin k\theta \ldots\ldots [5]$$

Tangential loads

$$Q = q_0 + \sum_k \bar{q}_k \cos k\theta + \sum_k q_k \sin k\theta \ldots\ldots [6]$$

Couples

$$B = R\left[b_0 + \sum_k \bar{b}_k \cos k\theta + \sum_k b_k \sin k\theta\right] \ldots\ldots [7]$$

The external loads are represented by expressions similar to Equations [5], [6], [7], in which all quantities are starred (P^*, ... b_k^*). Their resultants are

$$\left.\begin{array}{ll} X = \pi R(p_1^* - q_1^*); & M_x = \pi R N_1; \\ Y = \pi R(\bar{p}_1^* + \bar{q}_1^*); & M_y = -\pi R N_1; \\ Z = 2\pi R N_0 & M_z = 2\pi R(b_0^* - q_0^*) \end{array}\right\} \quad [8]$$

The constant term p_0^* represents a uniform pressure on a frame and is disregarded, since it produces a simple hoop load in the frame. The coefficients p, q, b, N, which do not appear in Equations [8], can be considered as "perturbations," while the terms which appear in Equations [8] represent the conventional beam distributions.

Terms q_0^*, b_0^* correspond to an applied torque, and the condition of equilibrium is

$$q_0^* - b_0^* = 0 \quad [9]$$

These terms do not cause any bending or axial load in the frame, and the shearing force in the frame is constant

$$S = s_0 = -Rq_0 \quad [10]$$

Terms N_0, N_1, $\bar{N}_1$ are distributed according to the beam theory and do not produce any stress in the frames.

Terms p_1^*, q_1^*, $\bar{p}_1^*$, $\bar{q}_1^*$, correspond to a transversal resultant passing through the center of the frame. The corresponding conditions of equilibrium are

$$p_1 - q_1 = 0; \quad \bar{p}_1 + \bar{q}_1 = 0 \quad [11]$$

Replacing p_1 by q_1 and $\bar{p}_1$ by $-\bar{q}_1$, the quantities M, S, F, can be represented by the expressions

$$\frac{M}{R^2} = (b_1 \cos\theta - \bar{b}_1 \sin\theta) + \sum_{K=2}^{\infty} \left\{ \left[\frac{kp_k - q_k}{k^2 - 1} + b_k \right] \frac{\cos k\theta}{k} + \left[\frac{k\bar{p}_k + \bar{q}_k}{k^2 - 1} - b_k \right] \frac{\sin k\theta}{k} \right\} \quad [12]$$

$$\frac{S}{R} = -q_0 - \sum_{K=2}^{\infty} \left[\frac{kp_k - q_k}{k^2 - 1} \sin k\theta - \frac{k\bar{p}_k + \bar{q}_k}{k^2 - 1} \cos k\theta \right] \quad [13]$$

$$\frac{F}{R} = (q_1 \cos k\theta - \bar{q}_1 \sin k\theta) - \sum_{k=2}^{\infty} \left[\frac{p_k - kq_k}{k^2 - 1} \cos k\theta + \frac{\bar{p}_k + k\bar{q}_k}{k^2 - 1} \sin k\theta \right] \quad [14]$$

These expressions satisfy the equations of equilibrium of the frame

$$\frac{dM}{d\theta} + RB - RS = 0; \quad \frac{dS}{d\theta} + RP - F = 0; \quad \frac{dF}{d\theta} + RQ + S = 0 \quad [15]$$

They also satisfy the conditions of compatibility of deformation; this can be verified in a straightforward manner by application of methods of strain energy to the terms corresponding to k greater than 1 and to the terms b_1, $\bar{b}_1$, q_0. The application of strain-energy methods to the terms q_1, $\bar{q}_1$ leads to a modification of Equations [12], [13], [14], but this conclusion is incorrect, because of an inconsistency of the conventional formulas for rings, which can be shown as follows:

The radius of a segment of a ring does not change under the action of an axial force, but the angle of the segment is modified. Under the action of forces of the type $q_1 \cos\theta$, the total angle for the ring does not change, which shows that no bending is required to close the ring and that the foregoing solution is correct. The coefficients q_1, $\bar{q}_1$ being defined by Equations [11] are disregarded hereafter.

Condition of Deformation

Deformations are examined hereafter by strain-energy methods. The strain energy of the structure is decomposed as follows, (even terms only are written, which correspond to cos $k\theta$ for normal stresses, normal forces and couples, and to sin $k\theta$ for shears):

(*a*) *Axial Stresses in Shell Between Two Frames, $j-1$, j.* Integration of $[N(\theta)]^2 d\theta$, with

$$N(\theta) = \frac{z}{L_j} \sum N_{k,j} \cos k\theta + \frac{L_j - z}{L_j} \sum N_{k,j-1} \cos k\theta \quad [16]$$

leads to an expression of the strain energy in the form of a sum of factors $W_{N,k,j}$

$$2W_{N,k,j} = \frac{\pi R L_j}{3Eh_j} (N_{k,j}^2 + N_{k,j-1}^2 + N_{k,j} N_{k,j-1}) \quad [17]$$

h is the effective skin thickness, which includes the correction for buckling and for the stringers (which are replaced by an equivalent skin).

(*b*) *Shearing Stresses in Shell Between Two Frames, $j-1$, j.* Integration of $[T(\theta)]^2 d\theta$ leads to an expression of the strain energy in the form of a sum of factors $W_{T,k,j}$

$$2W_{T,k,j} = \frac{\pi R^3}{G t_j L_j k^2} (N_{k,j} - N_{k,j-1})^2 \quad [18]$$

in which t_j is the skin gage to be used for shear.

(*c*) *Stresses in a Frame j.* The forces applied to a loaded frame are the external loads, defined by p_k^*, q_k^*, b_k^*, and the eccentric shear flows in the shell. A term $q_{k,j}$ due to shear flow is

$$q_{k,j} = \frac{R\Omega_{k,j}}{k}; \quad \text{with } \Omega_{k,j} = \frac{N_{k,j+1} - N_{k,j}}{L_{j+1}} + \frac{N_{k,j-1} - N_{k,j}}{L_j} \quad [19]$$

$\Omega_{k,j}$ represents the change of slope of the $N_{k,j}$ diagram at the frame j. The couple corresponding to $q_{k,j}$ is

$$q_{k,j} e_j = R\eta_j q_{k,j}$$

Thus, the quantities p, q, b are defined as follows:

Frame submitted to external loads

$$p_{k,j} = p_{k,j}^*; \quad q_{k,j} = q_{k,j}^* + \frac{R}{k}\Omega_{k,j}; \quad b_{k,j} = b_{k,j}^* + \frac{R\eta_j}{k}\Omega_{k,j} \quad [20]$$

Redistributing frame

$$p_{k,j} = 0; \quad q_{k,j} = \frac{R}{k}\Omega_{k,j}; \quad b_{k,j} = \frac{R\eta_j}{k}\Omega_{k,j} \quad [21]$$

The quantities which appear in the expressions of M, S, F (Equations [12], [13], [14]) can be grouped as follows (because of difference of signs, both odd and even terms are written)

$$\left.\begin{array}{l} M = \sum M_{k,j} \cos k\theta + \sum \bar{M}_{k,j} \sin k\theta \\ S = \sum S_{k,j} \sin k\theta + \sum \bar{S}_{k,j} \cos k\theta \\ F = \sum F_{k,j} \cos k\theta + \sum \bar{F}_{k,j} \sin k\theta \end{array}\right\} \quad [22]$$

with the relations

$$\left.\begin{array}{l} M_{k,j} = \dfrac{R^2}{K}\left[\dfrac{kp_{k,j} - q_{k,j}}{k^2 - 1} + b_{k,j}\right] = M_{k,j}^* - \Omega_{k,j}\mu_{k,j} \\ \bar{M}_{k,j} = \dfrac{R^2}{K}\left[\dfrac{k\bar{p}_{k,j} + \bar{q}_{k,j}}{k^2 - 1} - \bar{b}_{k,j}\right] = \bar{M}_{k,j}^* - \bar{\Omega}_{k,j}\bar{\mu}_{k,j} \end{array}\right\} \quad [23]$$

$$\left.\begin{aligned} S_{k,j} &= -R\,\frac{kp_{k,j} - q_{k,j}}{k^2-1} = S_{k,j}{}^{*} - \Omega_{k,j}\sigma_k \\ \bar{S}_{k,j} &= R\,\frac{k\bar{p}_{k,j} + \bar{q}_{k,j}}{k^2-1} = \bar{S}_{k,j}{}^{*} - \bar{\Omega}_{k,j}\bar{\sigma}_k \end{aligned}\right\} \quad \ldots [24]$$

$$\left.\begin{aligned} F_{k,j} &= -R\,\frac{p_{k,j} - kq_{k,j}}{k^2-1} = F_{k,j}{}^{*} - \Omega_{k,j}\varphi_k \\ \bar{F}_{k,j} &= -R\,\frac{\bar{p}_{k,j} + k\bar{q}_{k,j}}{k^2-1} = \bar{F}_{k,j}{}^{*} - \bar{\Omega}_{k,j}\bar{\varphi}_k \end{aligned}\right\} \quad \ldots [25]$$

In these expressions, the following notations are used

$$\left.\begin{aligned} &\mu_{k,j} = \frac{R^3}{k^2}\left(\frac{1}{k^2-1} - \eta_j\right);\quad \varphi_k = -\frac{R^2}{k^2-1}; \\ &\qquad\qquad \sigma_k = -\frac{R^2}{k(k^2-1} \\ &\bar{\mu}_{k,j} = -\mu_{k,j};\quad \bar{\varphi}_k = -\varphi_k;\quad \bar{\sigma}_k = \sigma_k \end{aligned}\right\} \quad \ldots [26]$$

$$\left.\begin{aligned} M_{k,j}{}^{*} &= \frac{R^2}{k}\left[\frac{kp_{k,j}{}^{*} - q_{k,j}{}^{*}}{k^2-1} + b_{k,j}{}^{*}\right]; \\ \bar{M}_{k,j}{}^{*} &= \frac{R^2}{k}\left[\frac{k\bar{p}_{k,j}{}^{*} + q_{k,j}}{k^2-1} - \bar{b}_{k,j}{}^{*}\right] \\ S_{k,j}{}^{*} &= -R\,\frac{k\bar{p}_{k,j}{}^{*} - q_{k,j}{}^{*}}{k^2-1}; \\ \bar{S}_{k,j}{}^{*} &= R\,\frac{k\bar{p}_{k,j}{}^{*} + \bar{q}_{k,j}{}^{*}}{k^2-1} \\ F_{k,j}{}^{*} &= -R\,\frac{p_{k,j}{}^{*} - kq_{k,j}{}^{*}}{k^2-1}; \\ \bar{F}_{k,j}{}^{*} &= -R\,\frac{\bar{p}_{k,j}{}^{*} + k\bar{q}_{k,j}{}^{*}}{k^2-1} \end{aligned}\right\} \quad \ldots [27]$$

Quantities $M_{k,j}{}^{*}$ ..... $F_{k,j}{}^{*}$ are the coefficients of moment, shear, axial force of the developments of conventional solutions in trigonometric series.

Integration of M^2, S^2, F^2 along a circle of radius $(1-\eta)R$ and division by the corresponding section constants gives the strain energy in a frame. The section constants are

I_j = moment of inertia of frame
A_j = section area of frame
a_j = section area of frame resisting to shear

The strain energy on a frame is thus expressed as a sum of terms $W_{R,k,j}$ (only even terms are indicated)

$$2W_{R,k,j} = \pi R(1-\eta_j)\left\{\frac{1}{EI_j}[M_{k,j}{}^{*} - \mu_{k,j}\Omega_{k,j}]^2 + \frac{1}{EA_j}[F_{k,j}{}^{*} - \varphi_k\Omega_{k,j}]^2 + \frac{1}{Ga_j}[S_{k,j}{}^{*} - \sigma_k\Omega_{k,j}]^2\right\} \quad \ldots [28]$$

Omitting terms which do not contain the redundant unknowns $N_{k,j}$, Equation [28] can be written as follows

$$2W_{R,k,j} = \frac{\pi R^3}{ED_{k,j}}[(\Omega_{k,j})^2 - 2V_{k,j}\Omega_{k,j}] \quad \ldots [29]$$

In these expressions

$$\frac{1}{D_{k,j}} = \frac{1-\eta_j}{R^2}\left[\frac{\mu_{k,j}{}^2}{I_j} + \frac{\varphi_k{}^2}{a_j} + \frac{E}{G}\frac{\sigma_k{}^2}{a_j}\right] \quad \ldots [30]$$

$$\left.\begin{aligned} V_{k,j} &= \frac{(1-\eta_j)D_{k,j}}{R^2}\left[\frac{\mu_{k,j}M_{k,j}{}^{*}}{I_j} + \frac{\varphi_k F_{k,j}{}^{*}}{A_j} + \frac{E\sigma_k S_{k,j}{}^{*}}{Ga_j}\right] \\ \bar{V}_{k,j} &= \frac{(1-\eta_k)D_{k,j}}{R^2}\left[\frac{\bar{\mu}_{k,j}\bar{M}_{k,j}{}^{*}}{I_j} + \frac{\bar{\varphi}_k\bar{F}_{k,j}{}^{*}}{A_j} + \frac{E\bar{\sigma}_k\bar{S}_{k,j}{}^{*}}{Ga_j}\right] \end{aligned}\right\} \quad \ldots [31]$$

Adding all the terms corresponding to a given value of the coefficient k, an even term W_k of the strain energy of the total structure is

$$\left.\begin{aligned} \frac{2W_k}{\pi R} &= \sum_j \frac{L_j}{3Eh_j}(N_{k,j}{}^2 + N_{k,j-1}{}^2 + N_{k,j}N_{k,j-1}) \\ &\quad + \sum_j \frac{R^2}{Gb_jL_jk^2}(N_{k,j} - N_{k,j-1})^2 \\ &\quad + \sum_j \frac{R^2}{ED_{k,j}}\left[\frac{N_{k,j+1} - N_{k,j}}{L_{j+1}} + \frac{N_{k,j-1} - N_{k,j}}{L_j}\right]^2 \\ &\quad - 2\sum_j \frac{V_{k,j}R^2}{ED_{k,j}}\left[\frac{N_{k,j+1} - N_{k,j}}{L_{j+1}} + \frac{N_{k,j-1} - N_{k,j}}{L_j}\right] \end{aligned}\right\} \quad \ldots [32]$$

The problem is thus reduced to the determination of groups of coefficients $N_{k,j}$ (or $\bar{N}_{k,j}$) corresponding to a given value of k.

Solution of Statically Indeterminate Problem

Differentiation of Equation [32] in respect to each unknown $N_{k,j}$ (or $\bar{N}_{k,j}$) leads to equations of the type

$$C_{k,j,j-2}N_{k,j-2} + C_{k,j,j-1}N_{k,j-1} + C_{k,j}N_{k,j} + C_{k,j,j+1}N_{k,j+1} + C_{k,j,j+2}N_{k,j+2} = H_{k,j} \quad \ldots [33]$$

in which

$$\left.\begin{aligned} C_{k,j,j-2} &= \frac{R^2}{D_{k,j-1}L_jL_{j-1}};\quad C_{k,j,j+2} = \frac{R^2}{D_{k,j+1}L_{j+1}L_{j+2}} \\ C_{k,j,j-1} &= \frac{L_j}{6h_j} - \frac{ER^2}{Gt_jK^2L_j} - \frac{R^2}{D_{k,j}L_j}\left(\frac{1}{L_j} + \frac{1}{L_{j+1}}\right) \\ &\quad - \frac{R^2}{D_{k,j-1}L_j}\left(\frac{1}{L_{j-1}} + \frac{1}{L_j}\right) \\ C_{k,j,j+1} &= \frac{L_{j+1}}{6h_{j+1}} - \frac{ER^2}{Gt_{j+1}K^2L_{j+1}} - \frac{R^2}{D_{k,j}L_{j+1}} \\ &\quad \left(\frac{1}{L_j} + \frac{1}{L_{j+1}}\right) - \frac{R^2}{D_{k,j+1}L_{j+1}}\left(\frac{1}{L_{j+1}} + \frac{1}{L_{j+2}}\right) \\ C_{k,j} &= \frac{L_j}{3h_j} + \frac{L_{j+1}}{3h_{j+1}} + \frac{ER^2}{GK^2}\left(\frac{1}{t_jL_j} + \frac{1}{t_{j+1}L_{j+1}}\right) \\ &\quad + \frac{R^2}{D_{k,j}}\left(\frac{1}{L_j} + \frac{1}{L_{j+1}}\right)^2 + \frac{R^2}{D_{k,j-1}L_j{}^2} + \frac{R^2}{D_{k,j+1}L_{j+1}{}^2} \end{aligned}\right\} \quad \ldots [34]$$

and

$$H_{k,j} = \left\{-V_{k,j}\left(\frac{1}{L_j} + \frac{1}{L_{j+1}}\right) + \frac{V_{k,j+1}}{L_{j+1}} + \frac{V_{k,j-1}}{L_j}\right\}\frac{R^2}{D_{k,j}} \quad \ldots [35]$$

When, in Equation [33], $N_{k,j}$ is replaced by $\bar{N}_{k,j}$, coefficients $C_{k,j}$ remain unchanged, while $H_{k,j}$ is replaced by

$$\bar{H}_{k,j} = \left\{-\bar{V}_{k,j}\left(\frac{1}{L_j} + \frac{1}{L_{j+1}}\right) + \frac{\bar{V}_{k,j+1}}{L_{j+1}} + \frac{\bar{V}_{k,j-1}}{L_j}\right\}\frac{R^2}{D_{k,j}} \quad \ldots [36]$$

Equation [33] can be applied to all the intermediate frames of a shell. It must be modified for the frames next to an end frame. The end frame corresponding to $j = 0$, the terms containing L_0

must be omitted. If the frame $j = 0$ corresponds to a free end, Equation [33] does not apply to it, and the constants $N_{k,0}$ are defined in terms of the applied longitudinal end loads.

In the special case of constant section properties (equal distances between frames, constant cross section, equal frames), Equations [33] can be written in the simplified form

$$N_{k,j-2} + N_{k,j+2} - (2\xi_k + 4)(N_{k,j-1} + N_{k,j+1}) + (\gamma_k + 2)N_{k,j} = L\{V_{k,j+1} + V_{k,j-1} - 2V_{k,j}\} = \psi_{k,j} \quad \ldots\ldots [37]$$

in which

$$\left.\begin{aligned} \xi_k &= \frac{1}{2}(\delta_k - \delta_k'/6); \quad \gamma_k = 4 + 2\delta_k + 2\delta_k'/3 \\ \delta_k &= \frac{ED_kL}{Gtk^2}; \quad \delta_k' = \frac{D_kL^2}{hR^2} \end{aligned}\right\} \quad \ldots [38]$$

(quantities $V_{k,j}$ and $D_{k,j}$ are defined by Equations [31]).

Equations [37] are equations of finite differences and can be solved by conventional methods.[3] For instance, when a series of consecutive frames is not loaded, quantities $V_{k,j}$ and $\psi_{k,j}$ are equal to zero for a series of frames, and solutions of Equations [37] can be written in the form

$$N_{k,j} = n_k'(\epsilon_k')^{-j} + n_k''(\epsilon_k'')^{-j} + m_k'(\epsilon_k')^{j} + m_k''(\epsilon_k'')^{j} \quad \ldots [39]$$

in which n_k', n_k'', m_k', m_k'' are defined by end conditions while $\pm\epsilon_k'$ and $\pm\epsilon_k''$ are the four roots of the equation

$$(\epsilon_k)^2 + (\epsilon_k)^{-2} - (2\xi_k + 4)(\epsilon_k + \epsilon_k^{-1}) + \gamma_k + 2 = 0 \quad \ldots [40]$$

This equation is solved in two steps by introducing the unknown λ_k defined by

$$\lambda_k^2 - 2\xi_k\lambda_k + \delta_k' = 0 \qquad [41]$$

so that the equation in ϵ_k becomes

$$\epsilon_k + \frac{1}{\epsilon_k} = \lambda_k + 2 \quad \ldots\ldots [42]$$

When quantities ϵ_k', ϵ_k'' are defined, substitution of Equations [39] for $N_{k,j}$ into the Equations [37] for which the second member is different from zero, or into the conditions of equilibrium at the end of the shell, leads to linear equations defining the constants n_k', n_k'', m_k', m_k''. In the case of a small number of frames, it is advantageous to use Equations [37] directly; this corresponds to the method used by Hoff.[2]

The solutions of Equations [37] can be of the types given in Table 1.

For an indefinite shell, the solutions must tend toward zero toward the infinite end and are

$$\left.\begin{aligned} &\text{Case 1} \quad N_{k,j} = (\alpha_k)^{-j}(n_k' \sin \beta_k j + n_k'' \cos \beta_k j) \\ &\text{Cases 2, 3} \quad N_{k,j} = n_k'(\epsilon_k')^{-j} + n_k''(\epsilon_k')^{-j} \end{aligned}\right\} \quad \ldots\ldots [43]$$

The limit cases 4, 5 are not examined hereafter.

The ratio δ_k/δ_k', equal to $(EhR^2)/(GtL^2K^2)$, defines the law of distribution of the quantities $N_{k,j}$. For large values of this ratio, the curve representing $N_{k,j}$ is aperiodic (case 3) or has a very long period (case 1). For small values of this ratio, the curve representing $N_{k,j}$ has a short period. Some curves $N_{k,j}$ are represented in Fig. 3.

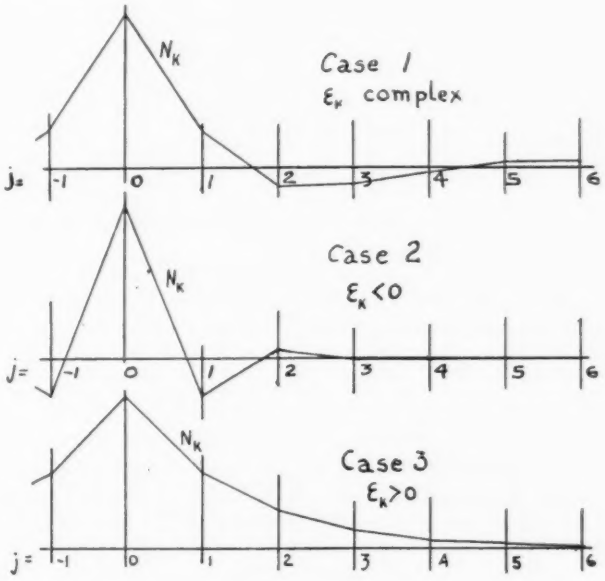

FIG. 3

Writing Equations [37] for the loaded frame and the adjacent frame, the end conditions which define N_k', N_k'' are defined as follows: Intermediate frame loaded in its plane

$$\left.\begin{aligned} N_{k,0}(\gamma_k + 2) - (4\xi_k + 8)N_{k,1} + 2N_{k,2} &= -2V_{k,0}/L \\ N_{k,1}(\gamma_k + 3) - (2\xi_k + 4)(N_{k,0} + N_{k,2}) + N_{k,3} &= +V_{k,3}/L \end{aligned}\right\} \quad \ldots [44]$$

End frame loaded (in its plane and by end forces N_k^*)

$$\left.\begin{aligned} N_{k,0} &= N_k^* \\ N_{k,1}(\gamma_k + 2) - (2\xi_k + 4)N_{k,2} + N_{k,3} &= +V_{k,0}/L \end{aligned}\right\} \quad \ldots [45]$$

These formulas are applied in part 2 for various loading conditions.

Load Reduction in Frame, Due to Shell Rigidity

Equations [23], [24], [25] can be rewritten in the form

$$\left.\begin{aligned} \Delta_{k,0}^m &= 1 - \frac{M_{k,0}}{M_{k,0}^*} = \mu_{k,0}\frac{\Omega_{k,0}}{M_{k,0}^*} = (1 - \rho_{k,0})\frac{\mu_{k,0}V_{k,0}}{M_{k,0}^*} \\ \Delta_{k,0}^f &= 1 - \frac{F_{k,0}}{F_{k,0}^*} = \varphi_k\frac{\Omega_{k,0}}{F_{k,0}^*} = (1 - \rho_{k,0})\frac{\varphi_kV_{k,0}}{F_{k,0}^*} \\ \Delta_{k,0}^s &= 1 - \frac{S_{k,0}}{S_{k,0}^*} = \sigma_k\frac{\Omega_{k,0}}{S_{k,0}^*} = (1 - \rho_{k,0})\frac{\sigma_kV_{k,0}}{S_{k,0}^*} \end{aligned}\right\} \quad \ldots [46]$$

[3] "Mathematical Methods in Engineering," by Th. von Kármán and M. A. Biot, McGraw-Hill Book Company, Inc., New York, N. Y., 1940, chapt. 11, sec. 2, and chapt. 10, sec. 2.

TABLE 1 SOLUTIONS FOR EQUATION [37]

Case	ξ_k^2/δ_k'	$6\delta_k/\delta_k'$	ϵ_k	Solutions
1	>1	$\gtrless 1$	Complex $\epsilon_k = \alpha_k(\cos\beta_k \pm i \sin\beta_k)$	$(\alpha_k)^{\pm j} \sin j\beta_k$; $(\alpha_k)^{\pm j} \cos j\beta_k$
2	>1	<1	Negative	$(\epsilon_k')^{\pm j}$; $(\epsilon_k'')^{\pm j}$
3	>1	>1	Positive	
4	=1	<1	Double negative	$(\epsilon_k)^{\pm j}$; $(\epsilon_k)^{\pm j}$
5	=1	>1	Double positive	

In these equations

$$\rho_{k,0} = 1 - \frac{\Omega_{k,0}}{V_{k,0}} \quad [47]$$

or

$$\left.\begin{aligned} \rho_{k,0} &= 1 - \frac{2(N_{k,0} - N_{k,1})L}{V_{k,0}} \quad \text{(intermediate frame)} \\ &= 1 - \frac{(N_{k,0} - N_{k,1})L}{V_{k,0}} \quad \text{(end frame)} \end{aligned}\right\} \quad [48]$$

Since terms such as $M_{k,0}$ and $M_{k,0}{}^*$ represent the bending moment due to the harmonic k, with and without skin effect, the coefficients $\rho_{k,0}$ represent the relative "decrease" of the load due to the continuity of the skin.

In redistributing frames, coefficients of the same type may be used to determine the relative "load" introduced in these frames by the continuity of the skin

$$\Delta_{k,j}{}^m = \frac{M_{k,j}}{M_{k,0}{}^*} = -\mu_k \frac{\Omega_{k,j}}{M_{k,0}}; \quad \rho_{k,j} = -\frac{\Omega_{k,j}}{V_{k,0}} \quad [49]$$

From Equations [44], it appears that ratios such as $N_{k,0}\,L/V_{k,0}$ are independent of the loading and can be expressed as functions of the structure constants γ_k, ξ_k or δ_k, δ_k'. This result applies to the quantities ρ, but not to the quantities Δ. Quantities NL/V and ρ are determined in part 2 for various values of δ_k, δ_k'.

When the frame deformations due to shear and axial load are neglected, $\Delta_{k,0}{}^m = 1 - \rho_{k,0}$, and the frame load in the loaded frame is thus reduced in the ratio $\rho_{k,0}/1$, as compared with the conventional solution. The factors $\rho_{k,0}$ and $\rho_{k,j}$ show how the moments in the frames along a definite section defined by the value of θ are distributed between the frames. When $\rho_{k,0} = 1$; $\rho_{k,j} = 0$, there is no redistribution, and the conventional methods can be applied. The sum of all the factors $\rho_{k,0}$, $\rho_{k,j}$ for all the frames is equal to 1, and the relative values of the factors ρ shows the trend of the distribution of bending between the frames. If exact values are required, it is necessary to use the coefficients Δ.

PART 2 FORMULAS FOR VARIOUS LOADING CONDITIONS

General Loading of Intermediate Frame of Infinite Beam

In the cases (1), (2), (3) of Table 1, Equations [44] are as follows:

Case (1)

$$\left.\begin{aligned} &2n_k'\left[-(2\xi_k+4)\frac{1}{\alpha_k}\sin\beta_k + \frac{1}{\alpha_k{}^2}\sin 2\beta_k\right] \\ &+ n_k''\left[\gamma_k + 2 - (2\xi_k+4)\frac{1}{\alpha_k}\cos\beta_k + \frac{2}{\alpha_k{}^2}\cos 2\beta_k\right] \\ &\qquad = -\frac{2V_k}{L} \\ &n_k'\left[(\gamma_k+3)\frac{1}{\alpha_k}\sin\beta_k - (2\xi_k+4)\frac{1}{\alpha_k{}^2}\sin 2\beta_k \right. \\ &\qquad \left. + \frac{1}{\alpha_k{}^3}\sin 3\beta_k\right] \\ &+ n_k''\left[(\gamma_k+3)\frac{1}{\alpha_k}\cos\beta_k - (2\xi_k+4)\right. \\ &\qquad \left.\left(1 + \frac{1}{\alpha_k{}^2}\cos 2\beta_k\right) + \frac{1}{\alpha_k{}^3}\cos 3\beta_k\right] = \frac{V_k}{L} \end{aligned}\right\} \quad [50]$$

Cases (2), (3)

$$\left.\begin{aligned} &n_k'[\gamma_k + 2 - (4\xi_k+8)\epsilon_k' + 2(\epsilon_k')^2] \\ &\quad + n_k''[\gamma_k + 2 - (4\xi_k+8)\epsilon_k'' + 2(\epsilon_k'')^2] = -\frac{2V_k}{L} \\ &n_k'[(\gamma_k+3)\epsilon_k' - (2\xi_k+4)\{1 + (\epsilon_k')^2\} + (\epsilon_k')^3] \\ &\quad + n_k''[(\gamma_k+3)\epsilon_k'' - (2\xi_k+4)\{1 + (\epsilon_k'')^2\} \\ &\qquad + (\epsilon_k'')^3] = \frac{V_k}{L} \end{aligned}\right\} \quad [51]$$

The values of $\Omega_{k,0}$ are as follows:

Case (1)

$$\Omega_{k,0} = -\frac{2}{L}\left[n_k'\frac{\sin\beta_k}{\alpha_k} + n_k''\left(\frac{\cos\beta_k}{\alpha_k} - 1\right)\right] \quad [52]$$

Cases (2), (3)

$$\Omega_{k,0} = \frac{2}{L}[n_k'(1-\epsilon_k') + n_k''(1-\epsilon_k'')] \quad [53]$$

The values of $\Omega_{k,j}$ are as follows:

Case (1)

$$\Omega_{k,j} = -\frac{2}{L(\alpha_k)^j}\left[\left\{1 - \frac{1}{2}\left(\alpha_k + \frac{1}{\alpha_k}\right)\cos\beta_k\right\}(n_k'\sin\beta_k j + n_k''\cos\beta_k j) + \frac{1}{2}\left(\alpha_k - \frac{1}{\alpha_k}\right)\sin\beta_k(n_k'\cos\beta_k j - n_k''\sin\beta_k j)\right] \quad [54]$$

Cases (2), (3)

$$\Omega_{j,k} = \frac{1}{L}[\lambda_k' n_k'(\epsilon_k')^j + \lambda_k'' n_k''(\epsilon_k'')^j] \quad [55]$$

When ϵ is nearly equal to 1, the previous equations do not give very accurate results and can be replaced by developments in series of powers, which are hereafter limited to the first terms

Case (1)

$$\left.\begin{aligned} &\beta_k \log\alpha_k = \frac{1}{2}\sqrt{\delta_k' - \xi_k{}^2}; \quad (\log\alpha_k)^2 - \beta_k{}^2 = \xi_k \\ &\log\alpha_k = \sqrt{\frac{1}{2}\left(\xi_k + \sqrt{\delta'}\right)}; \\ &\beta_k = \sqrt{\frac{1}{2}\left(-\xi_k + \sqrt{\delta_k'}\right)} \\ &n_k' = -\frac{V_k}{4\beta_k L}; \quad n_k'' = \frac{V_k}{4L\log\alpha_k} \end{aligned}\right\} \quad [56]$$

$$-\frac{\Omega_{k,0}}{V_k} = 1 - \frac{3(\log\alpha_k)^2 - \beta_k{}^2}{4\log\alpha_k} = 1 - \frac{2\xi_k + \sqrt{\delta_k'}}{\sqrt{8\left(\xi_k + \sqrt{\delta_k'}\right)}} \quad [57]$$

Cases (2), (3) [— for Case (2), + for Case (3)]

$$\left.\begin{aligned} &\log\epsilon_k' = \sqrt{\mp\,\xi_k + \xi_k'}; \quad \log\epsilon_k'' = \sqrt{\mp\,\xi_k - \xi_k'} \\ &\xi_k' = \sqrt{\xi_k{}^2 - \delta_k'} \end{aligned}\right\} \quad [58]$$

$$-\frac{\Omega_{k,0}}{V_k} = 1 - \frac{(\log\epsilon_k')^3 - (\log\epsilon_k'')^3}{4\xi_k'} \quad [59]$$

General Loading of End Frame of Infinite Beam

Equations [44] can be applied to this case

Case (1)

$$\left.\begin{aligned} & n_k'' = N_k^* \\ & n_k'\left[(\gamma_k+2)\frac{\sin\beta_k}{\alpha_k} - (2\xi_k+4)\frac{\sin 2\beta_k}{(\alpha_k)^2} + \frac{\sin 3\beta_k}{(\alpha_k)^3}\right] \\ & + n_k''\left[-(2\xi_k+3) + (\gamma_k+2)\frac{\cos\beta_k}{\alpha_k} - (2\xi_k+4)\right. \\ & \left.\frac{\cos 2\beta_k}{(\alpha_k)^2} + \frac{\cos 3\beta_k}{(\alpha_k)^3}\right] = \frac{V_k}{L} \end{aligned}\right\} \quad [60]$$

Cases (2), (3)

$$\left.\begin{aligned} & n_k' + n_k'' = N_k^* \\ & n_k'[-(2\xi_k+3) + (\gamma_k+2)\epsilon_k' - (2\xi_k+4)(\epsilon_k')^2 \\ & + (\epsilon_k')^3] + n_k''[-(2\xi_k+3) + (\gamma_k+2)\epsilon_k'' \\ & - (2\xi_k+4)(\epsilon_k'')^2 + (\epsilon_k'')^3] = \frac{V_k}{L} \end{aligned}\right\} \quad [61]$$

Numerical Tables

Two independent dimensionless variables (δ_k and δ_k') define the properties of a circular shell with frames for a given harmonic k. These quantities are designated by δ, δ'. The other coefficients are given in Table 2 as functions of δ and of δ/δ'.

Terms λ', λ'', ϵ', ϵ'' are given in the case of real roots, and log α, β, $\frac{1}{\alpha}$, β deg are given in the case of complex roots. Ratios such as ρ, Ln/V, LN/V are also calculated for the cases of load on an intermediate and an end frame.

Diagram, Fig. 4, gives ρ_0 for the case of an intermediate frame

Influence of Frame Eccentricity, and of Axial and Shearing Deflection of Frames

The quantity δ_k is proportional to D_k; in D_k, the term containing A is predominant for large values of k when there is no eccentricity. If there is an eccentricity, the terms containing η and A are predominant, which shows that great errors can be committed when the eccentricity is neglected. This explains the importance of the eccentricity, noted in the introduction: Terms of bending (without eccentricity) and shear are of sixth degree in k, while terms of flexure (due to eccentricity) and axial load are of fourth degree. Thus, when the eccentricity and the axial deformation are neglected in a frame, the influence of the high harmonics is underestimated, which leads to erroneous results, especially in the case of concentrated loads. On the contrary, no important error is made when the shear term is neglected, since it is of sixth order and normally of small importance for the first harmonics, at least for flexible frames. The relative influence of the eccentricity and of the axial deformation can be easily determined in a frame constituted by two flanges

$$I = Ae_0^2 = AR^2\eta^2$$

$$\frac{1}{D_k} = \frac{R^2(1-\eta)}{A(k^2-1)^2}\left\{1 + \left[1 - \frac{1}{k^2}\left(1 + \frac{1}{\eta}\right)\right]^2\right\}$$

If $1/\eta k^2$ is negligible (k large), D_k is equal to Ak^4/R^2. In this case bending and axial deformations equally contribute to the flexibility of the frame, while for a frame without eccentricity, the axial deformation only is important.

Distribution of Loads in Frame Under Action of Concentrated External Forces and Couples.

A unit impulse function[4] can be used to represent the load. Because of the periodicity of the solution, the integrals used in conventional representations of step functions are replaced by sums. Calling Γ_0 the applied concentrated load and $\Gamma(\theta)$ the equivalent step function, it is known that

$$\Gamma(\theta) = \frac{\Gamma_0}{\pi R}\left(\frac{1}{2} + \sum_{K=1}^{\infty}\cos k\theta\right) \quad [62]$$

By application of Equation [62] to various loading conditions, the following coefficients are obtained

$$\left.\begin{aligned} & \text{Radial force} \quad p_k^* = \frac{P_0}{\pi R};\ q_k^* = 0\ ;\ b_k^* = 0 \\ & \text{Tangential force} \quad \bar{p}_k^* = 0\ ;\ \bar{q}_k^* = \frac{Q_0}{\pi R}\ ;\ \bar{b}_k^* = \frac{Q_k\eta}{\pi R} \\ & \text{Couple} \quad \bar{p}_k^* = 0\ ;\ \bar{q}_k^* = 0\ ;\ \bar{b}_k^* = \frac{B_0}{\pi R^2} \end{aligned}\right\} \quad [63]$$

The load coefficients M, S, F are as follows:

$$\left.\begin{aligned} & \text{Radial} \quad M_{k,0}^* = \frac{RP_0}{\pi(k^2-1)};\ F_{k,0}^* = \frac{P_0}{\pi(k^2-1)}; \\ & \qquad S_{k,0}^* = \frac{KP_0}{\pi(k^2-1)} \\ & \text{Tangential} \quad \bar{M}_{k,0}^* = \frac{RQ_0}{\pi k}\left[\frac{1}{k^2-1} - \eta\right]; \\ & \qquad \bar{F}_{k,0}^* = \frac{Q_0 k}{\pi(k^2-1)};\ \bar{S}_{k,0}^* = \frac{Q_0}{\pi(k^2-1)} \\ & \text{Couple} \quad \bar{M}_{k,0}^* = -\frac{B_0}{\pi k};\ \bar{F}_{k,0}^* = 0;\ S_{k,0}^* = 0 \end{aligned}\right\} \quad [64]$$

The values of V_k are as follows:

$$\left.\begin{aligned} & \text{Radial} \quad V_k = \frac{R^2P_0}{\pi(k^2-1)^2} \\ & \left[\frac{R^2}{Ik^2}\left\{(1-\eta(k^2-1)\right\} + \frac{1}{A} + \frac{E}{Ga}\right](1-\eta) \\ & \text{Tangential} \quad \bar{V}_k = \frac{R^2Q_0}{\pi(k^2-1)^2} \\ & \left[\frac{R^2}{Ik^2}\left\{1-\eta(k^2-1)\right\}^2 + \frac{k}{A} + \frac{E}{Gak}\right](1-\eta) \\ & \text{Couple} \quad \bar{V}_k = -\frac{R^3B_0}{\pi k^3 I}\left[\frac{1}{k^2-1} - \eta\right](1-\eta) \end{aligned}\right\} \quad [65]$$

The values of $\Delta_{k,0}^m$ can be written in the following form:

$$\left.\begin{aligned} & \text{Radial load} \quad \Delta_{k,0}^m = (1-\rho_{k,0})\frac{f_k''(f_k''+f_k''')}{(f_k'')^2+f_k'} \\ & \text{Tangential load} \quad \Delta_{k,0}^m = (1-\rho_{k,0}) \\ & \text{Couple} \quad \Delta_{k,0}^m = (1-\rho_{k,0})\frac{(f_k'')^2}{(f_k'')^2+f_k'} \end{aligned}\right\} \quad [66]$$

In these expressions, constants f_k are as follows

$$f' = \frac{k^2I}{R^2}\left(\frac{k^2}{A} + \frac{E}{Ga}\right);\ f_k'' = 1-\eta(k^2-1);$$

$$f_k''' = \frac{k^2I}{R^2}\left(\frac{1}{A} + \frac{E}{Ga}\right) \quad [67]$$

The corrections to the conventional solutions are thus

[4] Footnote reference (3), p. 395.

TABLE 4 VALUES OF PARAMETERS IN FIGS. 5, 6, 7

Curve group	η	Parameter	Curve no. 1	2	3	4	5	6	7
I	0	IL/R^4t	0.1	0.01	0.001	0.0001	0.00001	..	..
II	1/30	$AL/(1-\eta)tR^2$	100	20	4	0.8	0.16	0.04	0.01
III	1/10	$AL/(1-\eta)tR^2$	20	4	0.8	0.16	0.04	0.01	..

NOTE: Curves nos. 0 correspond to conventional solution (infinitely rigid frame).

The quantities $M_{k.0}^*$ are defined by Equations [64] and, from the values of μ_k, σ_k, φ_k it results that

$$\frac{\sigma_k}{\mu_k} = \frac{k}{[1-\eta(k^2-1)]R}; \quad \frac{\varphi_k}{\sigma_k} = -k \ldots\ldots [69]$$

In the diagrams, Fig. 5, deflections in shear are neglected, and I is replaced by $Ae_0^2 = AR^2\eta^2$, so that

$$f_k' = k^4\eta^2; \quad f_k''' = k^2\eta^2 \ldots\ldots [70]$$

Thus, the resulting moment at any point of the frame is the difference between the conventional solution (equal to $\Sigma M_{k.0}^* \cos k\theta$) and the correction $\Sigma M_{k.0}^* \Delta_{k.0}^m \cos k\theta$ which is a rapidly converging series.

For an indefinite shell, the problem is defined in terms of three dimensionless quantities which, for each harmonic, can be δ_k, δ_k', η. In turn, δ_k and δ_k' can be expressed as functions of k and two other dimensionless quantities. This leads to the following three independent variables:

1 Ratio $\eta = e/R$ (eccentricity)

2 Ratio ALE/R^2tG; this ratio defines

$$\delta_k = \frac{ALE}{R^2tG} \frac{1}{\frac{1}{k^2}\left[\frac{1}{\eta(k^2-1)} - 1\right]^2 + \left[\frac{k}{k^2-1}\right]^2}$$

3 Ratio $\delta_1/\delta_1' = R^2hE/L^2tG$; this ratio defines $\delta_k/\delta_k' = (\delta_1/\delta_1')(1/k^2)$

DIAGRAMS FOR BENDING MOMENTS, AXIAL FORCES, AND SHEARING FORCES IN FRAMES

The diagrams, Figs. 5, 6, 7, represent bending moments, axial forces, and shearing forces, respectively, in the frames as functions of the eccentricity $\eta = e/R$ of the frame and of the two variables AL/tR^2 and R^2h/L^2t. It has been found that this last ratio has but a small influence on the results; generally, this influence, for R^2h/L^2t varying between 10 and 100, is less than 5 per cent. An average value of 31.25 has been chosen for this parameter.

In the case of a frame without eccentricity, the axial deformation has been neglected, and the variable replacing AL/tR^2 is IL/tR^4.

The coefficients for a loaded intermediate ring in an indefinite shell ($E/G = 2.6$) are given in Table 3.

The coefficients K are ratios such as

$$K_{MR} = \frac{M/R}{P_0}$$

so that

$$M = K_{MR}RP_0$$

They have been computed for angles θ varying by increments of 15 deg from 0 to 180°. The antisymmetric functions are marked (—).

Sliding Friction Under Extreme Pressures—1

By S. J. DOKOS,[1] EAST PITTSBURGH, PA.

The program of this investigation on sliding friction is concerned with the evaluation of the frictional forces which occur under very high contact pressures and under varying conditions of speed, temperature, and lubrication. The work presented herein covers the experiments which have been made on sliding friction at normal temperatures. Further experiments on boundary lubrication at normal temperatures and sliding friction at elevated temperatures will be reported in a second paper.

This report indicates the behavior of sliding friction when large normal loads react between surfaces in contact over a wide range of sliding velocities. At velocities less than one inch per second magnified photographs of the ruptured surfaces indicate clearly this phenomenon of stick-slip. From the experimental records obtained it was possible to show that a functional relation exists between the following variables: (1) The sliding velocity, (2) the normal load, and, (3) the frequency of stick-slip. New experimental evidence is presented indicating that the natural frequency of the apparatus involved influences the phenomenon of stick-slip.

Introduction

VERY little is known concerning the nature of sliding friction which accompanies plastic forming of metals at normal and at elevated temperatures. It is well known, however, that during the rolling of steel, the forging of shells, the extrusion of tubes, the drawing of wire, or the piercing of billets, very high frictional forces oppose the flow of metal. Numerous theoretical papers presented by Siebel (1),[2] Trinks (2, 3), Nadai (4, 5), Sachs (6) and others have investigated these plastic-flow problems.

Particular attention was paid in these investigations to the influence of friction on the surface of the metal undergoing plastic deformation and to the power requirements. The insufficient data which existed concerning both the effect of friction and the values of the coefficients of friction has retarded the complete solution of these problems. Recently, the wire-drawing process has been investigated, in connection with the present report, by E. A. Davis and the writer (7), as a possible means for an experimental determination of the coefficient of sliding friction under large contact pressures.

The machine used in this investigation for determining the frictional forces between metallic surfaces consists in general of a horizontal disk rotating around a vertical axis and a pin sliding on the surface of the disk. On the upper surface of the disk, at the suggestion of Dr. A. Nadai, a number of concentric ridges and grooves were machined. A cylindrical contact rests under a known load on one of the ridges while the disk rotates with a constant velocity. The frictional forces are automatically recorded by means of a special measuring device. The disk can be surrounded by an electric-resistance furnace and preheated to a given temperature. Although several investigators, among whom F. P. Bowden (8) and M. Muskat (9) should be quoted, have used this method, it is believed that several important improvements have been added to the apparatus for measuring the frictional forces and to study the behavior of sliding materials under very heavy pressures.

[1] Research Engineer, Westinghouse Research Laboratories.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Previous Investigations

A considerable amount of experimental research on friction has been done in the past both in England and in this country on special questions related to friction at normal temperatures. It cannot be the purpose of this report to offer a complete review of the vast amount of available literature on related questions. However, a few investigations which seem to have a relation to the present work will be quoted.

Various proposals have been made concerning the nature of sliding friction. The early investigations of Amontons (10) attributed it to resistance due to the mechanical interlocking of the irregularities of the surfaces in contact. This, in turn, has been superseded by the view that the resistance to motion is due to intermolecular forces at the point of contact. Tomlinson (11) has presented a molecular theory, according to which sliding friction is due to the attractive and repulsive forces between molecules at the surfaces in contact, so that friction is a surface phenomenon. More recently, from the work done by Bowden and his associates, it has been indicated that neither of these assumptions is entirely correct and that the frictional effects are not confined to the surfaces alone. The sliding which occurs causes a localized plastic deformation of the solid, which extends to a great depth beneath the surface; consequently, friction must also be dependent on the bulk properties of the solids. This interpretation has also been suggested by Merchant and Ernst (12).

Bowden and Ridler (13), while performing experiments on the friction between unlubricated surfaces, observed fluctuations in friction and concluded that kinetic friction may not be constant. In order to investigate this phenomenon Bowden and Leben (14) constructed a special apparatus for measuring these fluctuations. The measuring device incorporates two vibratory systems. One measures the tangential reaction between the surfaces, and its frequency is controlled by a bifilar suspension. The other applies the normal force and is controlled by a circular spring. Both systems have a high natural frequency of approximately 1000 cycles per sec. An apparatus of this type was assumed to be capable of recording any changes in friction provided the natural frequency of the measuring device is higher than the frequency of the variations in friction.

The measuring apparatus was used to apply the normal load to a flat plate which can be driven by a water piston. When the plate was set in motion the slider was observed to move along with the surface plate as though the two had stuck together until the friction force became sufficient to jerk the slider loose and bring it back into position to repeat the process. The investigators concluded that this phenomenon was a result of high pressures and of high temperatures (13) at the points of contact causing local welding and plastic flow, and that the observed "stick-slips" were the manifestations of these welds and the subsequent rupture of the contacts. Bowden and Leben believe that this phenomenon is inherent to the sliding of metals, and that these fluctuations are characteristic of the mechanism of friction.

In a later investigation Bowden, Leben, and Tabor (15) indi-

cated that the intermittent motion produced is influenced by the natural frequency, the moment of inertia, and the damping of the moving parts along with the sliding velocity of the metals in contact. However, it was also clearly shown that the nature of sliding was decidedly influenced by the properties of the metals in contact. In several subsequent experimental investigations the thought was expressed by Blok (16) and Morgan, Muskat, and Reed (9) that the periodic variations of the frictional forces observed by Bowden and Leben may have been influenced or even entirely caused by the elasticity of the apparatus.

Friction Machine

The machine used in the work described in this paper, Figs. 1 to 3, consists essentially of a disk holder approximately 12 in. in diameter, revolving around a vertical axis upon which exchangeable disks *a*, can be fastened. On one of the ridges of the machined disk the rubbing contact *b* rests under a known normal load. The vertical holder carrying the small contact cylinder, which

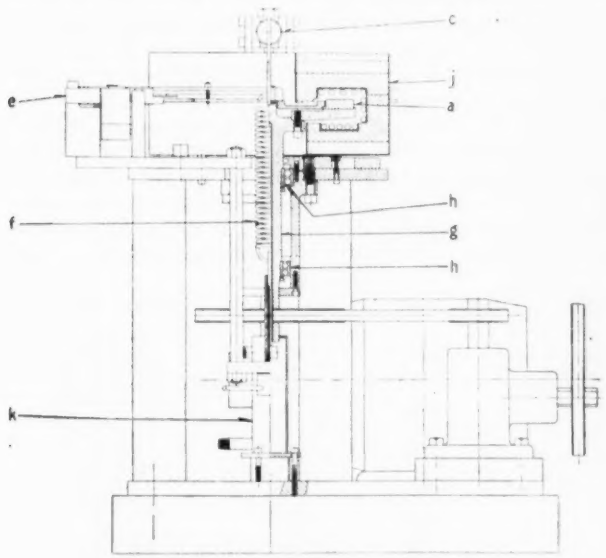

Fig. 1 Friction Apparatus, Front View

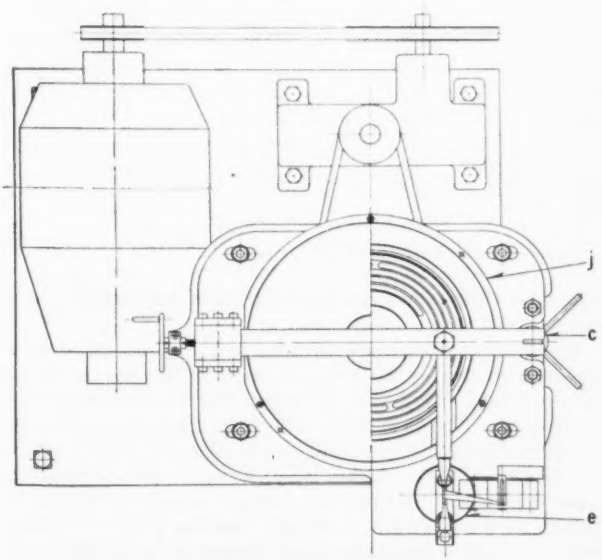

Fig. 2 Friction Apparatus, Top View

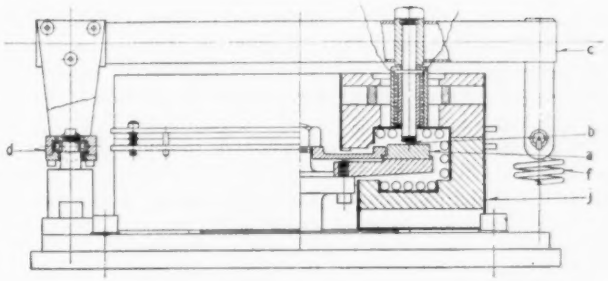

Fig. 3 Friction Apparatus, Deflecting Arm View

slides on the disk along one of its generatrixes, is attached to a rigid arm *c* pivoted on a universal-joint *d*, so that it can move freely up or down or to either side. The dynamometer for measuring the frictional force consists of a thin flexible steel ring *e*. The elastic deflection of the ring is a measure of the frictional force and is magnified by means of a pointer deflected by leaf springs.

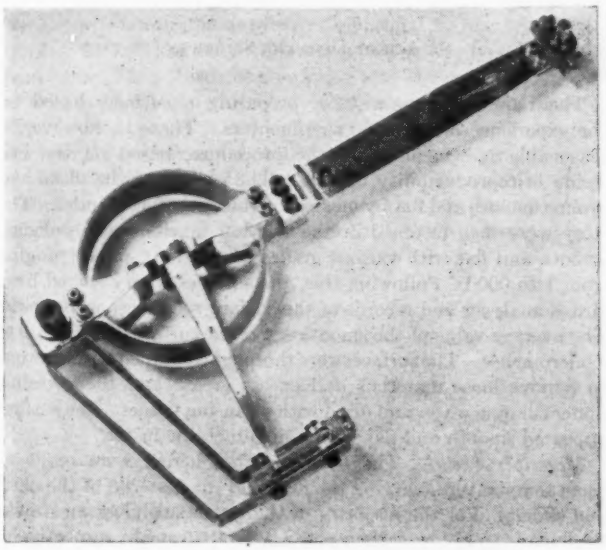

Fig. 4 System for Measuring Friction Force

Fig. 4 shows this device. The pointer scribes a fine scratch on waxed paper which is slowly moved by a clock device. The desired normal load is applied to the deflecting arm by a spring *f*. The rotating table which carries the metal disks is mounted on ball bearings and can, by suitable gearing, be driven at velocities varying from 1.6×10^{-4} to 300 ips. In the slowest test approximately 60 hr were required to make a complete revolution of the disk. An electric-resistance furnace *j* covers the ring, and the temperature can be varied from room temperature to 1200 C. The entire machine is rigidly constructed and well mounted to prevent any vibrations. The vertical shaft can be cooled by a water jacket.

Unlike the high-frequency measuring devices used by several investigators (9, 14), in which the phenomenon of stick-slip prevailed, it was thought advisable to design the normal load device and the dynamometer so that an average frictional force was obtained at sliding velocities larger than 1 ips. The normal loading system has a natural frequency in the vertical direction of 200 cycles per sec, and the measured frequency of the dynamometer for a motion in the horizontal direction is approximately 150 cycles per sec. Since stick-slip is influenced by the elasticity

of the measuring devices, the mechanical properties of the rotating mechanism, and the velocity of rotation, it is not present in the recorded diagrams at comparatively high speeds because of the low natural frequency of the system and the amount of damping in the moving parts.

Preparation of Surfaces. The width of the ridges, machined in the disk, is slightly less than the width of the contact cylinder. Thus the cylindrical contact covers the entire width of the ridge during the test, as shown in Fig. 5.

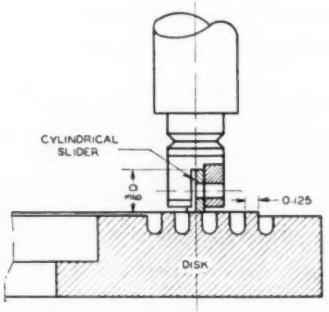

FIG. 5 SKETCH OF DISK AND SLIDER IN CONTACT

There are numerous ways of preparing a surface, based on the experience of various experimenters. There is, however, a reasonable agreement as to the procedure, based on the criterion of reproducibility of data. The surface of the disks was ground smooth and flat by means of a rotary surface grinder. The rings were then fastened in the friction machine and polished smooth and flat with various grades of polishing paper ranging from 1 to 0000. Following this, the surfaces were checked by a Brush analyzer and records of the surface roughness were made. The average value of the smoothness of the surfaces was from 2 to 7 microinches. The surfaces were thoroughly cleaned with acetone to remove loose materials and excess grease and then washed under running water and dried with cleansing tissue. The surface appeared smooth and flat with a high metallic luster.

Materials Tested. The tests reported herein were made at room temperature, varying the load and the material of the disks and sliders. For the majority of the tests the sliders and disks were made from low-carbon and S.A.E. 1045 steels, respectively. Three types of metals were used, as follows:

1 No. 1 steel; a low-carbon steel with 0.2 per cent carbon.
2 No. 2 steel; medium-carbon steel (S.A.E. 1045).
3 No. 3 steel; tool steel with 0.7 per cent carbon.

TESTS ON SLIDING FRICTION AT VARIOUS PRESSURES AND SLIDING VELOCITIES

This investigation deals with observations on the friction between sliding surfaces which are free from any lubricating agent. Although, as mentioned, numerous investigators have dealt with the theoretical and experimental aspects of dry friction, in most of these tests comparatively low normal loads were applied. It is hoped that the information presented herein will offer new observations on the mechanism of friction particularly under heavy normal forces. Consideration is given to the influence (*a*) of velocity, (*b*) of load, and (*c*) of various metals on friction. The sliding velocity was varied over a wide range in order to obtain, at relatively high pressures, a relation between the sliding velocity, the coefficient of friction, and the normal load.

Conflicting evidence on the effect of velocity on sliding friction has been presented by a number of the early investigators. In 1781, Coulomb (18) concluded that velocity has very little effect on dry friction between metals. On the other hand, the experiments of Galton and George Westinghouse (17) in which the braking action of a cast-iron block on a hard steel tire was measured indicated that friction decreased greatly with increased speed. Recently, numerous investigators have shown that a variation does exist and that sliding friction decreases with speed.

Papenhuyzen (18) has shown this velocity-friction relation as the velocity was varied over a wide range, while investigating the fundamentals of the skidding of automobile tires on road materials. From these experiments Papenhuyzen indicated three velocity ranges in which the frictional characteristics were of a different nature, namely, (*a*) that at low sliding velocities only uniform sliding was observed, (*b*) that at a sharply defined first critical velocity, frictional vibrations occurred of the stick-slip type, and (*c*) that at sliding velocities greater than the second critical velocity, frictional vibrations of the simple harmonic type occurred. In the first range, friction increased slightly with speed. At higher sliding velocities an average coefficient of friction was deduced which is considerably lower than the static friction.

The speed of the rotating disk was varied over a range of 2.6×10^{-4} to 500 rpm, corresponding to a relative sliding velocity of 1.6×10^{-4} to 300 ips. The observed coefficients of friction are plotted in Fig. 6, as the ordinate, and the sliding velocities are represented on a logarithmic scale for various values of the normal force. Materials in contact are various steels. In these tests the sliding cylinder was made of mild steel and the disk of an S.A.E. 1045 steel. The normal load was varied from 50 to 200 lb at the various velocities and as indicated by the curves has a decided influence on their shape. The results obtained from these tests are given in Table 1. The coefficient of friction at the slower velocities is measured at the point of maximum frictional force.

TABLE 1 EFFECT OF VELOCITY AND NORMAL LOAD ON FRICTION

Velocity of disk, ips	Normal load, lb	Coefficient of friction	Stick-slip frequency, cycles per sec

[a] Values of friction could not be determined.

Two types of friction are indicated in Fig. 6, one called stick-slip friction following the term introduced by Bowden and Leben, and the other a smooth sliding friction. Further analysis of stick-slip friction will be given later. It is sufficient at present to state that in general two distinct ranges of friction exist. At velocities less than 1 ips stick-slip takes place; at speeds greater than this value, which will be called the critical velocity of friction, a smooth friction record is obtained. Another point of interest, shown in Fig. 6, is that three velocity ranges can be distinguished, namely, (*a*) velocities less than 4×10^{-4} ips, in which the coeffi-

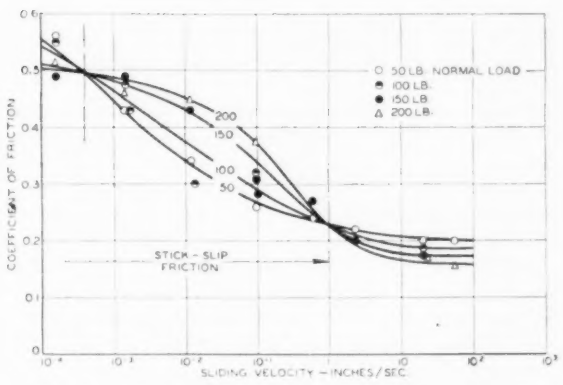

FIG. 6 VELOCITY-FRICTION CURVES AT VARIOUS LOADS

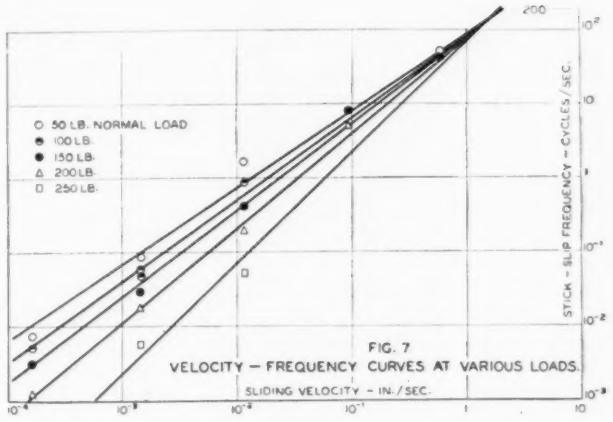

FIG. 7 VELOCITY-FREQUENCY CURVES AT VARIOUS LOADS

cient of friction decreases with increased normal load, (*b*) velocities greater than 4×10^{-4} ips and less than the critical velocity, in which the coefficient of friction increases with increased normal load, and (*c*) velocities greater than the critical velocity, in which the coefficient of friction decreases with increased load.

The following steel combinations in sliding contact were investigated: (*a*) Mild steel on Nos. 1, 2, and 3 steel disks, and (*b*) 18-8 stainless steel on Nos. 1, 2, and 3 steel disks. Along with these some friction tests using copper and aluminum rubbing on the various steel disks were made. In Table 2 are the friction

TABLE 2 COEFFICIENT OF FRICTION FOR VARIOUS METALS IN CONTACT

Disk material	Contact slider material	Coefficient of friction
No. 1 steel	No. 1 steel	0.18–0.23
	18-8 Stainless steel	0.18–0.22
No. 2 steel[a]	No. 1 steel	0.17–0.20
	18-8 Stainless steel	0.16–0.20
	Copper (V.H., 98)	0.23–0.32
No. 3 steel	No. 1 steel	0.18–0.22
	18-8 Stainless steel	0.16–0.19
	Commercial hard copper (V.H., 98)	0.18–0.28
	Aluminum	0.16–0.20

[a] The applied load and speed were constant throughout all tests. The applied load was 50 lb. The disk revolved at a velocity of 20 ips.
V.H. designates Vickers hardness.

values corresponding to these metal combinations. In each case more than one test was made with the exception of those in which copper and aluminum sliders on steel were used. The applied normal load and the velocity were constant throughout each test. The normal load was 50 lb, and the disk revolved at a velocity of approximately 20 ips. The maximum pressures observed as calculated from the measured area of contacts were of the order of 60,000 psi. Unit pressures in pounds per square inch were continuously decreasing during each test, since, due to wear, the apparent contact areas continuously increased.

An examination of the coefficient-of-friction values reveals that no noticeable variation exists between the various steel combinations. Therefore within reasonable experimental accuracy, we may conclude that at the same velocity, normal load, and surface finish, the coefficient of friction is the same for all steels which were investigated.

THE MECHANISM OF STICK-SLIP

As stated in the investigations of Bowden and Leben (14), and Bowden, Leben, and Tabor (15), it has been shown that stick-slip is a general characteristic of the mechanism of friction and of the experimental apparatus. With the present apparatus the critical velocity is 1 ips, due to the natural frequency of the tangential measuring device and the damping in the system. Since the natural frequency of the apparatus and stick-slip seem to be related in some manner, the frequency of stick-slip and the sliding velocity were plotted on log-log paper, as shown in Fig. 7. An examination of the curves reveals that their point of intersection is at the velocity at which the fluctuations recorded cease and the stick-slip frequency is approximately equal to the natural frequency of both the tangential measuring device and the normal load arm. Thus it can be concluded that the natural frequency of the apparatus has a decided effect on the frequency of stick-slip.

From the experimental results shown in Fig. 7, a definite relation exists between the frequency of stick-slip and the sliding velocity. Thus the stick-slip frequency f_s can be expressed as a function of the sliding velocity v, in the following form

$$f_s = kv^n \quad [1]$$

The physical constants k and n are functions of the normal load. Thus for the various loads plotted, the equations of the curves are

$$\left.\begin{array}{ll} (50\text{ lb}) & f_s = 87.4\, v^{1.04} \\ (100\text{ lb}) & f_s = 84.5\, v^{1.11} \\ (150\text{ lb}) & f_s = 82.2\, v^{1.17} \\ (200\text{ lb}) & f_s = 77.2\, v^{1.27} \\ (250\text{ lb}) & f_s = 63.0\, v^{1.48} \end{array}\right\} \quad [2]$$

(The units of f_s and v are cycles per second and inches per second, respectively.)

Since the velocity is constant throughout a test, an expression can be obtained for determining the distance of slip. The distance s traversed per cycle is proportional to the sliding velocity and inversely proportional to the frequency of stick-slip. Thus

$$s = \frac{v}{f_s} = \frac{1}{kv^{n-1}} \quad [3]$$

From the preceding equation the distance of slip can be calculated at any normal load and at any sliding velocity.

In addition to the velocity-frequency curves which are analyzed, some consideration is given to the effect of the normal load on the stick-slip frequency at a constant velocity. This effect is shown by two curves at different velocities in Fig. 8. For the particular velocities chosen the stick-slip frequency can be expressed as a function of the normal load L, in the following manner

$$f_s = C_1 e^{C_2 L} \quad [4]$$

where C_1, C_2 are constants.

This equation will hold for normal loads greater than 35 lb and less than 200 lb. From a test run by Bowden and Leben at a velocity of 0.006 cm per sec and a reaction of 400 g between the

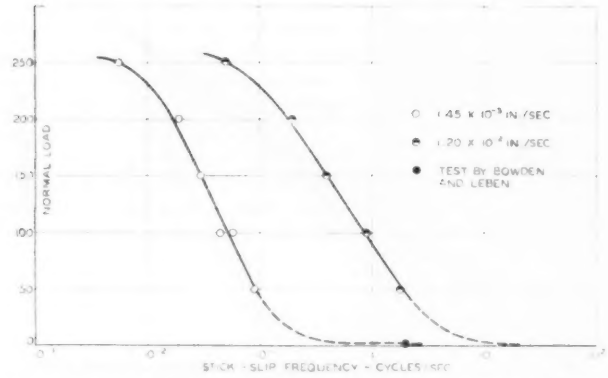

FIG. 8 FREQUENCY - NORMAL LOAD CURVES AT VARIOUS VELOCITIES

surface, the nature of the curve at the higher loads can be deduced. When the normal load is increased in magnitude to greater than 200 lb, the curves taper off in the form of an inverted *S*. This seems reasonable, since eventually pressures are reached in which the contact slider plastically deforms very rapidly. Similarly, at lighter loads, the frequency of stick-slip would increase at an accelerated rate. Thus it can be concluded that the curves become asymptotic to the abscissa and to a maximum normal load line.

Photographs of both the surfaces of the disks and the friction records were taken. Fig. 9 shows a magnification of the surface of the disk and a typical record of the test taken with the lower surface moving at a velocity of 1.6×10^{-4} ips and with a reaction of 50 lb between the two surfaces. The passage of time is from left to right. The upper trace of the record is used as a zero position in determining the coefficient of friction. The pointer, as shown in Fig. 4, deflects upward as the tangential force is increased. The distance between the maximum friction and the zero trace can be measured and the load determined. The measured frictional force divided by the normal load is the value of the coefficient of friction. Increments of the coefficients of friction are indicated in the figure. The recorded trace represents the variation of the tangential force with time. As indicated by the records, the force opposing motion is not constant but varies in definite cycles during sliding. These fluctuations follow a definite pattern in which the tangential force increases steadily up to a maximum force and instantly drops to a lower value. The dis-

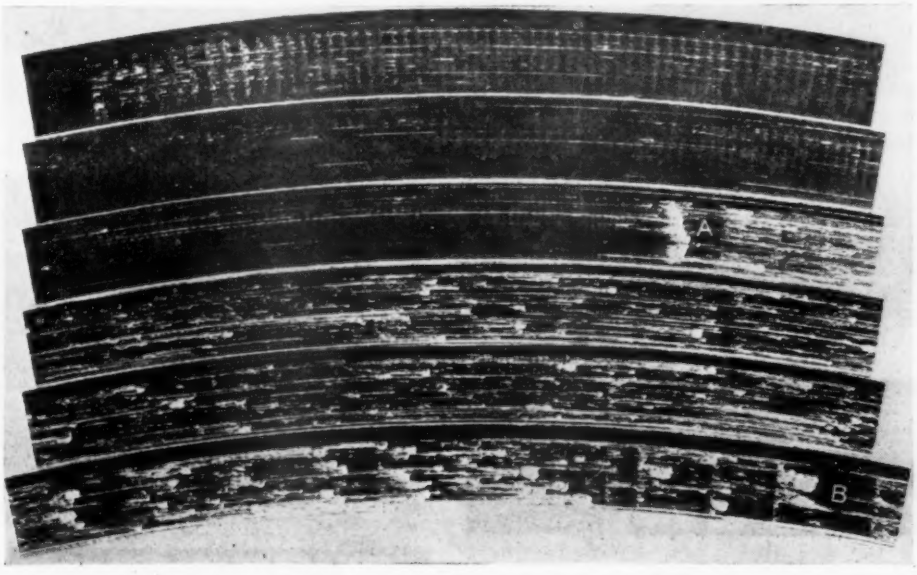

FIG. 12 CONDITION OF COMPLETE SURFACE AFTER TEST
(Record of test shown in Fig. 13.)

tance through which the slider slips is a function of the velocity. The vibrations are of the stick-slip type at the slower speeds; as the speed of the disk is increased and approaches the critical velocity of the apparatus, the fluctuations take the form of simple harmonic vibrations, as shown in Fig. 10. At the higher loads stick-slip continues until the surface of the metal is ruptured, after which plastic smearing of the metal occurs. The friction varies in a radical manner and is, with exceptions, void of the stick-slip phenomenon. An examination of Figs. 11 and 13 indicates what may occur after the surface is severely ruptured.

Fig. 11 shows the effect of increased load when compared with Fig. 9, the velocity remaining the same. At the higher loads the surface of the disk is more susceptible to rupture. This is shown to illustrate that the identical number of stick-slips was recorded, as there are stick-slip markings on the surface of the disk. The time required for the tangential force to reach its maximum value, as determined from the record, is 300 sec. The distance through which the slider slips can be measured directly from the photograph of the magnified surface, or it can be calculated from Equation [3]. The average value of one cycle measured from the disk is 0.051 in., which is in close agreement with that calculated by Equation [3] (0.053 in.).

In order to illustrate what happens to the entire surface of the disk throughout a complete test, a magnified photograph of the complete surface was made as shown in Fig. 12. As the disk rotates in a counterclockwise direction, the cylindrical contact moves in a relative direction from left to right. The complete record of the test is shown in Fig. 13. The amplitude of the frictional force decreased, and the frequency of stick-slip increased as the test progressed. The surface of the disk was ruptured at point *A* where large portions of the metal were torn from the slider and adhered to the surface of the disk. After rupture occurred, the surface became rougher as the test proceeded. As the contact slider passed over the ruptured surface, stick-slip occurred in a radical manner, as shown at *B*, on the surface.

The wear produced by high pressures on the surface of the disk and on the contact slider is shown in Figs. 14 and 15. The worn surfaces (*a*) and (*c*) mark the beginning, and the surfaces (*b*) and (*d*) the ends of the tests. The contact (*a*) had a normal reaction between the surfaces of 50 lb and contact (*b*) had a reaction of

Velocity = 1.44 × 10⁻³ ips.)

150 lb. The leading edge of the contact sliders is smooth in comparison to the rest of the sliding surface. This should be the case since the leading edge was continually in contact with the highly polished surface of the disk. However, as the disk continued to rotate, portions of metal were torn from the slider. These particles of metal adhered to the surface of the disk.

In order to illustrate more clearly what occurs when high pressures are applied to sliding metals, two tests were made at different velocities. Fig. 16 shows magnified reproductions of the surface of the disk. The normal reaction between the surfaces

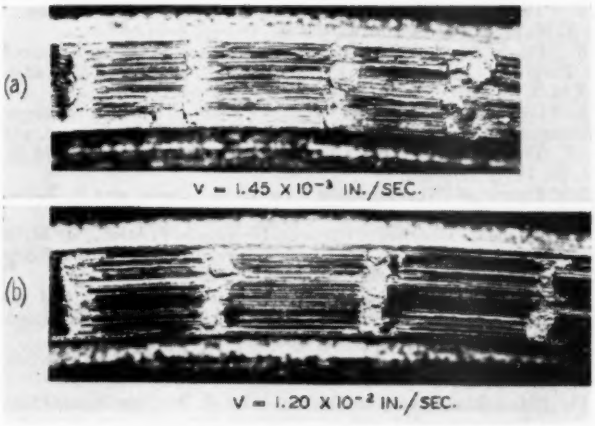

FIG. 16 SURFACES OF DISK UNDER EXTREME PRESSURES
(Normal load = 250 lb.)

was 250 lb in both tests. The distance of slip measured from the photograph of Fig. 15 (*a*) is 0.205 in., and at the faster speed the distance of slip is 0.160 in. At the load applied in these tests the particles torn from the cylindrical sliders are clearly outlined in both photographs. At these velocities enough time prevailed for plastic deformation to occur between the two surfaces. The irregularities of the polished surfaces in contact are points of highly concentrated pressures which caused the elevated portions of the surface to flow plastically and to interlock. As the tangential force increases, a point is reached where the actual area of the metal being sheared, multiplied by the ultimate shearing stress of the metal, is approximately equal to the maximum frictional force before slip occurs. This is graphically illustrated by the reproduced photographs of the surfaces. In these tests the projected areas of shear were measured; although this is not the actual area of shear, it illustrates what does occur in all cases where these effects are not clearly seen. The average projected area as measured with a planimeter is 3×10^{-3} sq in. The frictional force as measured from the record is approximately 150 lb. The ultimate shearing strength of the mild steel is assumed to be 35,000 psi. Therefore the calculated force necessary to shear the steel is approximately 105 lb. However, the actual area of shear cannot be measured and is greater than the projected area which should increase the calculated value. Another consideration is that the slider may have sheared some metallic junctions from the disk. In most cases this would not occur, since the disk has a higher hardness than the slider, as is illustrated by the slider reproductions in Fig. 15.

DISCUSSION

When metal surfaces slide on one another, penetration and distortion of the metals occur to some depth beneath the surface. The frictional force and the nature of sliding are influenced by the bulk properties of the metals, and the mechanism of friction cannot be regarded as only a surface effect. The early investigations of Amontons (10) attributed the nature of sliding friction to the resistance to motion due to the mechanical interlocking of the irregularities of the surface. Recently, Bowden and Leben (14) have suggested that the frictional resistance of metals is primarily due to the shearing of metallic junctions formed by adhesion and welding at these points of contact, and to the work of ploughing surface irregularities of the harder metal through the softer one.

From the work presented herein, in which extreme pressures are employed, the nature of the surfaces previously in contact indicate on a rather quantitative basis the amount of plastic deformation which has occurred. Thus the interlocking of the surface irregularities, brought about by the plastic deformation of the surfaces of the disk and slider, cause the shearing of these metallic junctions. This is particularly significant, when an examination is given to the magnified reproduction of these surfaces. Bowden, Moore, and Tabor (19), in the investigation of the ploughing and adhesion of sliding metals, show by microexamination the nature and extent of the welding and ploughing which occurred at smaller pressures. A reasonable explanation can be given for the shearing of metal. Although the surfaces in contact may be carefully polished, ridges and valleys will still be present in the surfaces.

In a recent publication by Bowden and Tabor (20), the actual area of contact between stationary and moving surfaces was determined by measuring the electrical conductance between the metals. The results showed the real area of contact was very small and was almost independent of the apparent area of contact. These tests have also shown that the deformation of the surfaces was mainly plastic, although elastic deformation has also a decided effect on the surfaces.

The early work of Coulomb and Amontons (21) concluded that the frictional force was (*a*) independent of the area of contact, and (*b*) proportional to the applied load. These relations between the frictional force, the area of contact, and the load, in the light of recent work, are not very apparent. As has been shown in this report, the frictional force is decidedly influenced by both the velocity of sliding metals and by the applied load. This is clearly shown in Fig. 6 of this paper.

The effect of this type of apparatus on the nature of motion has been of particular interest to various investigators. Bowden, Leben, and Tabor (15) have indicated that the intermittent motion produced is influenced by the natural frequency, the moment of inertia, and the damping of the moving parts. Along with the mechanical properties of the system, the type of motion will be decidedly influenced by the velocity. This has been clearly shown by the reproduced records of the stick-slips at various velocities, and at the same applied load. Beyond question, however, the nature of sliding is decidedly influenced by the properties of the metals in contact.

From the experimental curves in Fig. 7 the range of stick-slip, for steel on steel has been defined. At velocities greater than the critical velocity, stick-slip has not been recorded due to the frequency of stick-slip. At the slower velocities the surfaces remain in contact for a relatively long time during the "stick" period. While the surfaces are at rest relative to each other, plastic deformation occurs which allows the macroscopic irregularities of the surfaces to flow and interlock. This welding and adhesion produces larger coefficients of friction than would be obtained under the same conditions of load and surface smoothness at higher velocities.

CONCLUSIONS

1 For clean contact surfaces the coefficient of slidng friction greatly increases with decreasing velocity.

2 Two distinct types of sliding friction are recorded by the dynamometer at the various velocities. At velocities less than the critical velocity stick-slip friction is present and at sliding velocities greater than the critical velocity, a uniform friction record is obtained.

3 Three velocity ranges were obtained in which the coefficient of friction is decidedly influenced by the normal load. In the slowest and fastest velocity range the coefficient of friction decreases with increasing load. In the intermediate range of velocity the opposite occurs.

4 The sliding velocity - stick-slip frequency curves indicate that the nature of sliding friction is influenced by the mechanical properties of the apparatus.

5 The point of intersection of the various velocity-frequency curves occurs at a certain critical velocity, beyond which stick-slip is no longer recorded. The frequency at this point is approximately equal to the natural frequency of the dynamometer and the normal load arm.

6 The stick-slip frequency f, can be expressed as a simple function of the normal load L, and the sliding velocity v. This relation holds for the range of the normal load investigated.

7 The validity of the laws of Amontons and Coulomb are not apparent from the results of this investigation.

8 When high pressures exist between the surfaces, great distortion occurs beneath the surface of the metals in contact. Thus friction is not merely a surface effect but is dependent on the bulk properties of the metals in contact.

9 At high pressures large particles of the softer metal are sheared off and adhere to the plastically deformed surface of the harder metal.

A Photoelectric Method of Measuring Damping in Metal Forks at Elevated Temperatures

By T. E. POCHAPSKY[1] AND W. J. MASE,[1] COLUMBUS, OHIO

Engineering measurements of internal friction in metals have been obtained from the decay characteristics of tuning forks of metals of interest. A damping program at Battelle Memorial Institute, conducted for the Office of Scientific Research and Development, called for such measurements at temperatures up to 1500 F, and it was necessary to develop suitable apparatus for obtaining accurate results at those elevated temperatures. A photoelectric method of measuring tine amplitude decay, using shutters on a vibrating fork to modulate light directed at a photocell, was developed. It proved to give very satisfactory results and had none of the mechanical difficulties in operation and uncertainties in results that were encountered at high temperatures when platinum-wire Sauereisen-cemented strain gages were used. It was necessary to reduce energy losses from the fork to its support by using a compliant coupling. This suspension worked so well that the lower limit of decrement measurements was probably determined by acoustic losses. It is believed that such losses added less than 0.00004 to the decrements of steel forks. This report includes details of construction of the equipment and reviews tests performed to establish its accuracy.

Introduction

INFORMATION on the damping capacities of metals has become important in designing high-speed machinery which utilizes the natural internal friction of metals to suppress resonant vibrations. A method of obtaining such data from the free-vibration decay characteristics of tuning forks made of metals of interest was recently described by Carl Schabtach and R. O. Fehr.[2] A similar approach was used at Battelle to obtain measurements at temperatures up to 1500 F.

Strain gages, used by Schabtach and Fehr, did not prove to be an accurate means of measuring tine vibration amplitudes at the desired elevated temperatures. Experience with the ceramic-body gages showed that they failed mechanically at high temperatures and that they absorbed energy from vibrating forks. Consequently, results were uncertain. This prompted an investigation of a photoelectric method of measurement which was developed and found to give almost trouble-free operation and satisfactory results. In addition, it was necessary to take steps to reduce energy losses to the fork support, so extending the useful range of measurements. The following sections describe the photoelectric equipment, methods of reducing extraneous losses, and tests carried out to establish the accuracy of the apparatus. Comments on experience with the strain-gage method are also included.

Photoelectric Method of Measuring Damping in Tuning Forks

After a tuning fork is excited, it continues to vibrate until the energy of excitation is dissipated, partly as heat in the fork and partly as sound in the air and the fork support. If external losses are sufficiently small, the logarithmic decrement of the amplitude of tine vibration can be used as a measure of the internal dissipation or damping of the fork metal.

The percentage of strain energy lost during a cycle generally varies with the stress and is not constant throughout the fork. The decrement obtained from the tine displacement, however, is a reliable value of the average which would be obtained in the usual types of bending. Following Schabtach and Fehr, decrements in the present work were determined at various nominal peak bending stresses at the base of a tine during vibration decay.

Records of fork amplitude decay were obtained with the electro-optical system illustrated in Figs. 1 and 2. To obtain a measurement, shutters were fastened rigidly to each tine, as illustrated, and the fork was supported so that the shutters interrupted a beam of light on its way to a photocell. The shutter separation varied directly with the tine amplitude and vibration of the tines caused a corresponding modulation of the light flux. This variation at the cell generated an alternating voltage which was amplified and passed through a recording galvanometer. From the photographic record it was possible to determine both the frequency and the logarithmic decrement of the amplitude of the fork at any stress maximum during decay. A typical record is shown in Fig. 3.

A diagram of the associated electrical equipment is shown in Fig. 4. The amplifier circuit was conventional and any good commercial unit could be modified for the purpose. Microphonics and hum were reduced sufficiently by using inverse feedback, careful filtering, and shockproof mountings.

Fidelity of Measuring System

The following tests were made to guarantee the proportionality between record and fork amplitudes:

1 The uniformity of illumination in the shutter plane was checked by passing 1000-cycle modulated light through a small opening in a screen in that plane, and noting that there was no variation in the signal when the opening was moved about the plane. Further confirmation was obtained when no signal resulted from vibrating a slit screen in the shutter plane.

2 The photocell was checked by determining that its output was proportional to the light flux directed at it. One especially

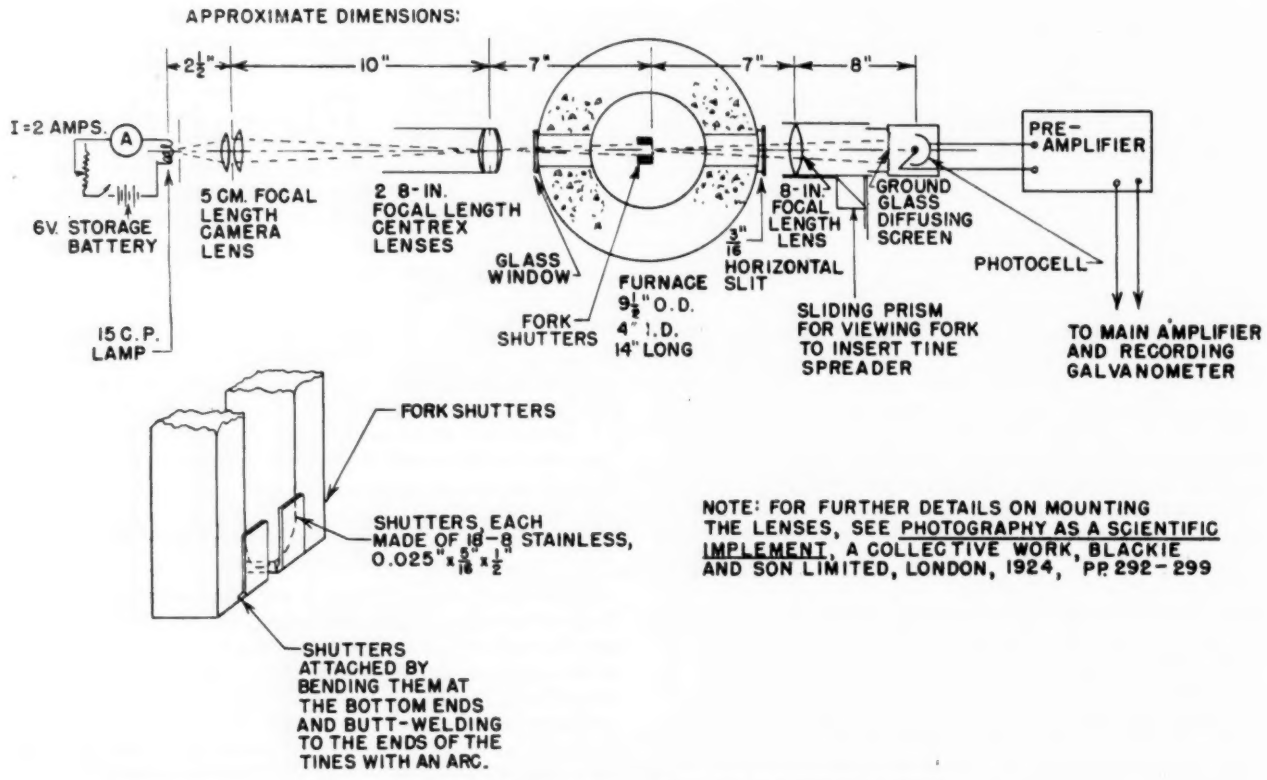

FIG. 1 DIAGRAM OF OPTICAL SYSTEM USED FOR MEASURING DAMPING

revealing test was run in which the cell was exposed to light from an unobstructed filament, 60-cycle a c heated, as well as to the steady light passing between the shutters of an excited fork.

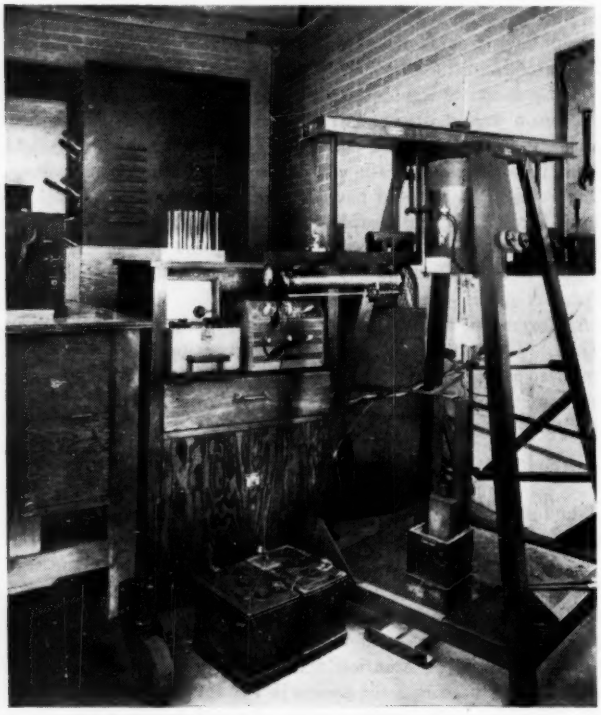

FIG. 2 EQUIPMENT USED TO MEASURE DAMPING

Analysis of the amplified and recorded output showed that the gain of the system remained constant and that electrical transients following excitation were dissipated within a few hundredths of a second. Cross-modulation was of the order of 1 per cent.

3 The over-all linearity of the system was confirmed by measuring initial record amplitudes and finding them to be proportional to the corresponding initial time displacements. Damping measurements with the system also agreed with similar measurements on the same fork obtained with SR-4 paper strain gages at low temperatures.

ENERGY LOSSES FROM VIBRATING FORKS TO THE EXTERIOR

To make certain that most of the fork vibratory energy was dissipated in internal friction, measurements were made to determine whether any significant losses took place through the support or at the shutters.

Losses to the Support. Energy flow through the support was apparent in tests on a normally machined low-damping fork when a decrement of 0.00055 was obtained with a rigid connection to the support bar, while a value of 0.00033 was obtained with a cushioned connection. Further investigation showed that the drainage of energy through the rigid support was serious when the tines were unbalanced, as shown in Fig. 5. A compliant coupling between the fork and the support bar practically prevented such losses, so that reliable results, Fig. 5, could be obtained even for a badly unbalanced low-damping fork.

The construction of the coupling was such that it kept the fork positioned in the light field even after a spreader was jerked abruptly from between the tines. The design is illustrated in Fig. 6. As can be seen, the fork was suspended from two crossed horizontal springs fastened to a ring which, in turn, was suspended by four vertical wires. This bird-cage-type construction minimized mass motion of the fork, but at the same time did not

FIG. 3 TYPICAL RECORD OF AMPLITUDE DECAY FOR A FORK EXCITED AT 1500 F
(Timing lines occur every 0.01 sec.)

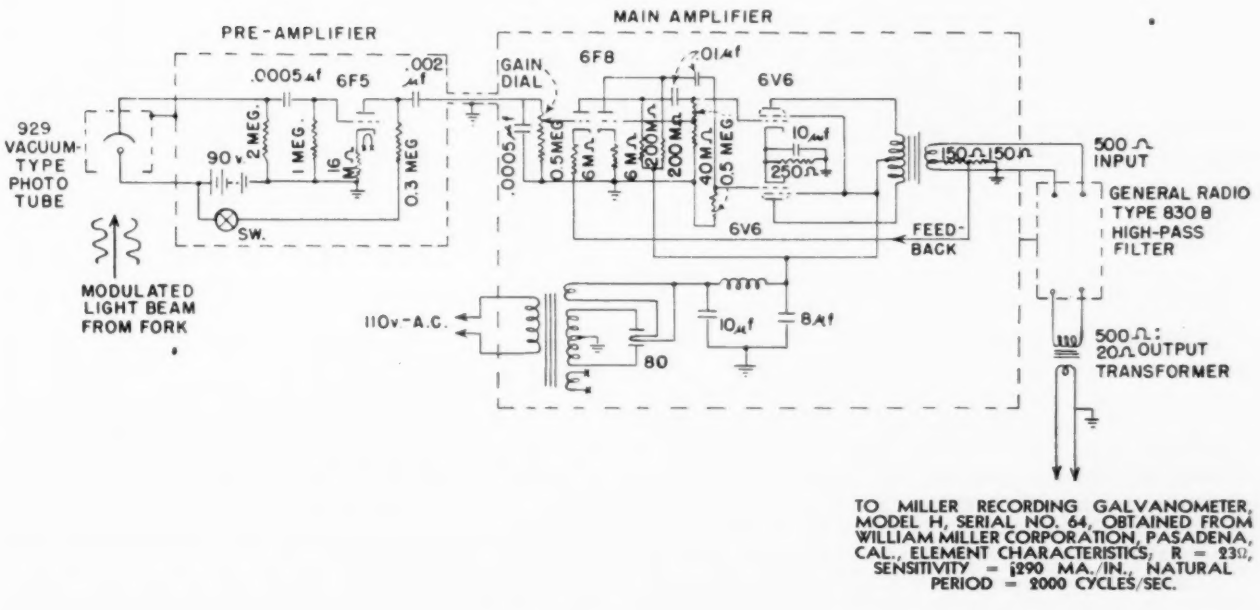

FIG. 4 AMPLIFIER CIRCUITS USED TO RECORD FORK VIBRATION

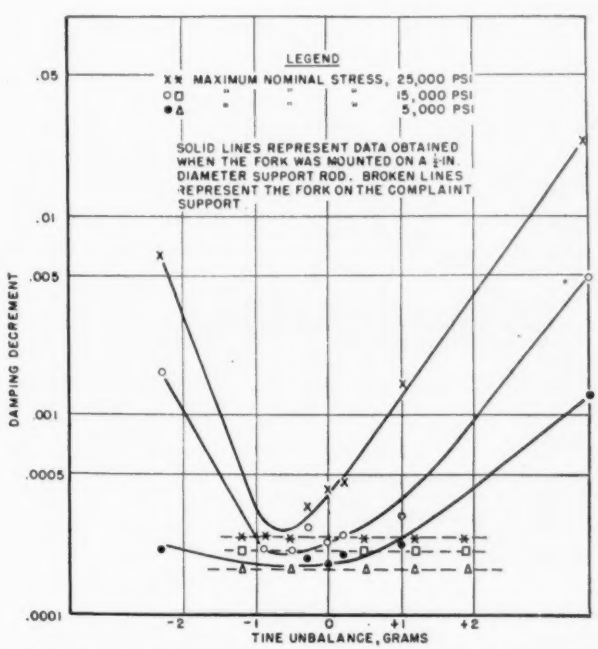

FIG. 5 EFFECT OF TINE UNBALANCE ON DAMPING OF A FORK AT ROOM TEMPERATURE

offer much loading to high-frequency vibratory motion at the base of the fork. A washer supported by four solid posts, so as to form a table just under the springs, prevented damage to the delicate springs when the spreader was jerked out.

The coupling was made of a low-damping high-temperature alloy and measurements showed that it reduced losses as effectively at a temperature of 1200 F as it did at room temperature. It was strong enough to take the punishment of repeated tests at 1500 F. Significant dimensions are noted in the illustration.

Shutter Losses. The stainless-steel shutters on the forks received a slight amount of vibratory strain energy when they followed the motion of the tines. Dissipation, however, was negligible, and shutter weights could be increased from ½ g up to 3.3 g without definitely influencing results at 1200 F. The decrement of the test fork was 0.00035 at that temperature.

Energy Radiated as Sound. No measurements were made of acoustic-energy losses inasmuch as they were considered small enough to ignore in the test program for which the equipment was built. Rough computation suggested that decrements determined for steel forks had an addition of the order of 10^{-5} because of air loading. A decrement of 0.0002 was obtained for a Dowmetal fork, indicating that air loading added less than 0.00004 to decrements for steel. Lacking definite data, it is suggested that the latter figure be used as the error of measurement in the low-decrement range. This is sufficiently accurate for most

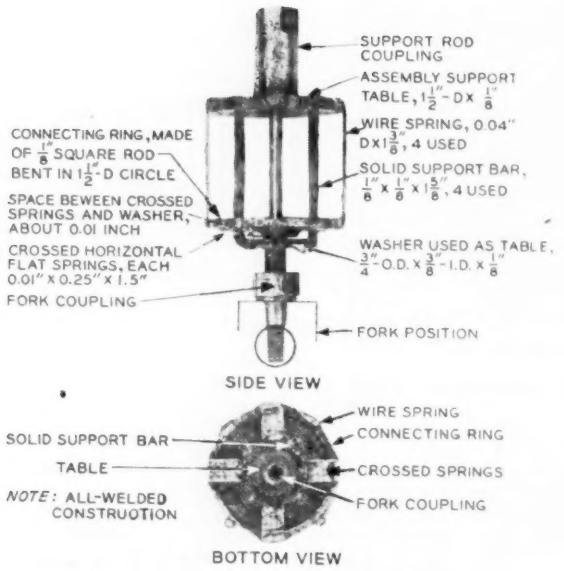

FIG. 6 ILLUSTRATION OF COMPLIANT SUPPORT

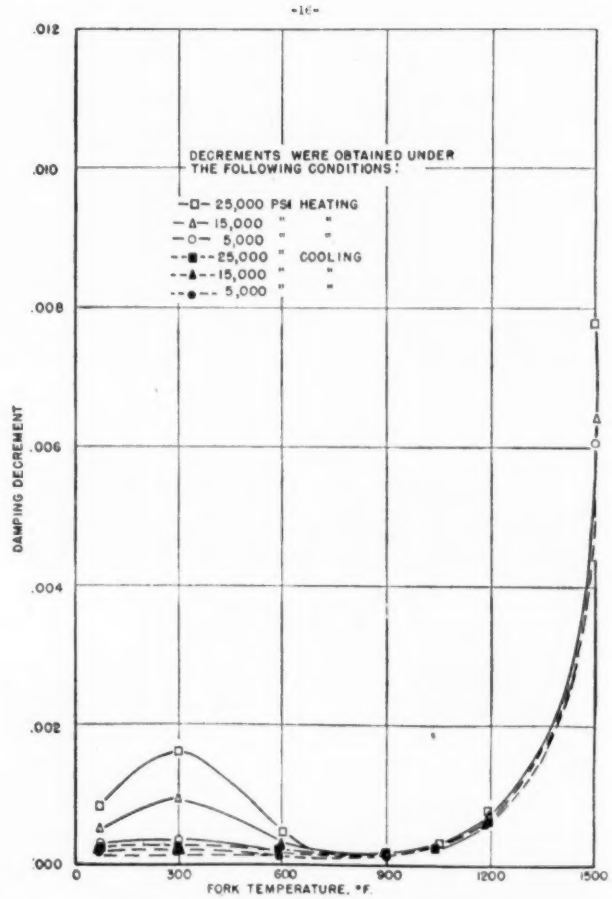
engineering work; a fork with a decrement of 0.0001 can normally be heard for over a minute after striking.

COMMENTS ON PHOTOELECTRIC AND STRAIN-GAGE MEASUREMENTS

Operation of the apparatus was practically trouble-free, especially when compared to the trials of earlier measurements with strain gages. Details of these gages are shown in Fig. 7. Most of the difficulties with gages resulted because it was necessary to use platinum-wire elements to withstand corrosion by the ceramic gage body at the higher temperatures and such elements were relatively insensitive to strain. Consequently, weak and noisy signals were obtained. Tests were frequently interrupted because of element failure at the time of excitation during the measurements at the 900 F test temperature. At higher temperatures the ceramic tended to blister from the fork. These factors led to an uncertainty in results which could not always be checked because the properties of the metals changed markedly with the history of the forks. It was also found that a ceramic gage, advanced 1/4 in. up the base of a tine, absorbed enough energy to add about 0.0002 to the decrements of steel forks near room temperature.



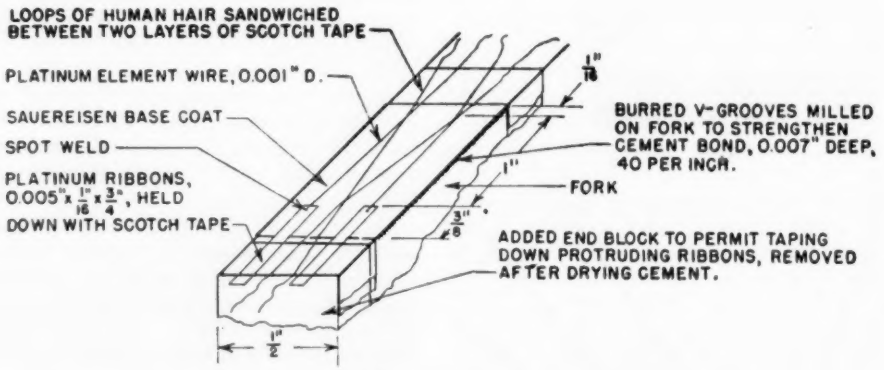


FIG. 8 TYPICAL DAMPING RESULTS FOR A HEAT-RESISTING ALLOY

Failure of the gages in this work was a consequence of steps

NOTE: THE SCOTCH TAPE WAS REMOVED AFTER COATING THE ASSEMBLY WITH A THIN LAYER OF SAUEREISEN CEMENT AND BAKING AT 400° F. THIS CONSTRUCTION WAS PATTERNED AFTER THAT USED BY SCHABTACH AND FEHR, EXCEPT THAT A PLATINUM WIRE, RATHER THAN NICHROME, GAGE ELEMENT WAS USED. NICHROME WIRE COULD NOT WITHSTAND CHEMICAL ATTACK BY THE CEMENT AT HIGH TEMPERATURES.

FIG. 7 CONSTRUCTION OF A HIGH-TEMPERATURE STRAIN GAGE ON SIDE OF A TUNING FORK

taken to obtain results at high temperatures. At lower temperatures, sensitive and carefully placed gages could be used successfully, and might be preferred instead of the optical arrangement because of the simpler associated equipment. On the other hand, the new procedure may have advantages in a long series of tests because it is easier to install shutters than to build gages on forks. The relatively high sensitivity of the photocell is also desirable.

Accuracy of Equipment

The over-all accuracy of measurements with the photoelectric apparatus could not be established definitely for lack of forks to be used as standards. Based on the favorable characteristics of the equipment, in most cases a ± 10 per cent accuracy should include the slight errors caused by distortion in the circuits, as well as by inaccuracies in measuring the slopes of traces. Repeat tests on stable forks gave results which were consistent within less than these limitations. A fixed decrement error of less than $+0.00004$ for steel would include acoustic losses. Techniques of measurement could probably be elaborated to give a much better certified accuracy, but damping was found to be so dependent on fork history that the present accuracy was more than sufficient for the measurements of interest. This accuracy should hold at temperatures up to at least 1500 F. Measurements could probably be made at substantially higher temperatures with small loss in precision.

Some of the vibration records showed a spurious low-frequency transient modulation 5 to 10 per cent in magnitude following excitation. The source of this was not satisfactorily determined although rotation of the compliantly suspended fork may have contributed in producing it. There is also a possibility that it was caused, at least in part, by energy interchanges in the fork, inasmuch as similar modulation was found on some of the records obtained with strain gages. Most of the effect of these transients was averaged out by using a graphical method of analyzing records, but they would probably cause important errors at very high decrements, say, above 0.1.

The present equipment has been used in measurements on a series of alloys. Typical results are shown in Fig. 8.

Acknowledgment

The authors are indebted to the Office of Scientific Research and Development for permission to publish these results.

The authors also wish to thank Carl Schabtach and R. O. Fehr of the General Electric Company, for volunteering information on their strain-gage method of measuring damping with tuning forks, prior to publishing the results of their work.

Discussion

A New Device for the Solution of Transient-Vibration Problems by the Method of Electrical-Mechanical Analogy[1]

E. N. KEMLER[2] AND C. R. FREBERG.[3] The method of using analogies which the authors outline has, as they point out, been well known for some time. Many of the earlier articles have been concerned with use of the analogue as a qualitative tool rather than as a quantitative one. Actually the methods which have been proposed along these lines permit the design of electrical models of mechanical, acoustical, or fluid systems. Several references are available which show other applications than those mentioned by the authors of the paper. These give a more detailed approach to the general problems than is given in the paper (1, 2, 3, 4, 5, 6).[4]

The significance of the mass-inductance and mass-capacitance circuits can best be illustrated by the fundamental difference between many common electrical and mechanical systems. The ordinary electrical system has a known signal or voltage applied to it. In the normal or mass-inductance analogue, this corresponds to putting a known force on the mechanical. Many mechanical systems, however, have a known motion rather than a known force applied to them. This would correspond to impressing a known velocity on the electrical analogue. Since voltage generators are more common than current generators, it is desirable to be able to have an analogue on which the equivalent of the velocity could be readily imposed. The mass-capacitance circuit is such a one. This is also known as the inverted system because some measurements have no immediate meaning in the mechanical system. Measurements that are desired may therefore become extremely difficult. The type of analogue to be used will therefore depend on the type of problem to be solved, as well as on the information desired.

In the solution of transient problems, a time scale is often needed. One means of introducing a time scale is to use an oscillograph with a Z-axis gain. An oscillator connected to this terminal can be used for putting timing marks on the diagram (2).

The simplest type of problem to which the electrical model can be put is that of finding the natural frequencies in multimass systems (1, 4). Here an oscillator can be applied to the system, and its response over a wide range of frequencies can be determined. The determination of such frequencies is usually not too critically influenced by the amount of damping if high-quality inductances are used. When amplitudes, velocities, or accelerations are to be measured, however, the effect of damping becomes critical. The problem usually is one of determining the amount of equivalent velocity damping in the mechanical system.

The terms connecting the mechanical and electrical systems can be obtained by reducing the differential equations to dimensionless form, dimensional analysis, or by the procedure developed in the paper (1, 4, 5). Once these relations have been worked out, the setting up of the equivalent electric circuit is simple. This general method of solving multimass problems certainly deserves more use than it has been given.

The Theory of Ejectors[1]

G. M. DUSINBERRE.[2] The writer has been accustomed to think of the air ejector, in steam-condenser service, as having approximately a constant volume characteristic, that is, it behaves like a reciprocating compressor at constant speed and volumetric efficiency. It tends to handle at a constant volume rate whatever mixture of steam and air may enter its suction, whatever the partial and total pressures may be, within the normal operating range. Will the author comment on how this empirical relation checks with his theory?

The "efficiency" or criterion of performance proposed by the author is novel, simple, and has obvious merit in setting a standard for this type of apparatus. It deserves further study and one hopes that the author will continue his experimental and analytical work in this direction.

It may be pointed out that this criterion offers a direct basis of comparison only as between ejectors and not with other systems of compression. This is not objectionable from a practical viewpoint because the ejector wins a place on the basis of first cost, compactness, and maintenance rather than on economy of actuating fluid. However, it is of theoretical interest to compare the author's standard with that of an engine-compressor system in which the actuating fluid expands to the discharge pressure in a reversible adiabatic engine, and the induced fluid is handled in a reversible adiabatic compressor driven by the engine.

For simplicity, assume both fluids the same pure substance so the conventional h-s diagram may be used, Fig. 1 of this discussion. Let A represent the state of the actuating fluid, B the state of the induced fluid, and solid line CD the discharge pressure. Then E will represent the result of reversible mixing as outlined in the author's Appendix 1. The flow ratio will be AE/EB.

[1] By H. G. Elrod, Jr., published in the September, 1945, issue of the JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 67, p. A-170.

[2] Assistant Professor of Mechanical Engineering, Virginia Polytechnic Institute, Blacksburg, Va. Now on duty at U. S. Naval Academy, Annapolis, Md. Mem. A.S.M.E.

For the engine-compressor system, AC will be the engine work and BD the compressor work, per pound. In this system the flow ratio will have to be inversely as the work per pound, or as AC/BD.

Now if we deal with a part of the wet-vapor region where the discharge-pressure line is straight at all points involved, the broken line FED represents this situation. The engine work is

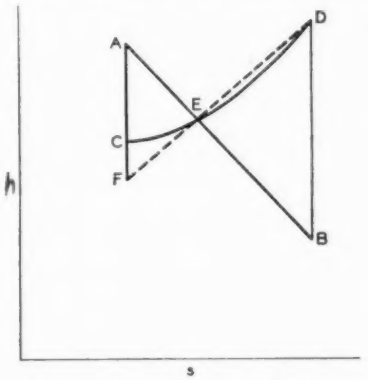

FIG. 1 CONVENTIONAL h-s DIAGRAM

now AF, per pound, and the flow ratio is AF/BD. Inspection shows that this is equal to the ratio AE/EB for the reversible mixing system and greater than the ratio AC/BD for the more general case of the engine-compressor system.

This is to say that the author's criterion sets a higher standard than is attainable in general by an engine-compressor system operating adiabatically.

R. B. ENGDAHL.[3] This paper presents for the first time for dissimilar fluids a comparison between theoretically and experimentally determined performance curves of ejectors. The agreement is good and indicates that the analysis with its assumptions can be used with confidence to explore areas uncharted either analytically or experimentally.

One such area is entered when the boiler operator applies steam-actuated secondary-air jets to a furnace operating under a strong induced draft. The performance of the jets under this condition has never been measured. In Fig. 7 of the paper all points above the curve $P_{30} = 1.0$ are in this region. The theoretical curves show that for an area ratio of 13.5 and for low actuating pressure ratios, the entrainment is increased by the reduced outlet pressure so long as the outlet velocity is below the velocity of sound. This was to be expected, but the author's equations now permit calculation of the amount of this increase for the area ratios commonly used for overfire jets.

The conclusion that neglect of wall friction has little effect on the calculated performance bears out the experimental finding that considerable additional length of mixing tube beyond the optimum 7.5 diam reduces the performance only very little. That wall friction is such a minor item emphasizes the well-known profligacy of jets as consumers of energy. Many well-conceived ideas for jet-actuated thermal equipment will remain economically unfeasible until the mechanical efficiency of the jet can be improved. The author has contributed distinctly toward an understanding of jet action which may bring about that improvement.

R. E. HANSEN.[4] The author's proof (Appendix 1 of the paper) that a reversible mixing apparatus gives the best possible flow ratio is predicated on the conditions

$$p_i > p_3 > p_a \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The conditions necessary for the operation of a reversible ejector are

$$p_i > p_a \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

$$p_3 > p_a \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

$$(h_i - h_a) > (h_2 - h_b) \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

where h_a is enthalpy of the actuating fluid after adiabatic expansion to pressure p_a, and h_b that of the final mixture if expanded adiabatically to pressure p_a. Condition [3] is not strictly necessary to operation of an ejector, but it is necessary to justification of one, because if it does not hold, the induced fluid will proceed to pressure p_3 unaided. For an actual irreversible ejector condition [4] would become

$$e_1(h_i - h_a) > \frac{1}{e_2}(h_3' - h_b') \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

where e_1 is efficiency of the actuating nozzle and e_2 that of the diffuser. Conditions [2], [3], [4], and [5] do not exclude the boiler injector operated by exhaust steam at low pressure ($p_3 > p_i$) as does condition [1].

Condition [4] follows from the kinetic-energy equation of the ejector

$$w_i(h_i - h_a) = (w_i + w_a)(h_3 - h_b) \quad \ldots\ldots\ldots\ldots\ldots\ldots [4a]$$

For the case of interest, $(w_i + w_a) > w_i$; moreover, $(h_i - h_a)$ and $(h_3 - h_b)$ must always be positive. Condition [4] follows therefore from [4a]. It may be possible to state the conditions of operation without direct reference to conditions [2] and [4], but it is believed that these conditions will be implicit in any such statement.

Analysis presented in Appendix 1 of the paper cannot be extended to cover the case where $p_3 > p_i$, because if W and Q become negative, that is, if work is converted into heat instead of vice versa, there is no exception to the second law.

J. H. KEENAN.[5] This paper will bear careful scrutiny by those interested in ejectors. It is based on the well-established one-dimensional analysis which has proved so effective in predicting the performance of ejectors of large area ratio with small pressure ratio. The significance of the restrictions employed here and of the differentiation for maximum flow ratio is not immediately evident. Unfortunately, the accord with experiment is not expressly indicated.

The second-law analysis for limiting flow ratios is apparently new. The efficiency defined in terms of this analysis is more rational than any previously proposed. To be serviceable, however, an efficiency must be so defined that it does not vary too widely with ordinary variations in the conditions for which ejectors are designed. The present paper offers no information on this point.

AUTHOR'S CLOSURE

The author acknowledges with appreciation the interesting contributions of the discussers.

The empirical relation suggested by Commander Dusinberre might be restated as follows:

"If the temperature and pressure of the actuating fluid, the temperature of the induced fluid, and the exhaust pressure are

[3] Research Engineer, Battelle Memorial Institute, Columbus, Ohio. Jun. A.S.M.E.

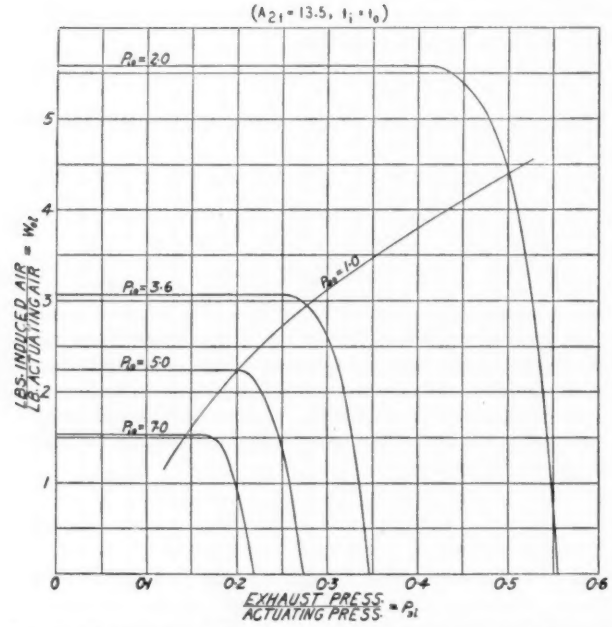

FIG. 2 THEORETICAL PERFORMANCE OF COMPLETE AIR EJECTOR

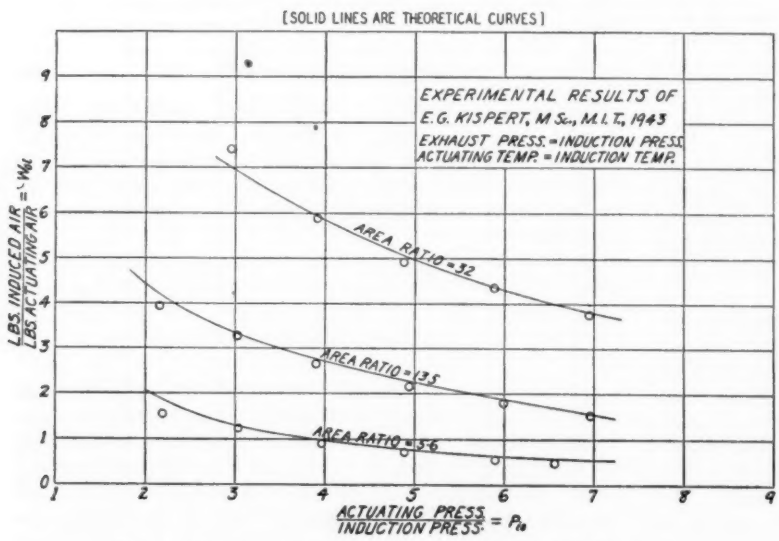

FIG. 3 PERFORMANCE CURVES OF COMPLETE AIR EJECTOR

specified, V' the induced volume flow rate (cu ft per sec) will remain constant."

This statement is interpreted to apply only to high-vacuum ejectors. At a high vacuum and at a fixed temperature all vapors behave as perfect gases. Hence we write

$$w_0 = \left(\frac{V'}{RT_0}\right) p_0$$

According to this equation, the induced flow does not cease until the induction pressure reaches zero. However, it is a consequence of Equations [4] to [9], inclusive, of the paper, that the induced flow ceases at a finite pressure. This pressure corresponds to a blocked-off suction, when the ejector is, in reality, a sudden enlargement. Therefore the rule suggested by Commander Dusinberre is inconsistent with the ejector theory, although this inconsistency may not invalidate the rule as a useful approximation over the normal operating range of high-vacuum ejectors.

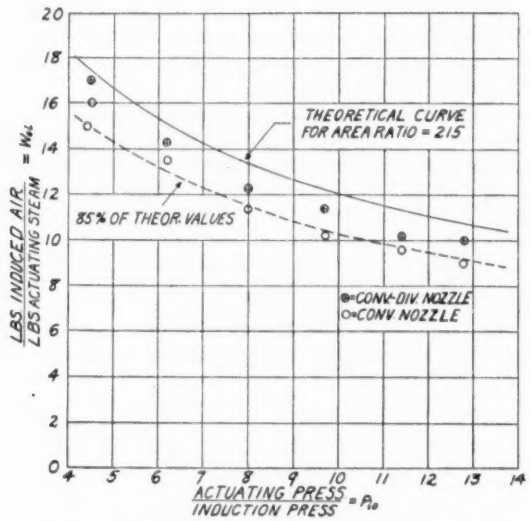

FIG. 4 PERFORMANCE OF SIMPLE STEAM-AIR EJECTOR
(This illustration appears as Fig. 10, in reference 5 of the paper.)

Commander Dusinberre has provided an apt and interesting comparison between the ejector efficiency proposed by the author and that commonly used. The author's criterion sets a higher standard because it allows for utilization of the difference in temperature between the actuating and induced fluids. Although the effect of this temperature difference upon actual ejector performance is rather uncertain, it is logical and necessary that an allowance be made for it. For example, using the engine-compressor standard, we should find the efficiency of a boiler-water injector to be infinite.

For the special case where the isobar FD (Commander Dusinberre's Fig. 1), lies in the wet-vapor region, the temperature difference does not exist, and the two efficiencies are identical.

Mr. Engdahl's discussion pertains to an unabridged, unpublished paper on ejectors. The illustrations to which he refers are included in this closure as Figs. 2, 3, and 4. Their terminology is the same as that of the present paper, except that capital letters are used to denote ratios. In the computation of the theoretical curves the following assumptions were made: Actuating-nozzle exit in mixing-tube throat, nozzle efficiencies 100 per cent, diffuser efficiency for complete ejector, 75 per cent. The refinements mentioned in the sixth section of the paper were employed, although the friction and velocity-distribution allowances affected the results but slightly.

If (1) the inlet conditions and outlet pressure of the working fluids are prescribed, and if (2) $p_i > p_3 > p_0$, Appendix 1 of the paper proves that a reversible ejector yields the maximum, or limiting, flow ratio. Since certain types of ejectors, such as the boiler-water injector, can operate in exception to the second condition (that is, with $p_3 > p_i$), Appendix 1 does not, in such instances, guarantee the reversible flow ratio as a proper standard for comparison. Mr. Hansen writes with this thought in mind.

The general condition necessary to the operation of a reversible

ejector is that there exist a state on the exhaust isobar, p_3, such that

$$w_i h_i + w_o h_0 = (w_i + w_o) h_3$$

$$w_i s_i + w_o s_0 = (w_i + w_o) s_3$$

where, by convention, w_i and w_o are understood to be positive. The additional condition, $p_i > p_3 > p_o$, is sufficient, but unnecessary, to insure the more general condition given.

Mr. Hansen's Equation [2] is not a condition, but a definition of p_i and p_o. His Equation [3] follows from the general condition just mentioned. Equation [4] follows from Equation [4*a*], but Equation [4*a*] does not follow from the conservation of energy, and the author does not believe it can be substantiated. But despite these limitations, the conditions postulated by Mr. Hansen are fulfilled in many practical situations.

The graphical proof for the limiting flow ratio as given in the second section of the paper is valid for the case of the boiler-water injector. This proof depends only upon the following general properties of a Mollier chart:

1 Isobars have finite, positive slope

$$\left(\frac{dh}{ds}\right)_p = T$$

2 Their slope either increases or remains constant

$$\left(\frac{d^2h}{ds^2}\right)_p = \left(\frac{dT}{ds}\right)_p = \frac{T}{C_p} \geq 0 \text{ because } C_p \geq 0$$

3 A given isobar lies continuously above all isobars of lower pressure

$$\left(\frac{dh}{dp}\right)_s = v$$

No proof has yet been given for the case of dissimilar fluids when $p_3 > p_i$.

Professor Keenan correctly states that Flugel's one-dimensional analysis has proved effective in predicting ejector performance. However, a paper by Professor Keenan and E. P. Neumann[6] constituted the only comparison with experiment published in the English literature at the time of preparation of the present paper. This comparison was for ejectors without diffusers. Personally, the author did not consider the theory as "well established" until he made many numerical comparisons with published data. Figs. 3 and 4 of this closure are two such comparisons.

The significance of the differentiation for maximum flow ratio is that it provides an expression for the optimum area ratio explicitly in terms of the specified operating conditions. Optimum area ratios for many different vapors and conditions can be speedily obtained. The accord with experiment can be judged by comparison with Fig. 5 of this closure. This figure shows the purely experimental results of A. D. Third.[7] For the example illustrated in his figure, the method of "A Design Problem" in the paper yields

$$\frac{\text{Diffuser diam}}{\text{Nozzle diam}} = 2.68$$

$$\text{Air suction (per } {}^1/_{10} \text{ sq in. nozzle area)} = 0.0674$$

$$\text{Efficiency} = 17.1 \text{ per cent}$$

In the author's opinion, an efficiency, to be serviceable, must be so defined that it provides a desired answer, whether or not it simultaneously becomes a good "G" factor. Ejector efficiencies, as computed from the definition of the present paper, vary

[6] Refer to Bibliography (2) of the paper.

[7] Refer to Bibliography (4) of the paper.

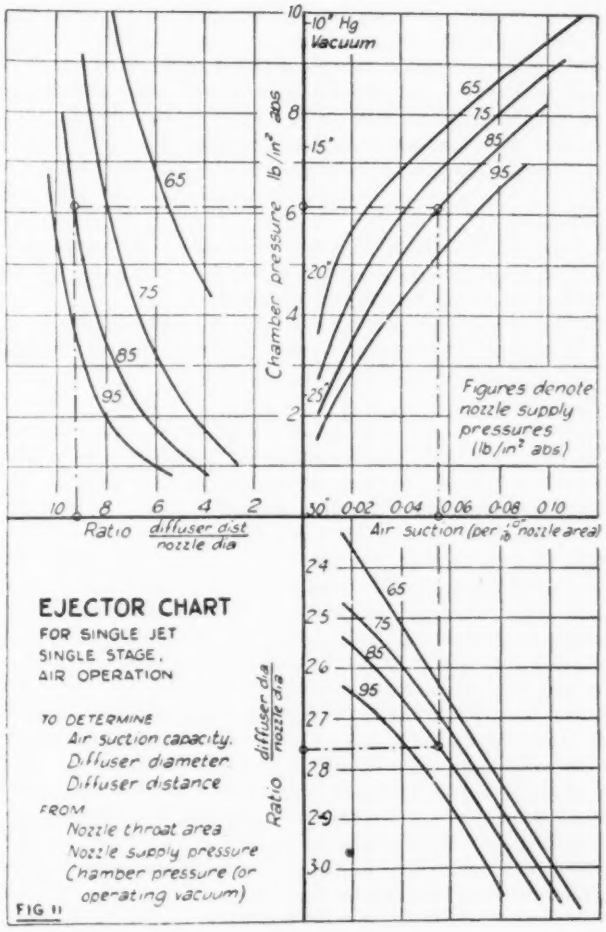

FIG. 5

widely with operating conditions. This variation is significant, since it emphasizes the inflexibility of the average ejector.

Since publication of the paper the author has proved that Table 1 is exact for any substance of which the enthalpy may be expressed by

$$h = A + Bpv$$

between states (2) and (3). Thus the validity of Table 1 is greatly extended.

Fatigue Strength of $5^1/_4$-In-Diam Shafts as Related to Design of Large Parts[1]

R. E. PETERSON.[2] The results of the most recent Timken tests are of considerable interest. Referring to footnote 7 of the paper, the values of k_t' turn out to be 1.36 for the $^{27}/_{32}$-in-radius fillet and 1.86 for the $^9/_{32}$-in-radius fillet. The corresponding q values are 0.50 and 0.72, respectively.

The statement is made that an endurance limit of 36,000 psi was obtained, and it is estimated that a similar plain polished

[1] "Fatigue Strength of $5^1/_4$-In-Diam Shafts as Related to Design of Large Parts," by O. J. Horger, T. V. Buckwalter, and H. R. Neifert, published in the September, 1945, issue of the JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 67, p. A-149.

[2] Manager, Mechanics Department, Westinghouse Research Laboratories, East Pittsburgh, Pa. Mem. A.S.M.E.

specimen of about 5 in. diam would give 30,000 psi. In calculating q values where low factors are used, much depends upon the basic endurance-limit value used. If a value of 34,500 psi is used for the q calculations, it is interesting to note that full sensitivity is obtained for both cases. From a research standpoint, tests of 5-in-diam polished specimens without stress concentration would represent a valuable contribution, and it is hoped that such tests will be made by Timken since no other laboratory can do so.

The results of fillet-rolling show again the large improvement obtainable in this manner. It is our understanding that this method is in considerable use in Germany.

Tests with large specimens are difficult and expensive; the Timken Laboratory deserves a great deal of credit from the engineering profession in general for its work.

E. L. Robinson.[3] This paper contributes some valuable and much-needed data on the fatigue strength of shafts with variable diameter. This is a subject about which there is much too little reliable information and great uncertainty. There are innumerable applications, all of which stand to benefit from the accumulation of the type of information given. Not only is information needed on the effect of fillet radii of different sizes but also on the size effect. Furthermore, data accumulated on one composition of alloy may not be applicable to others. Indeed there are results to show that this is the case. Thus the tests need repetition on other materials and with various finishes.

One detail of the discussion seems to require comment, and that is the wording used to describe the characteristic coefficients which represent and evaluate the results. Table 4 of the paper gives the test values for k_f, k_t, and q each of which has a separate and distinct value which should be given attention in analyzing the results. This type of analysis follows a theory of behavior which, in so far as the writer knows, was first attributed to Ernst Lehr and Richard Mailänder.[4]

The reasoning is simple: Each geometric shape has a definite characteristic stress concentration as long as the deformation is elastic, which Lehr called the "shape factor." The words "elastic stress concentration" describe this factor k_t. With simple sections, k_t may be calculated mathematically. With more complicated sections it may be found by photoelastic analysis. Sometimes it can only be guessed at and then analysis can be no better than the guess.

Only with materials which are 100 per cent "sensitive" is the strength reduced correspondingly with the increase in stress at the point of concentration. The tests give the ratio of strength of a plain shaft to a filleted shaft k_f which Lehr called the "notch factor," or "fillet factor." It is confusing when the authors speak of k_f as the "stress-concentration factor." If it were, there would be no point in computing the stress concentration k_t or the degree of sensitivity q.

The "sensitivity" is the ratio of the actual weakening of the shaft due to the fillet to the theoretical weakening, assuming failure to be due to elastic stress concentration. Some materials approach 100 per cent sensitivity, which is an undesirable characteristic. Other materials have very little sensitivity, and such materials do not suffer much due to stress concentration. This is desirable, provided the base endurance strength is not also low.

In offering these comments the writer would not like to appear unappreciative of the work done. Rather it appears to him to be so important that a plea for a little more meticulous use of terminology in presenting results seems appropriate.

A Simplified Method of Determining Hoop Stresses in Fan Rotors[1]

S. H. Christensen.[2] If we find the true mean value of tangential (hoop) stress by integrating Equation [6] of the paper, and also use this equation for the true boundary stresses f_1 and f_4, we find that the true ratio of boundary to mean stress differs from the author's approximation, Equations [5] and [7], according to the curves given in Fig. 1 herewith.

Another relation of interest is f_1/f_4, the ratio of inner to outer boundary tangential stress when given by Equation [6] of the paper. Its deviation from the ratio r_4/r_1 is shown in Fig. 2.

These second-order differences are primarily due to the effect of lateral fiber contraction as given by Poisson's ratio (our curves were based on $\sigma = 0.3$ for steel). These relations also occur, but in a more complicated form, in disks having varying thickness.

Large errors in the computed boundary stresses will occur if any of the methods reviewed in the author's paper (including Haerle's method[3]) is applied to "side-wheel-plate rotors" or disks

[1] By G. F. Lake, published in the June, 1945, issue of the Journal of Applied Mechanics, Trans. A.S.M.E., vol. 67, p. A-65.

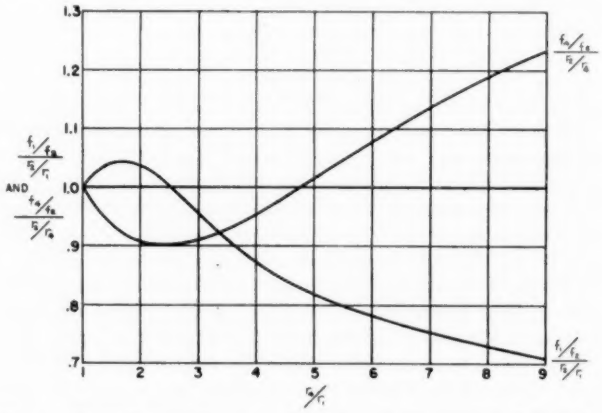

Fig. 1 True Stress Ratio of Tangential Boundary Stress to Tangential Mean Stress, From Equation [6] of Paper, Divided by Author's Approximate Stress Ratio, From Equations [5] and [7]

(For constant-thickness disk. Poisson's ratio, $\sigma = 0.3$.)

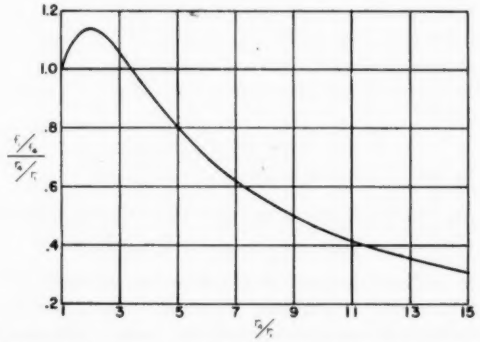

Fig. 2 True Ratio of Inner-Boundary Stress f_1 to Outer-Boundary Tangential Stress f_4, From Equation [6], Divided by Radius Ratio, r_4/r_1

(For constant-thickness disk. Poisson's ratio, $\sigma = 0.3$.)

whose meridian plane is (even slightly) inclined from the perpendicular to the axis of rotation. This is due to an additional degree of freedom being imposed upon the deflection by this inclination. At small angles of inclination (only 5 deg in some cases), the hoop-stress distribution in thin disks is already reversed, being greatest at the outer radius and least at the inner radius. The tangential stress distribution in inclined disks (conical shells) nearly follows, with radius, that of a thin ring (proportional to the radius squared).

Since the practical construction of high-efficiency side-wheel-plate rotors demands a conical or inclined section and not a surface whose meridian plane is perpendicular to the axis of rotation, as idealized in this paper, the method proposed is therefore not applicable to the computation of stresses in side-wheel-plate rotors of the type usually met with in practice.

A. M. G. Moody.[4] Although the author's method is approximate, it should give satisfactory results and be very helpful in problems where the radial extent of the rotor is small relative to the outside radius, and where the radial load to be carried is small. In presenting this method, however, the author makes a comparison which to the writer seems most unfair. In estimating the saving in time and effort made by using this method, the standard of reference is a so-called exact method. The impression one gets is that the author has read some textbook and has set out from there to produce a shorter method. In practice, one does not use the method which the author assumes to be the standard.

The field of disk and rotor stresses happens to be one of the most richly treated in all the literature of stress analysis. Not only do we have fundamental treatments by Stodola, Holzer, Grammel, Martin, and others, but we also have a wealth of short-cut methods based on the use of families of curves. These include the methods of Donath, Keller, Malkin, Martin, and others. These differ primarily in the nature of the profile chosen as standard. Among the profiles which have been treated are parallel-sided, conical, hyperbolic, and exponential. Each of these has something to recommend it and the relative merits will not be discussed here. They have been well treated in a paper by S. Tumarkin.[5]

Now the method of Donath, for instance, is quite easily applied to such a case as that treated by the author. Offhand, it would be hard to say whether or not it is quicker than the author's, although there is surely no great difference in the time and effort involved. But Donath's method is general, and enormously flexible, while the author's method is special and sharply restricted in applicability. Thus even if the new method made possible a slight saving, there would be a strong argument for using the more general one, except in the unlikely event that many rotors of this type and none of any other were to be figured.

Stanley Thompson.[6] Since radial stresses are neglected, no account can be made of the effect of abrupt changes in section. If we consider a portion of a disk for which a step occurs in the central portion of the disk (say, at a bolt circle) as shown in Fig. 3 of this discussion, the tangential strain will be the same on each side of the step for a short distance (neglecting stress concentrations). Using the author's nomenclature, we can write

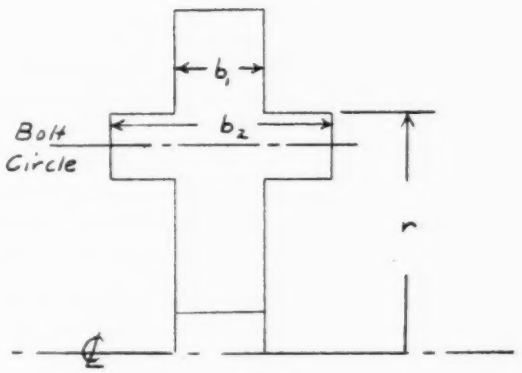

Fig. 3

$$\epsilon_t = \frac{1}{E}(f_1 - \sigma q_1) = \frac{1}{E}(f_2 - \sigma q_2)$$

From this

$$f_1 - f_2 = \sigma(q_1 - q_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

Considering the equilibrium equation

$$\frac{1}{b}\frac{d(rbq)}{dr} - f + \rho\omega^2 r^2 = 0$$

this can be rewritten

$$\frac{db}{b} + \frac{dq}{q} + \frac{dr}{r}\left(1 - \frac{f - \rho\omega^2 r^2}{q}\right) = 0$$

This can be written in difference form

$$\frac{\Delta b}{b} + \frac{\Delta q}{q} + \frac{\Delta r}{r}\left(\frac{1 - f - \rho\omega^2 r^2}{q}\right) = 0$$

Since for the step

$$\Delta r = 0, \quad \frac{\Delta b}{b} = \frac{b_1 - b_2}{b_1}, \quad \frac{\Delta q}{q} = \frac{q_1 - q_2}{q_1}$$

then

$$q_1 - q_2 = q_1\frac{(b_2 - b_1)}{b_1} \quad \ldots\ldots\ldots\ldots\ldots [2]$$

Combining Equations [1] and [2]

$$\frac{f_1 - f_2}{f_1} = \frac{\sigma q_1}{f_1}\frac{(b_2 - b_1)}{b_1} = \frac{\sigma q_1}{f_1}\left(\frac{b_2}{b_1} - 1\right) \quad \ldots\ldots [3]$$

If we assume a step for which

$$\frac{b_2}{b_1} - 1 = 1$$

$$\sigma = 0.3 \qquad \frac{q_1}{f_1} = \frac{1}{2}$$

then

$$\frac{f_1 - f_2}{f_1} = \frac{0.3}{2} = 0.15, \text{ or } 15 \text{ per cent}$$

The error in this step by the approximate method would be 15 per cent. This error would always be on the conservative side for a step outward from the disk.

Using the parallel-sided disk checked by the author, the maximum radial stress divided by the tangential stress at the same point is

[4] Blower Division, Elliott Company; formerly, Chief Research Engineer, De Laval Steam Turbine Company. Mem. A.S.M.E.

[5] "Methods of Stress Calculation in Rotating Disks," by S. Tumarkin, Report No. 262 of the Central Aero-Hydrodynamical Institute, Moscow, Russia, 1932; now issued in translation as N.A.C.A. Technical Memorandum No. 1064, Sept., 1944.

[6] Development Engineer, Westinghouse Electric Corporation, Lester, Pa.

$$\frac{q_1}{f_1} = \frac{\left(1 - \frac{1}{3}\right)}{1 + \frac{2 \times 0.7}{3.3 \times 3} + \frac{1}{9}} = \frac{4}{9(1.267)} = 0.35$$

The error for a 2-1 step here would be $(0.3 \times 0.35 = 0.105)$ $10^1/_2$ per cent. For a disk with high radial loading (blades on periphery) this error would become greater in direct proportion to the increase in radial stress. If radial and tangential stresses were equal the error would be 30 per cent for a 2-1 step.

Hence the method does not enable one readily to allow for stress concentration due to holes in the disk, etc.

In the example used by the author, the assumption that one half the blade load is carried by each rotor should be tentative. Since the structure is redundant, a close approximation to the stress picture would require revising this estimate to correlate the deformations in the two wheels. In the present case, the less heavily loaded main wheel would tend to carry part of the load assumed to be carried by the side-wheel-plate rotor.

Where it is not necessary to determine stresses too accurately (by sum and difference curves), this method seems to offer a rapid means of finding the approximate stress picture. Formulas [4] and [5] of the paper show at a glance the advantage of keeping the mass of the disk concentrated as near the center as possible (assuming density of blades and rotor have the same radial distribution), but it is important to realize that the stress distriubtion can be changed without changing the position of r_2.

Author's Closure

The curves in Figs. 1 and 2 prepared by Mr. Christensen, are useful in showing the limiting ratio of boundary radii of fan rotors to which the simplified method could be applied. As the author suggested, these curves show that the approximation involved becomes too coarse beyond an $\frac{r_4}{r_1}$ ratio of about 3.

With regard to the effect of the inclination of rotating-disk sections, the author agrees that it would be necessary to take account of this in the case of single disks. However, in the case of side-wheel-plate rotors, the author is of the opinion that the freedom allowed by the inclination is largely prevented by the restraint imposed as a result of attachment through the blades to the main rotor.

The author would like to refute Mr. Moody's charge of unfairness in presenting the simplified method, as he has no wish to detract from the work of recognized authorities in the field of disk and rotor stresses. The exact methods were chosen as a basis of reference in order to make the comparison as concise as possible. The short-cut methods of the authorities cited do not appear to be so well known in England as in America. It seems to the author that graphical methods such as Donath's can only be used with ease after acquiring a certain degree of familiarity with them, which can only be gained by fairly frequent practice. Where this is so the author has no doubt that results can be quickly obtained and readily applied to design problems. The author has, however, approached the problem from the point of view of the fan user rather than that of the fan designer. He is consulted occasionally on the effect on fans in service of such factors as corrosion, increase in speed, and increase in operating temperature, and has felt the need for a method of assessing quickly the stresses involved.

The author is indebted to Mr. Thompson for his method of analysis whereby the error at a step can be deduced but is inclined to think that a value of $^1/_2$ for $\frac{q_1}{f_1}$ will in most cases overestimate the radial stress. He is not clear how the value of $\frac{q_1}{f_1} = 0.35$ is derived for the example chosen in the paper. The value deduced by the author is as follows

$$\text{Mean hoop stress in hub (radius 9 in.)} = f_m \times \frac{r_2}{9} = \frac{18.6 \times 10.2}{9} = 21.1 \text{ tons per sq in.}$$

The hoop stress in the hub, considered as a ring detached from the side wheel plate, would be

$$31.1 \times \left(\frac{9}{15}\right)^2 = 11.2 \text{ tons per sq in.}$$

The radial stress at the step must be sufficient to account for the difference of 9.9 tons per sq in. between these two values. This is obtained as

$$9.9 \times \frac{\text{Cross-sectional area of hub}}{\text{Radius to step} \times \text{width of disk at step}} = \frac{9.9 \times 1.92}{9.5 \times 1.125}$$

$$= 1.78 \text{ tons per sq in.}$$

The hoop stress at the step (radius 9.5 in.) = 20 tons per sq in. so that

$$\frac{q_1}{f_1} = \frac{1.78}{20} = 0.089 \text{ only}$$

With regard to the blade loading, it is agreed that the less heavily loaded main wheel would tend to carry a greater share of this loading than the side-wheel-plate rotor, but the author is of the opinion that the departure from equal sharing of the loading would not be great, because it is thought that the action of the blades in resisting the centrifugal loading would approach more nearly to that of beams than cantilevers fixed to the main wheel.

Parallel Columns With Common Lateral Supports[1]

K. R. Jackman[2] and C. Conaway.[3] Since the theory developed in this paper conforms with what theoricians might call "exact methods" in elastic-stability theory, it may be expected that it furnishes an accurate description of the behavior of the idealized structure which the author has investigated. However, the semimonocoque structures which have suggested the problem may differ in their behavior from the hypothetical structure. In fact, three reasons for conservatism of the theory in design applications are apparent:

1 A semimonocoque beam such as an airplane wing may sometimes be loaded considerably in excess of the point where buckling of the compression panels occurs before total failure results. The theory is designed to give only the buckling stress.

2 Bulkheads in a semimonocoque beam are often supported by the tension surface. The theory does not take account of such support.

3 Restraints that arise from membrane action of the skin are significant in a cambered wing. The author has not considered these restraints in the present theory.

The writers' company has recently performed several tests which serve to indicate how important these factors may be. These will be discussed as follows:

[1] By H. L. Langhaar, published in the Dec., 1945, issue of the Journal of Applied Mechanics, Trans. A.S.M.E., vol. 67, p. A-253.

[2] Chief Test Engineer, Engineering Test Laboratories, Consolidated Vultee Aircraft Corporation, San Diego, Calif.

[3] Research Engineer, Engineering Test Laboratories, Consolidated Vultee Aircraft Corporation, San Diego, Calif.

Beam No. 18. This was a flat-topped box beam with four simple-beam-type bulkheads with simply supported ends. It is therefore the type of beam for which the theory should determine the buckling load quite accurately. The following constants are given:

I = 0.028 in.[4] bulkhead
L = 8 in., w = 29 in., r = 0.0895 in.
t_e = average thickness of plate-stringer combination = 0.168 in.

By Equation [7] of the paper, the bulkhead spring coefficient is

$$C = \frac{\pi^4 EI \text{ (bulkhead)}}{w^4} = \frac{\pi^4 \times 10.5 \times 10^6 \times 0.028}{29^4} = 40.3 \text{ psi}$$

Hence

$$\frac{CL^3}{EI} = \frac{CL^3}{Et_e} = \frac{40.3 \times 8^3}{10.5 \times 10^6 \times 0.168 \times 0.0895^2} = 1.46$$

The theory of Shou-Ngo Tu[4] then yields

$$S_{cr} = 3500 \text{ psi}$$

r = radius of gyration
S_{cr} = buckling stress

Actually, the compression surface of this beam did not buckle in the Euler sense. Rather, the behavior of the compression panels was an accelerated bending which eventually became so severe that the beam would carry no additional load. Fig. 1 of this discussion is an experimental curve which shows the buckling deflection ("humping" with respect to the spars) versus axial stress. It is questionable whether the predicted buckling stress indicated on this curve coincides with actual buckling. However, it is clear that the beam carried considerable load in excess of buckling. This is undoubtedly due to the fact that buckling occurred early, and that the spar flanges were capable of picking up the load when the compression panels buckled.

Beam No. 17. Beam No. 17 was like beam No. 18, but it had full-depth bulkheads with three vertical struts. No diagonal trussing was provided and therefore the bulkheads had very little shear stiffness. The bulkhead coefficient, based upon the combined stiffness of the upper and lower bulkhead chord members, has been calculated by the theory of Equation [7] of the paper to be 59.6 psi. Hence, by the theory of Shou-Ngo Tu,[4] the buckling stress should have been 4100 psi.

An experimental deflection curve for the panels of this beam is shown in Fig. 1. Here, again, the theoretical buckling stress was greatly exceeded, partly because of the capacity of the spar flanges to pick up load, and partly because the bulkheads were supported by the tension surface.

Beam No. 11. This beam was similar to beam No. 18, but the compression surface was cambered. The ratio of beam width to radius of camber was 0.41. Since the theory takes no account of camber the same computation procedures apply as in the example of beam No. 18. These calculations yield S_{cr} = 3200 psi.

Fig. 1 shows an experimental deflection curve for this beam. It is seen that the beam carried a much higher stress than the predicted buckling stress (3200 psi). A comparison of the curves for beam No. 11 and beam No. 18 shows that camber has a decidedly beneficial effect.

The general conclusion to be drawn from the three tests cited is that the theory establishes a conservative procedure for calculating the requisite stiffness of wing bulkheads.

[4] "Column With Equal-Spaced Elastic Supports," by Shou-Ngo Tu, *Journal of the Aeronautical Sciences*, vol. 11, no. 1, Jan., 1944, p. 67.

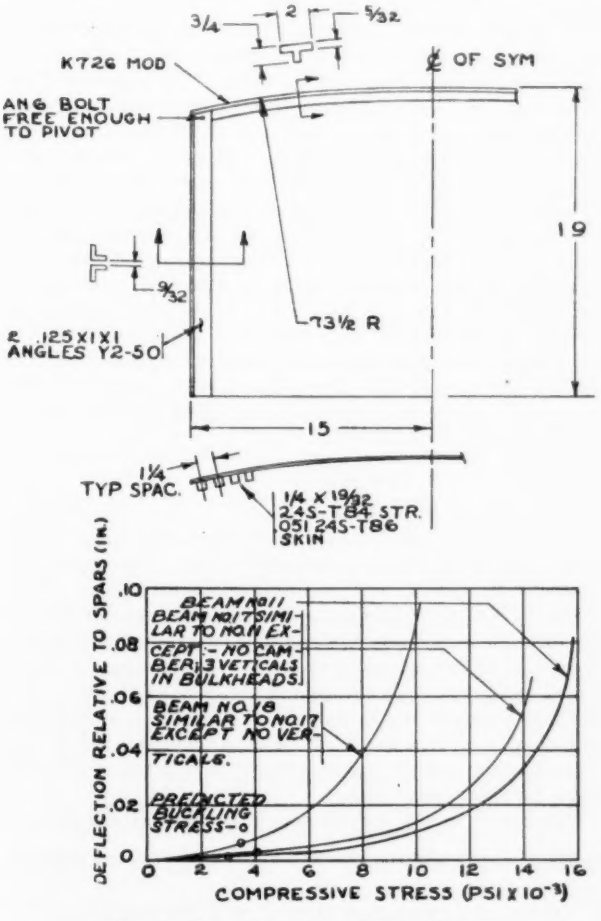

FIG. 1 BEAM DEFLECTION VERSUS STRESS

AUTHOR'S CLOSURE

The author believes that the comments of Messrs. K. R. Jackman and C. Conaway on his paper Parallel Columns With Common Lateral Supports are correct. The tests which they discuss had not been performed at the time the original paper was written, and therefore a discussion of the test data could not be included in it.

Cumulative Damage In Fatigue[1]

R. B. BLAND[2] AND A. A. PUTNAM.[3] Of the four assumptions upon which the author bases his development of the damage concept, the first two should be put in more general form. In regard to the first assumption, rather than specify a sinusoidal loading cycle, it only appears necessary to specify a "simple" cycle, i.e., one in which $d\sigma/dt$ changes sign only twice during a cycle. No work can be recalled by the writers in which it has been shown that the shape of a simple cycle is important. Furthermore, if the shape is an important factor, rate of loading and creep effects would be significant and thus the cycle frequency would also be an important variable.

In regard to the second assumption, the derivation of $\sum \frac{n}{N} = 1$

[1] By M. A. Miner, published in the September, 1945, issue of the JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 67, p. A-159.
[2] Structural Engineer, National Advisory Committee for Aeronautics, Washington, D. C.
[3] Mechanical Engineer, National Advisory Committee for Aeronautics, Washington, D. C. Jun. A.S.M.E.

presented implies that the work per cycle is constant for each magnitude of cycle. This assumption is not necessary for the derivation. All that is required is that (*a*) the rate of work input as a function of the fraction of total cycles to failure at any one magnitude of cycle be independent of the cycle size, and (*b*) that the material does not care how the work is put in. This results in an equation for the rate of work input of the form

$$\frac{dw}{d\left(\frac{n}{N}\right)} = f\left(\frac{n}{N}\right)$$

rather than the special case

$$\frac{dw}{d\left(\frac{n}{N}\right)} = W$$

and would allow the rate of work input and the damage to remain small until just before failure, thus explaining the absence of significant effects of fatigue-stressing on other properties such as tensile strength and impact resistance.

The third assumption is not pertinent to the concept of damage and is apparently only to be used to justify an approximate method of relating various stress ratios. It so happens that one of the writers was formerly associated with a major airplane manufacturer in this same field of work and had occasion to develop methods of fatigue analysis that could be applied to parts still on the drawing board. Due to the lack of adequate material data, it was necessary to attempt to predict fatigue strength at various range ratios and cycle numbers from fatigue-strength data for completely reversed stress. It was subsequently found that the results obtained from the use of the Goodman diagram for this purpose were so seriously in error that the entire project had to be discarded.

As an example of the error involved in this approximation, it is possible to compare the extreme range of test values given in Fig. 1(*b*) of the author's paper, with the derived value. At $\frac{S}{S_u} = 0.5$ the possible R values range from 0.65 to 0.2 and the corresponding minimum stress values range from 0.32 S_u to 0.1 S_u; at $\frac{S}{S_u} = 0.3$ the possible R values range from 0.2 to —1 and the minimum stress values range from 0.06 S_u to —0.3 S_u (compression). The writers would not consider this range of values to be a good approximation, and still wider deviations are to be found when applying the Goodman diagram at lower cycle numbers. The writers believe that due to the inherent inaccuracies of the "approximation" the Goodman diagram is not usable at all for this type of work, where margins greater than 10 to 15 per cent, on stress, are considered excessive. In fact, if data are available to define the actual shape of the Goodman diagram so that the straight-line approximation need not be used, then those data can define the entire fatigue surface and the Goodman diagram is superfluous. Parenthetically, the writers would like to know if the derived curve in Fig. 1(*b*), likewise represents the other extreme range of test values.

The confirmation of the concept of cumulative damage is based upon 22 tests in which a large number of variables were present. For this reason it is difficult to determine if any trends are present due to the magnitude of cycles, sequence of cycles, or range ratio. However, statistical tests were applied to the data in which only two magnitudes of cycles were used, with the result that a correlation was found between the difference in ranges of stress and the absolute value of $\sum \frac{n}{N} - 1$. Such a correlation is to be expected if the concept of cumulative damage is not exactly correct.

Again, if it is assumed that a stabilization of the work input associated with a certain magnitude of cycle takes place in about 100 cycles, it would be expected that the concept of cumulative damage would not be seriously in error for tests such as these where one magnitude of cycle is run for about 10^4 times before a different magnitude of cycle is run. However, it does not follow that this law should hold when the number of the same magnitude of cycles in sequence is only of the order of 10^2, 10^1, or even 10^0. The data presented, plus the data of Stickley which is mentioned (6 different magnitudes of cycles), show an increased deviation of the results from those predicted on the basis of cumulative damage with increasing number of different magnitudes of cycles.

If failure is the result of strain hardening as outlined by the theory of Orowan,[4] a family of curves, on a plot of per cent damage at the second stress to the per cent cycle ratio at the first stress, would result, one curve for each combination of stress and cycle ratio. These curves would be centered about the curve determined by $\sum \frac{n}{N} = 1$. However, a small number of tests which give only one or two points on a curve would give a pattern of points which would not reveal the curves (especially with the scatter inherent in fatigue tests) but which would appear random about the curve for $\sum \frac{n}{N} = 1$. In other words, the number of variables in these tests is so large and the number of tests is so small that from them no conclusions can be drawn as to the correctness of any theory.

The concept of cumulative damage does give a method of making an estimate of life of structures with discrete types of loading, and what may be more important at the present state of knowledge, it gives a basis for comparing various structures under the same loading. However, caution must be used in extending the theory to many of the problems common to industry. For example, the loads on an airplane wing, caused by atmospheric turbulence, occur in a more or less random manner about a fairly constant mean load. If the fatigue life of a structural member in the wing is to be determined by using this concept, should the deviations from the mean load be paired in pairs of equal absolute but opposite numerical magnitude to form cycles about the mean load, or considered each separately, or grouped statistically to form cycles of various amplitudes and mean stresses similar to actual sequence of loads? Large factors will separate the lives so obtained and there is no reason to believe that any one of these methods is least in error.

Author's Closure

Messrs. Bland and Putnam's comments regarding the more general nature of both the cycle of loading and the broader form of the expression for damage are appreciated. The remarks are justified by experimental information available at present. Their comments concerning the lack of accuracy of the modified Goodman diagram are correct; however, it should be pointed out that no use of this method was made in the development or experimental confirmation of the cumulative-damage concept. The Goodman diagram was introduced to provide an approximate method in cases where suitable SN-curves are not available. The author heartily concurs that this approach is at best a poor substitute for experimental data.

With regard to any possible correlation between difference in ranges of stress and the absolute value of $\sum \frac{n}{N}$, the following

[4] "Theory of the Fatigue of Metals," by E. Orowan, Proceedings of the Royal Society of London, series A, vol. 171, 1939, p. 79.

additional tests have been completed using steel specimens, and they do not show a significant trend.

Seven rotating-beam specimens (flash-welded 4130 steel tubes) were tested at various numbers of stress magnitudes ranging from two to ten. The average value for $\sum \frac{n}{N}$ was 1.11; for a specimen run at ten different stress values, $\sum \frac{n}{N} = 1.06$; for nine levels, 0.86; and for five levels, 1.20.

Nine flat sheet specimens of S.A.E. 4130 steel were tested at from two to four different stress levels and at various stress-ratio values. The average value was $\sum \frac{n}{N} = 0.94$, the maximum 1.43 (at two levels), and the minimum 0.69 (also at two levels).

It is noted that the over-all average for the original 22 aluminum-alloy specimens plus these 16 steel specimens results in $\sum \frac{n}{N}$ deviating by only 1.5 per cent from the theoretical value of 1.

To establish the effects of a number of different magnitudes of stress, another experimenter has tested an aluminum-alloy specimen for 28 excursions of a repeating stress pattern which contained four different magnitudes of stress, all at a constant value of mean stress.

The failure occurred at a $\sum \frac{n}{N}$ only 1 per cent different from the theoretical value. No significant correlation with the number of magnitudes of stress is apparent for the data presented on either aluminum or steel specimens.

The suggestion that stabilization of work input occurs at some relatively small number of cycles, say, 100, offers interesting possibilities for modification if the cumulative-damage concept does not accurately represent this region of loading. However, the author has conducted experiments at very high loads (95 to 100 per cent of the ultimate strength for 24S-T alclad sheet specimens), obtaining results that are not subject to rational analysis owing to scatter. However, since the structural aluminum alloys normally fail at from 1000 to 10,000 cycles of loading (varying with stress ratio and normal scatter) at 95 per cent of the ultimate tensile strength, there is only this narrow region at very high stresses within which the cumulative damage is not adequate for present analysis purposes. Of course for a practical case, material with various stress concentrations must be considered, but here again the usual margin of safety found in a structure will normally obviate stresses of such a magnitude as to result in fatigue failures in less than 1000 cycles.

The use of the cumulative-damage concept provides considerably greater accuracy in the analysis of the effects of gust loads on aircraft structures than is warranted by presently available information on the frequency of occurrence of atmospheric disturbances. Also, it is the task of the analyst and the experimenter to determine the proper method for handling gust loadings, a problem independent from that of the damage question.

The general comments regarding conclusions drawn from a small number of tests with a large number of variables are valid to the extent that a precise analysis is not possible at present by use of the cumulative-damage concept nor is that the intent. The present status of all fatigue-analysis methods, and experiments, is such that any significant trend which may be shown to exist is very useful in spite of limited accuracy. The need is great for further experimentation on general fatigue problems and the damage question in particular.

The author wishes to acknowledge an original theoretical approach to the problem of repeated loadings of aircraft structures in which a damage criterion was previously proposed by P. H. Denke, of the Douglas Aircraft Company, Santa Monica, Calif.

Book Reviews

Theory of Structures

THEORY OF STRUCTURES. By S. Timoshenko and D. H. Young. McGraw Hill Book Company, Inc., New York, N. Y., 1945. Cloth, $5^3/_4 \times 8^3/_4$ in., xiv and 488 pp., 477 illus., $5.

REVIEWED BY J. N. GOODIER[1]

THIS is a theory of structures in the orthodox sense of civil engineering, reflecting the authors' lifelong interest, both scholarly and practical, in the subject. The text, as will be expected by readers of other works from the same pens, is extremely clear. It makes minimum demands on the reader—a reviewable knowledge of elementary mechanics and strength of materials—and at the same time maintains a scrupulous regard for logical completeness and continuity.

The required elements of plane statics are given in the first chapter, in the form of a review extended to the funicular polygon and the method of virtual displacements, which is subsequently used to very good advantage in many places. The required space statics is given under "statically determinate space structures" in the fourth chapter. The reader thus needs only a first course in mechanics, and for the second part of the book also strength of materials, to be able to proceed. He will be led through the simple truss problems normally encountered in statics to Maxwell diagrams, compound and complex trusses, and the application of virtual displacements. Influence lines are developed for beams, three-hinged arch ribs, simple trusses, compound trusses, and three-hinge arch trusses. Statically determinate problems end with a chapter on space trusses completing rather less than half the book.

The second half begins with strain energy, the principle of virtual displacements, Castigliano's theorem (and its offshoots such as least work), and the reciprocal theorem. These theorems then find application to the deflection of pin-jointed trusses. Graphical determination of deflections, like all the methods developed, is well illustrated, even if one of the diagrams seems to be there as a warning to the student that sometimes a formidable tangle will result in spite of the best of intentions! The fictitious load methods of Mohr and Müller-Breslau follow. The chapter on statically indeterminate pin-jointed trusses includes a discussion of influence lines when there are several redundant members and a brief section on space trusses. The chapter on beams and

[1] Professor in Charge, Department of Mechanics of Engineering, Cornell University, Ithaca, New York, N. Y. Mem. A.S.M.E.

frames proceeds through the slope-deflection equations, continuous beams, simple bents and frames, to continuous frames and solutions by successive approximation culminating in the Hardy Cross method. Data are given for haunched beams. In the last chapter, the thorough discussion of arch analysis is supplemented by several tables useful in calculating thrust, and there is a critical discussion of the "thin bar" formulas, based on the thick-curved-bar theory which is developed as a preliminary.

The book is a valuable treatise on methods for the engineer and is well arranged for the use of students. It has 269 problems covering all parts except the more advanced questions of frames and arches.

The Meaning of Relativity

THE MEANING OF RELATIVITY. By Albert Einstein. Second Edition. Princeton University Press, Princeton, New Jersey, 1945. Cloth, 5 × 7¾ in., 135 pp., 6 figs., $2.

REVIEWED BY J. ORMONDROYD[1]

THE first edition of this book, published in 1922, covered a series of lectures given by Mr. Einstein in May, 1921, at Princeton University. The text of this edition differs from that of the first edition only by the inclusion of an Appendix on the "Cosmologic Problem." The dust cover states that the book is "intended for the general reader who has some understanding of modern physics and advanced mathematics." It is probably fair to remark at the outset that the understanding of modern physics and advanced mathematics of most engineers will not suffice for the intelligent reading of this book. The physical knowledge required by the putative reader is a thorough understanding of Newtonian mechanics and Maxwell's electrodynamical theories. On the mathematical side Riemannian geometry and tensor analysis must be known. One further prerequisite would be that the reader had already attempted some serious study of the theory of relativity from some other source. For anyone having the complete background as outlined above, Mr. Einstein's four lectures would be considered a magnificent summary by the master to his disciples.

In the first chapter of the book Einstein gives a brief introduction to prerelativistic physics and the notation, concepts, and operations of tensor analysis. Here again if the reader knows this subject in advance he will probably recognize a masterful summarization, but if he does not he will gain nothing but confusion and a sense of futility.

[1] Captain, U.S.N.R., David Taylor Model Basin, Navy Department, Washington, D. C. Mem. A.S.M.E.

The second chapter deals with the theory of special relativity. The engineering reader would probably find it easier to get the ideas of special relativity from some other book. A great many expositions of the theory of special relativity have been published, some of them treated in language suitable to the background which most engineers actually possess.

The third chapter gives the underlying physical ideas of the general theory of relativity. These are followed by an extensive consideration of the tensor analysis and the tensor equations which form the mathematical foundation of the theory. If the engineering reader pays close attention to the physical reasoning he will gain a clear insight into the meaning of General Relativity. The tensor analysis and tensor equations will probably leave him bewildered as in chapter one.

The fourth chapter contains a discussion of the three widely known triumphs of the general theory of relativity. Pages 92 to 97 of this chapter show the quantitative deductions which predicted the shift of spectral lines toward the red in radiations which emanate from the sun and other heavy stellar bodies, the bending of light rays in the neighborhood of the sun or any concentration of mass, and the motion of the perihelion of the planet Mercury. All of these are small effects totally outside the possibility of prediction by Newtonian mechanics; but all capable of observational confirmation.

The theory of relativity has enjoyed widespread interest because the principles and experiments which form its foundation, and the few outstanding results which it has predicted, are understandable to a public reasonably well versed in physics and mathematics. For this reason the Appendix which treats the "Cosmologic Problem" is probably the most understandable and enjoyable chapter in the whole book. Here the relationship between the Hubble expansion and the average curvature of the space of the universe, the age of the universe, and the conflict between the relativistic age and the age deduced from the consequences of nuclear physics are discussed. These are all questions which would interest any reader who possesses even mediocre physical and mathematical knowledge.

The reviewer of this book has decided that in order to understand Mr. Einstein's summary of the theory of relativity he would have to make a serious study of some such books as "The Elementary Theory of Tensors," by T. Y. Thomas, "Applications of the Absolute Differential Calculus," by A. J. McConnell or "Riemannian Geometry," by L. P. Eisenhart (named in order of sophistication), and at least the chapters on relativity in some general work on mathematical physics such as "Foundations of Physics," by Lindsay and Margenau. There is no easy road to the understanding of the meaning of relativity.

Internal Friction in Engineering Materials

By J. M. ROBERTSON[1] AND A. J. YORGIADIS[2]

This paper is a report on some experiments conducted on the subject of internal friction or damping in solid engineering materials, with apparatus and technique comparatively new to the field. The use of this equipment and technique enabled the measurement of internal friction in a more direct way than most if not all of the methods used by previous investigators. In the light of the results reported, empirical relations are presented for the variation of internal friction with stress amplitude in the range of engineering stresses. These relations are compared with the findings of others.

Internal Friction—Damping Capacity

INTERNAL friction or damping capacity is that property of a solid material which results in energy absorption when the material is stressed cyclically.

Concept of Internal Friction. The original conception of internal friction or damping in solids was that this phenomenon is associated with a viscous force proportional to the strain velocity. This reasoning was through analogy with viscous friction in fluids. Kelvin (1),[3] one of the early researchers in this field, presented internal friction as a viscous phenomenon; but his experiments made in 1865 on wires in torsion did not verify this hypothesis. As early as 1912 internal friction was presented by Hopkinson and Williams (2) as a hysteresis phenomenon in which the loss was due to the noncoincidence of the upward and downward portions of the stress-strain diagram of a material under cyclic loading. The stress-strain diagram for a complete stress cycle thus corresponded to a closed loop. Through analogy with the phenomenon of magnetic hysteresis, Hopkinson and Williams suggested the appelation "elastic hysteresis." This term was somewhat of a misnomer for, as noted by Föppl (3) it is due to the lack rather than the presence of an elastic quality of the material.

In analyzing internal friction, Föppl (3) assumed that any strain may be considered to be composed of an elastic and plastic portion, the latter being the cause of the hysteresis and energy loss. The energy stored in a strained body is only partly recoverable in release of the stress and strain; that associated with the plastic component of the total strain is not recoverable and is dissipated into heat. Föppl and his co-workers (3, 4) preferred to call this the "damping" or the "damping capacity," as it represented the amount of energy a vibrating system would dissipate through internal friction in one cycle of vibration.

Methods of Expression. Internal friction has been expressed in various ways by different investigators, depending partly on the method of measurement and analysis involved. Although incorrect and decidedly misleading, internal friction is still sometimes expressed in terms of a viscosity coefficient, due to the convenience of analytical treatment. A large number of observers have presented data on internal friction in terms of the logarithmic decrement or rate-of-vibration-decay factor δ, which in many cases was the quantity determined experimentally. This representation lacks considerably in physical significance when applied to the steady vibrations of structural members. Although his test involved the measurement of vibration decay, Föppl presented his data in terms of the "specific" damping capacity, as von Hydekampf (4) termed it. This is the ratio of the energy loss per cycle ΔW, to the vibrational energy in the member W

$$\psi = \frac{\Delta W}{W} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [1]$$

On the basis of certain assumptions it can be shown that ψ is approximately equal to 2δ, see Lazan (5).

Since the time of Hopkinson and Williams (2) and Rowett (6), many experimenters have expressed internal friction in terms of the energy loss per cycle of vibration, ΔW, which is termed the damping capacity in this paper. Other methods of expressing internal friction are in terms of the bluntness of the resonance curve, in terms of a "frictional stress" related to the width of the hysteresis loop (Canfield 7), and in terms of the resonance amplification factor A_r, a reciprocal function of the damping. Some of the foregoing methods are open to serious objections especially when used quantitatively for engineering materials.

Significance of Internal Friction. The function of internal friction in aiding the other sources of damping in keeping down the amplitude of vibratory motion, and hence the stress amplitude by absorbing energy is of prime significance, as is well known. As Föppl pointed out in connection with the vibration of long transmission wires, airplane structures, airplane propellers, turbine blades, and engine crankshafts, the presence of internal friction in large amounts is a desirable property of materials. He noted that a material of high damping capacity and comparatively low fatigue strength may be superior to one of high fatigue strength and lower damping. In this country the extreme importance of damping in connection with the vibrations of turbine blades has been pointed out by Hague (8).

Internal friction is not always a desirable property of engineering materials. It is the presence of internal friction which is responsible for the phenomenon of shaft "whirl," see Kimball, (9, 10, 11). Also materials of high internal friction heat up when subjected to repeated vibratory stresses, resulting in a decrease in the strength of the material, as at higher temperatures the strength of materials, especially plastics, is lower than at normal temperatures. Besides this, internal friction is of some interest in connection with the fatigue properties of materials. Dorey (12) concluded that the fatigue strength of a material could be ascertained from a plot of the damping capacity as a function of stress. Föppl (3) disagreed with this idea but felt that the notch sensitivity of the material is dependent upon its damping capacity. However, not all materials show this dependency. A good summary of the significance of internal friction in relation to

fatigue strength was presented in the Battelle Memorial Institute book (13).

Measurement of Internal Friction. The most common method used for the measurement of internal friction is the rate-of-vibration-decay method, using the torsional-pendulum form of apparatus, or vibrating bars or beams. More data have been taken by this method than all the other methods combined. The drawbacks of the freely decaying vibrations method, due to the apparatus and method of evaluating test data, are such as to mask the fundamental nature of the variation of damping capacity with stress. At high rates of decay the decrement cannot be associated with any specific stress or strain amplitude; transforming values of the decrement into the damping capacity involves assumptions concerning the elastic modulus; and the tests are performed in a transient state when stress surges exist, resulting in variations in the stress distribution.

Föppl (3) listed several methods of measuring damping which were used under his direction at the Wöhler Institute in Germany: namely, (*a*) Static measurement, as first used by Rowett (6); (*b*) starting-up tests, involving measurement of the rate of temperature rise; (*c*) a steady-state thermal-equilibrium method, first used by Hopkinson and Williams (2); (*d*) a resonant-vibration method, involving measurement of energy input; and (*e*) the torsional-vibrations-decay method. The last was the basic method used by Föppl and his co-workers. Although he claimed to have obtained good agreement between the methods listed, they are open to various objections. The static method, also used by Dorey (12), involves the measurement of the width of the hysteresis loop for a complete stress cycle (generally in torsion), cannot be used for materials subject to creep, and requires high-precision measurements. Data obtained by thermal means have little significance as internal friction varies with temperature. The resonance-vibrations method can be successfully used if the measured losses are only those which are due to damping in the specimen. This is possible with the equipment developed by Lazan (5).

Kimball and Lovell (11) used a novel method in which the lateral deflection (whip) of a loaded cantilever rotating beam was measured. Another method which has been used involved the measurement of the width of the resonance curve of a vibrating bar or beam, such vibration being caused by a magnetic or crystal oscillator. The data obtained by this last method are generally at such low stresses as to be lacking in engineering significance. Furthermore, such measurements cannot be identified with any particular stress amplitude as different parts of the test are carried on at different stresses.

Principal Factors Affecting Internal Friction

In spite of a large amount of theoretical and experimental work on the nature of internal friction in solids, there is available no physical theory for this phenomenon, except at the very lowest strains which are out of the range of engineering interest. A good summary of these theories is presented in a book by Seitz (14), where the effects due to thermoelastic causes, ferromagnetism, and internal dislocations in the structures of the crystal lattice are discussed theoretically and in the light of experiment. In the realm of engineering stresses internal friction is probably the result of irreversible plastic actions.

The factors of importance in regard to internal friction of engineering materials in the engineering range of stresses appear to be as follows: Stress or strain amplitude, nature of the stress or strain (i.e., normal, shearing, or combined), frequency, temperature, and the nature or kind of material.

Frequency Effect. A conclusive proof of the lack of frequency effect on internal friction in the range of engineering stresses was obtained by Kimball and Lovell (11) in their experimental study of metals, glass, celluloid, rubber, and wood (a total of 18 different materials). They found the logarithmic decrement to be entirely independent of frequency (i.e., stress or strain velocity) for frequencies between 2 and 200 cps. According to Föppl (3), there is no frequency effect except at very low frequencies for materials subject to creep when the frequency is so low that the strain velocity is of the same order of magnitude as the creep velocity. The occurrence of creep as a separate phenomenon not of concern in damping was also noted by Leaderman (15). Ockleston (16), in a study of a vibrating steel beam, found practically no frequency effect between 23 and 45 cps. Gemant (17) measured the damping in a steel tube at frequencies between 300 and 4600 cps and noted no significant variation, although his data showed some scatter.

Prior to this the complete lack of frequency dependence of damping was indicated by Hopkinson and Williams (2) and Rowett (6). In the first of these investigations measurements were made dynamically (under resonant vibrations) at 136 cps by thermal methods and statically for a steel under normal (tension-compression) stresses. Continuing this work but with thin-walled tubes in torsion (thus making the static tests susceptible to greater sensitivity), Rowett studied a similar steel statically and at 67 cps by means of the torsional-pendulum-decay method. The static torsion methods allowed the measurement of the width of the loop over the complete stress cycle for several stress ranges. In Fig. 1 is shown one of his measured loops and in Fig. 2 plots are given of his data on damping capacity as a function of stress amplitude. From this figure the agreement he noted between static and dynamic data is apparent. Rowett was able to re-evaluate the static data of Hopkinson and Williams and to show that it agreed with their dynamic data within the experimental accuracy.

A few experimenters have noted a frequency variation, but their results were obtained at much higher frequencies and at much lower stresses in the material. It does not appear certain that their measurements at the different frequencies were necessarily at the same stress amplitude, with which variable the internal friction varies greatly.

Stress Amplitude. The most important variable affecting internal friction in solids is the stress or strain amplitude of the cyclic action. Some attention has been paid to this fact by certain investigators but many have ignored it or tried to minimize its importance. Hopkinson and Williams (2) and Rowett (6) were among the first to indicate this stress dependency. The first of these investigators found the energy loss per cycle (damping capacity) to vary about as the fourth power of the stress amplitude. Their data were probably influenced by temperature variations due to the method of measurement. Rowett's measurements both static and dynamic, indicated that the damping capacity ΔW varied as the third power of the stress. In the presentation of his data in Fig. 2 the straight lines, representing the trend of the points, are drawn to the third power. The line for the hard-drawn material represents the equation he derived from his dynamic tests. In a study of the hysteresis loss in five crankshaft steels by static tests, such as used by Rowett (except that they were on solid specimens), Dorey (12) found that up to a certain stress (6000 to 12,000 psi), the damping capacity increased with the third power of the stress amplitude.

If the third-power stress variation of damping capacity, noted by Rowett and Dorey, is expressed in terms of the specific damping capacity ψ (see Equation [1]), it is found that ψ should vary about as the first power of the stress amplitude. This assumes, among other things, that the dynamic modulus of elasticity of the material is constant. Föppl (3), von Hydekampf (4), Hatfield, Stanfield, and Rotherham (18, 19), and Contractor and Thompson (20) presented data on internal friction in the form of graphs

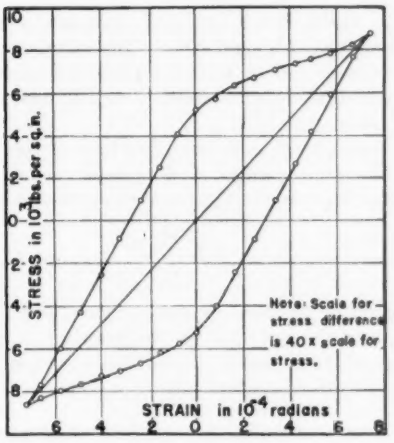

FIG. 1 HYSTERESIS LOOP FOR STEEL (ANNEALED) UNDER TORSION AS OBTAINED BY ROWETT

(This is the static stress-strain curve obtained by measuring the stress width of the loop for different strains. Note that the stress width is shown greatly exaggerated.)

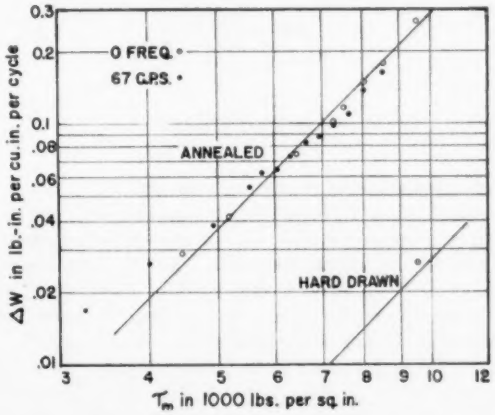

FIG. 2 ROWETT'S DATA ON DAMPING CAPACITY OF STEEL IN TORSION PLOTTED VERSUS MAXIMUM SHEARING UNIT STRESS AMPLITUDE

(For the annealed steel the open symbols represent the data obtained statically; the solid symbols represent that obtained at 67 cps. In the case of the hard-drawn steel, the solid line represents data obtained at 67 cps; the single point shown, open symbol, was obtained statically.)

of ψ or δ versus stress or strain amplitude. Due to the effect of other factors, perhaps, the first-power variation was not too apparent.

Kimball and Lovell (11) found the energy loss per cycle per unit volume (damping capacity, ΔW) to vary as the second power of the stress amplitude, from which it followed that the rate of vibration decay was logarithmic, i.e., the logarithmic decrement δ was constant for any material. However, Ockleston (16), who attempted to compare this relation with data obtained from a vibrating steel beam, found the decay of vibration was not logarithmic and δ, therefore, to be a function of amplitude. Interpreting his data in terms of the damping capacity, it appears that ΔW varied about as the third power for a considerable range. The correct interpretation of such tests as these is quite difficult if not impossible, as in both cases the stresses varied considerably throughout the specimens.

Other Factors. Temperature, nature of the stress involved, and the nature or kind of material are other factors upon which the internal friction depends. Measurements by Hatfield, Stanfield, and Rotherham (18, 19) showed that the specific damping capacity increased rapidly with increase in temperature above normal for a considerable range of temperature. Other papers presenting data on the influence of temperature are those of Contractor and Thompson (20) and Schabtach and Fehr (21).

As to the effect of the nature of stress involved, there are few data available since most of the experiments have only been performed in torsion. There is evidence that the internal friction under shearing stress is different from that under normal stress (3, 5). The effect of previous stress history of the specimen was noted by Kelvin (1), Föppl (3), Dorey (12), Lazan (5), Kutsay and Yorgiadis (22), and Hempel (23). Briefly, their results indicate that if a material is undergoing repeated cyclic straining at essentially constant amplitude, its internal friction is changed with the number of stress cycles, ultimately reaching a constant value for any specific stress. Kutsay and Yorgiadis (22) noted a change of as much as 10 times in the damping capacity of magnesium alloys due to cyclic straining. It has also been noted that the damping capacity of mild steels decreases due to cyclic stressing at low amplitudes and increases at high stress amplitudes see Lazan, (5).

Hempel (24) in a study of the damping and fatigue properties of cast irons, found that the value of ψ, corresponding to a certain stress amplitude, was lower the higher the tensile strength of the cast iron. For plastics it has been noted that the damping capacities of different materials were an inverse function of their elastic moduli (25). This type of relation cannot be expected to apply to metals such as steels, for which there is no variation in modulus but a large variation in damping.

APPARATUS AND METHODS USED

The method of test used in obtaining the data presented in this paper corresponds to method 4 listed by Föppl. The particular equipment used was developed by Lazan (5) and used by him and Kutsay and Yorgiadis (22). Briefly, the vibratory system consists of a centrifugal-force mechanical oscillator, maintaining resonant vibration in a specimen which is the flexible member of the vibrating system. The energy input to the system is obtained from measurement of the amplitude of the motion and the force amplitude of the oscillator.

Torsional Tests. The arrangement used to measure the damping under torsional vibration is shown in Fig. 3. The upper end of the specimen is rigidly attached to a heavy frame by means of collet and chuck. From the lower end of the specimen are suspended the mechanical oscillator and its synchronous driving motor. The oscillator was driven at different multiples and submultiples of synchronous speed by means of interchangeable gears. As shown, the oscillator is adjusted to produce a sinusoidal torque by means of eccentric masses at the ends of two counterrotating shafts. In Fig. 3 only one pair of the eccentric masses is visible; the other pair is on the rear face of the oscillator, rotating 180 deg out of phase with those shown. The result is a sinusoidally varying torque about the axis of the specimen. The magnitude of this torque at any particular speed is adjusted by varying the size of the masses and their eccentricities. The movable poises shown on oscillator-motor assembly in Fig. 3 are used to adjust the moment of inertia of the assembly. Such adjustment enables the tuning of the system to resonance. This is a single-degree-of-freedom system under forced torsional oscillation, the specimen acting as the spring, and the oscillator-motor unit acting as an adjustable inertia. The exact condition of resonance is determined by a 90-deg phase lag between the oscillator torque and the angular displacement of the unit; this lag is measured under stroboscopic light by means of the phase indicator shown on the oscillator. The amplitude of the torsional oscillations is measured with a micrometer microscope.

On the basis of the assumption of sinusoidal torque and sinusoidal motion, the following analytical equations may be ob-

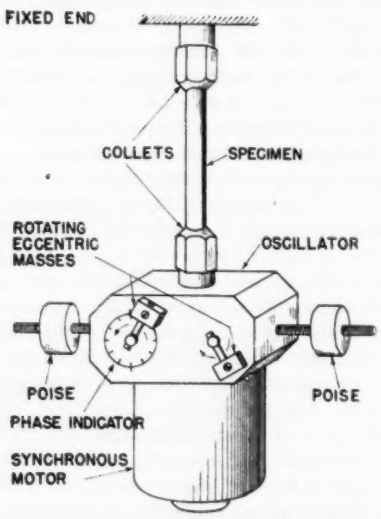

FIG. 3 EXPERIMENTAL ARRANGEMENT USED TO OBTAIN TORSIONAL OSCILLATIONS IN SPECIMEN WITH MECHANICAL OSCILLATOR FOR DAMPING-CAPACITY DETERMINATIONS

tained for resonance conditions of vibration. The maximum shear stress at the surface of the cylindrical specimen is

$$\tau_m = \frac{D\omega^2 I\theta}{2Jg} \quad [2]$$

where

D = outside diameter of specimen
J = polar moment of inertia of specimen
ω = circular frequency = $2\pi f$
g = acceleration of gravity
I = moment of inertia of oscillator-motor unit
θ = amplitude of torsional oscillation (radians)

The damping capacity, the energy absorbed by internal friction per unit volume of material per cycle, is determined from the relation

$$\Delta W = \frac{\pi T\theta}{AL} \quad [3]$$

where

T = amplitude of applied torque
A = cross-sectional area of specimen
L = length of specimen

The dynamic modulus of rigidity (shear modulus) of the material is

$$G = \frac{L\omega^2 I}{Jg} \quad [4]$$

Direct-Stress Tests. The experimental setup used to test materials under direct stress (tension-compression) consists of the two-mass single-degree-of-freedom system shown in Fig. 4. The same oscillator is used, with the rotating eccentric masses adjusted to produce a sinusoidal axial force in the specimen (masses on same shaft now rotating in phase). The specimen acts as the spring between the two weights, W_1 and W_2, vibrating in opposite phase. These two weights are supported on rollers, which gives them freedom of horizontal movement with negligible frictional losses (as noted from the experimental results). The magnitude of the oscillator force at any particular speed is adjusted by varying the size of the rotating masses and their eccentricity. The system is tuned to resonance by changing W_1 and W_2 with weights ΔW_1 and ΔW_2. The exact condition of the resonance is determined by a 90-deg phase lag between the oscillator force and the displacement of W_2, as measured with a micrometer microscope.

The relationships for resonant vibrations of this system are based upon the same assumptions as those for the torsional case. The maximum direct stress (tension or compression) is

$$\sigma = \frac{\omega^2 W_2 a}{Ag} \quad [5]$$

W_2 is the weight of the block, oscillator, motor, and other attachments shown on the right side of the specimen in Fig. 4; a is the amplitude of the motion W_2; and, the other symbols are the same as for the torsional case. The damping capacity is determined from

$$\Delta W = \frac{\pi F a}{AL} \quad [6]$$

where F is the amplitude of the oscillator force. The dynamic modulus of elasticity of the material is

$$E = \frac{L\omega^2 W}{Ag} \quad [7]$$

Here

$$W = \frac{W_1 W_2}{W_1 + W_2}$$

is the effective weight of the two-mass system.

Equations [2] to [7], inclusive, were used to obtain the damping capacity and dynamic modulus of materials under resonant vibrations with the apparatus described. All the data presented in this paper were obtained within 10 deg of resonance, most of them being obtained within about 5 deg. A more complete description of the apparatus and its uses can be found in papers by Lazan (5) and Kutsay and Yorgiadis (22). In connection with the question of the external losses due to the supporting structure for the apparatus, it might be mentioned that considerable difficulty was experienced in finding a sufficiently rigid support from which to suspend the torsional setup. In fact, for the lower stresses the data given for the torsional damping capacity probably include some energy which was lost through the supports. No such difficulty was noted in the case of the horizontal direct-stress apparatus as the vibratory load in the specimen is not transmitted to the foundation and the losses in the rollers are apparently negligible.

DATA ON DAMPING CAPACITY

Measurements were made of the damping capacity of six metallic alloys under both torsional and longitudinal vibrations. Three

NOTE: All data in inch-pound-second units.

plastic materials were tested under longitudinal vibrations only. The particular materials studied are listed in Table 1; their static yield strengths being given in columns 3 and 4. All tests were conducted under completely reversed stress cycles in which the variation was from a maximum positive value to a numerically equal maximum negative value, the range of stress being twice the stress amplitude, i.e., the mean stress was zero. In all cases the stress to which the data are referred is the maximum amplitude measured from zero. The inch-pound-second dimensional system is used throughout and the data are presented in such units.

For the three plastic materials, lucite (methyl-methacrylate resin), bakelite (paper-base laminated phenolic, grade X), and a plywood (resin-bonded plywood molded under high pressure), the relationship between damping capacity and stress (tension-compression) is shown in Fig. 6. It will be noted that the data are presented on logarithmic co-ordinates. The straight lines, drawn with a slope of 3, indicate that the damping capacity of these materials is proportional to the third power of the stress amplitude, as noted by Rowett; thus

$$\Delta W = C_1\sigma^3 \quad [8]$$

In column 6 of the table are given the minimum and maximum stresses for which experimental verification of Equation [8] was obtained. The value of C_1 in this equation is recorded in column 5 of the table, for these three materials; ΔW is in inch-pounds per cubic inch per cycle and σ is in pounds per square inch.

Each of these materials was run at two speeds, 48 and 68 cps, without any noticeable speed effect appearing in the data, as may be seen in Fig. 6. The plywood was also tested in two diameters 1/2 and 3/4 in. at both speeds and showed no size effect. For each speed, size, and material, tests were run with specimens of at least two lengths to enable the evaluation of end-condition effects, which were sometimes significant. The sharp discontinuity in the bakelite data at about 3000 psi could not be checked due to a lack of material.

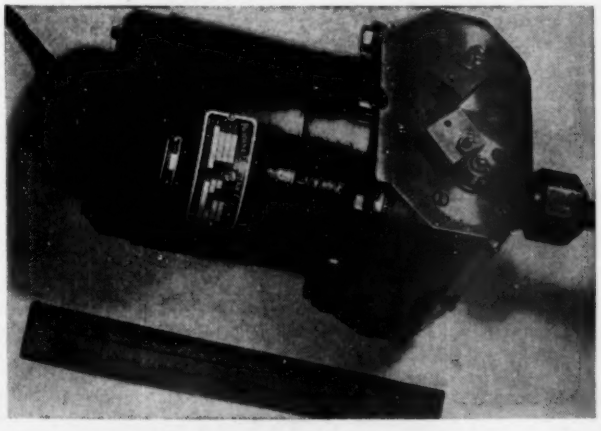

FIG. 5 MECHANICAL OSCILLATOR

In Fig. 7 data are presented for four of the metals, namely, the extruded magnesium-alloy tubing (Dowmetal J-1), S.A.E. 1025 seam-welded steel tubing "as welded," S.A.E. X 4130 seam-welded alloy-steel tubing normalized, and a cast iron. All materials were tested in the as-received condition. The duration of each particular measurement was kept as short as possible to prevent the introduction of work-hardening effects. The results are again plotted on logarithmic co-ordinates and include data obtained under both longitudinal and torsional vibration. In some cases more than one specimen was studied to eliminate any accidental factors. The results obtained under longitudinal vibration (tension-compression stresses) have been brought into

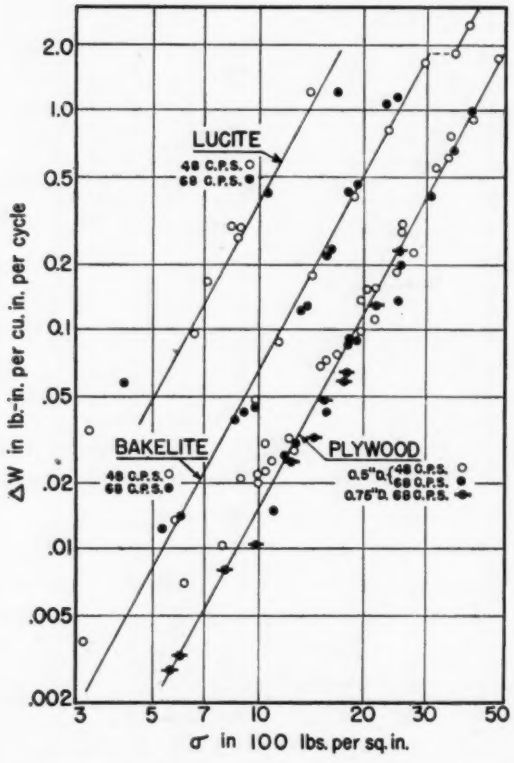

FIG. 6 DAMPING CAPACITY ΔW VERSUS σ, AMPLITUDE OF DIRECT STRESS, I.E., TENSION-COMPRESSION FOR PLASTIC MATERIALS

agreement with those obtained under torsional vibration (shearing stresses) by multiplying the longitudinal-stress amplitudes by a factor K, whose value for each material (except the cast iron which was tested only in torsion) is shown on the figure and is listed in Table 1. Again the data lie very close to the straight lines representing the relations

$$\Delta W = C_1\sigma^3 \quad [8]$$

$$\Delta W = C_2\tau_m^3 \quad [9]$$

The limits of stress for which these were found to apply, and the values of the constants C_1 and C_2 are given in Table 1. The torsional tests for the steels include data taken at two frequencies 9 and 19 cps, while the cast-iron data were taken at 19 and 30, cps, again indicating no frequency effect.

It will be noted that beyond a certain value of the stress, the data deviate from the straight line of slope 3, the damping then increasing at a much higher rate. Such a phenomenon was noted especially by Dorey (12), at comparatively lower stresses. There is some variation among the different specimens of the materials as to the exact stress at which this change occurs. It appears to occur at a stress corresponding approximately to the yield strength of the material. For example, in the case of the 1025 steel a rough static test indicated that the shearing yield point was about 17,000 psi, which is about the transition point in Fig. 7.

Ideally, to evaluate correctly the effect of stress on the damping or internal friction, all fibers of the specimen should be stressed the same amount. This condition was achieved in the longitudinal-vibration tests but could not be ideally attained in the torsional tests. All torsional data are plotted against the shear stress in the outermost fiber of the specimen, this being the maximum stress. Both grades of steel specimens were $^3/_4$-in-diam tubes of 0.035-in. wall, in which the stress variation throughout the specimen was less than 10 per cent of the maximum. In the case of the steel, therefore, the conditions were not far from the ideal. In the case of the magnesium data, however, the specimens were $^3/_4$-in. tubes of $^1/_8$-in. walls; the variation between maximum and minimum stress then being approximately one third the maximum. Nevertheless, the damping capacity varies as the third power of the stress amplitude, and the actual error due to this factor is considerably less than that indicated by the stress variation.

Experiments have also been run on monel-metal drawn seamless tubing under both torsional and longitudinal vibration, as indicated in Table 1. Two sizes were studied, $^3/_4$-in. and $^1/_2$-in. diam of 0.028 in. wall thickness. Due to slight differences in treatment, as was verified by hardness measurements, the properties of these two were slightly different. Also given in the table are similar data obtained for extruded magnesium alloy M, which was tested under the same conditions as alloy J-1. Finally the table contains data obtained by Rowett (6) on $^5/_8$-in-diam 0.05-in. wall tubing in torsion. These data are presented graphically in Fig. 2 and are included for comparative purposes.

It is common practice to present data on internal friction as the dimensionless ratio ψ, which is called the "specific damping capacity" or "relative damping." As indicated by Equation [1], this is the ratio of the damping capacity to the elastic energy stored in a unit volume of material at the maximum stress. In the direct-stress case this elastic energy is taken as $W = \frac{\sigma^2}{2E}$. Values of ψ thus determined from the experimental data are plotted in Fig. 8 for the bakelite, X4130 steel, and magnesium

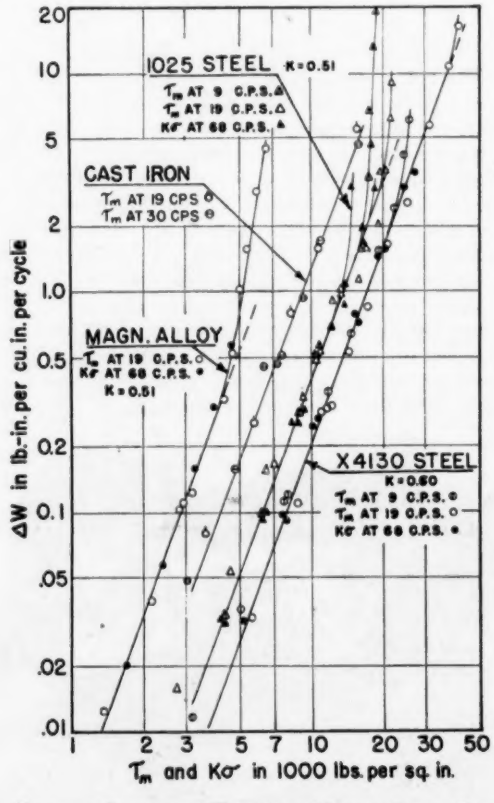

FIG. 7 DAMPING CAPACITY ΔW OF FOUR METALS UNDER TORSIONAL VIBRATIONS, OPEN SYMBOLS, AND LONGITUDINAL VIBRATIONS, SOLID SYMBOLS

(The torsional data are plotted versus the maximum shear stress amplitude. The longitudinal data are plotted versus the direct stress amplitude times the factor K.)

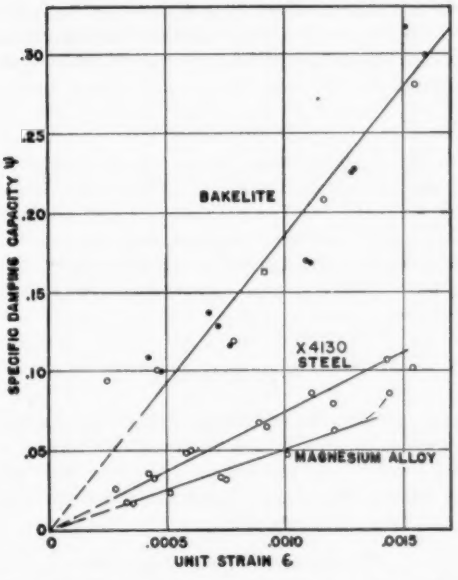

FIG. 8 SPECIFIC DAMPING CAPACITY ψ VERSUS UNIT STRAIN ϵ IN DIRECT STRESS FOR LAMINATED BAKELITE AT 48 CPS, OPEN SYMBOLS AND 68 CPS, SOLID SYMBOLS; AND S.A.E. X4130 STEEL AND MAGNESIUM ALLOY J-1 AT 68 CPS

alloy J-1. The variable ϵ is used as the abscissa in this plot, as it is more fundamental to plot one dimensionless quantity as a function of another rather than as a function of a dimensional one, i.e., the unit stress σ. This plot indicates that the specific damping capacity is roughly a linear function of the unit strain.

DYNAMIC MODULUS

In the course of the experiments, data were obtained on the variation in the dynamic modulus of elasticity of the materials with stress amplitude. Such data are of interest in the interpretation of internal-friction data as it is often necessary to make certain assumptions concerning the nature of the dynamic modulus. For instance, it is generally assumed that the dynamic modulus has a constant value identical with that of the static modulus.

The dynamic moduli of rigidity (shearing moduli) for the S.A.E. X4130 steel and magnesium alloy J-1 are presented in Fig. 9 as functions of the maximum shear stress. These moduli were calculated from the experimental data with Equation [4] and are seen to decrease with increasing stress.

The dynamic moduli of elasticity (tension-compression moduli) of the S.A.E. X4130 steel, magnesium alloy J-1, and the bakelite are shown in Fig. 10. These were calculated by means of Equation [7], and as in the case of the moduli of rigidity, are seen to

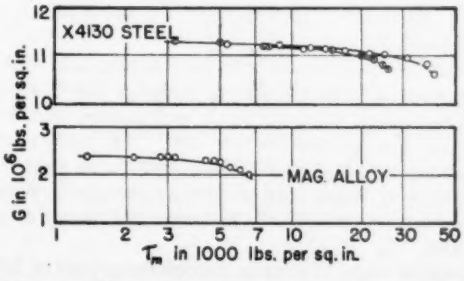

FIG. 9 DYNAMIC MODULUS OF RIGIDITY, I.E., SHEAR MODULUS AS A FUNCTION OF MAXIMUM SHEAR STRESS-AMPLITUDE FOR S.A.E. X4130 STEEL AND MAGNESIUM ALLOY J-1

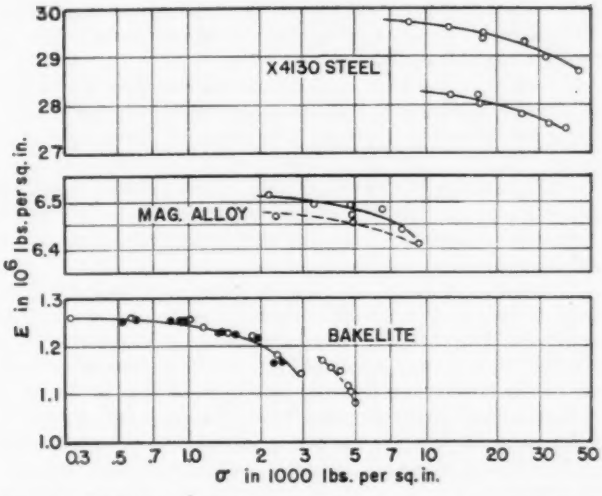

FIG. 10 DYNAMIC MODULUS OF ELASTICITY AS A FUNCTION OF DIRECT, I.E., TENSION-COMPRESSION, STRESS AMPLITUDE FOR S.A.E. X4130 STEEL, MAGNESIUM ALLOY J-1, AND LAMINATED BAKELITE

decrease with increasing stress amplitude. In the case of the steel the 5 per cent discrepancy between the two curves, obtained on supposedly identical specimens from the same piece of tubing, is of the same order of magnitude as the effect of variations noted in the wall thickness of the specimens. In the case of the magnesium the lower dotted curve was obtained after the material had been worked slightly in testing at the higher stresses. The discontinuity previously noted in the bakelite data at about 3000 psi is again apparent in the modulus.

DISCUSSION OF RESULTS

The behavior of materials under static or dynamic forces is governed by complex laws not expressible by simple exact relationships. However, in nearly every case this behavior can be represented approximately by simple, empirical relationships which have been found to possess sufficient accuracy for engineering purposes. Hooke's law and Poisson's ratio are good examples of approximate relationships which have been universally accepted for use in engineering calculations. While most mechanical properties of materials have been interrelated by such simple expressions, internal friction has not been so related to other properties due to the conflicting experimental results.

It is believed that the drawbacks of the experimental techniques commonly used in damping-capacity determinations have masked the existence of the general relationships such as were revealed by the tests in this paper. These tests were by no means exhaustive enough to warrant generalization for all materials under all possible conditions. The kinds of materials (ferrous and nonferrous metals, wood, and plastics) and ranges of stress amplitudes covered are felt to be complete enough to indicate a few of the general relationships applicable to internal friction. Under a great number of widely varying conditions, internal friction as measured by the damping capacity is subject to variations expressible by simple approximate rules to be discussed.

Stress Amplitude. For the engineering range of stresses, the damping capacity of a material (energy loss per unit volume per cycle) for completely reversed stress cycles is directly proportional to the third power of the stress amplitude. This third-power variation noted by Rowett and Dorey for steel in shear, applies equally well to other engineering materials under both shearing and normal stresses as long as the stress amplitude is below the yield strength. Whether or not a lower limit exists,

below which this variation does not hold, is beyond the scope of this paper for if such a limit exists it appears to be below the range of engineering interest.

If a material has been subjected to working effects at a particular stress amplitude, then the third-power variation may not apply for stresses in the immediate vicinity. Kutsay and Yorgiadis (22), as a result of tests on the effect of cold-work on the damping capacity of magnesium alloys, reported very significant discontinuities in the damping capacity versus stress relationships in the vicinity of the stress at which cold-working was done.

Frequency. Although the range of frequencies studied was too small to be used as the basis of definite conclusions, the data reported indicate that the damping capacity of materials is independent of frequency of stressing. This is in agreement with the results of the majority of investigators, at least in the range of engineering stresses, as noted in an earlier part of this paper.

Nature of Stress. For the two types of stress systems covered in these tests, the damping capacity of a material was found to be the same under shear stress as under normal (tension-compression) stress, provided the shear-stress amplitude was K times the normal-stress amplitude. Experimental values of the constant K obtained for six of the materials tested are presented in the last column of Table 1, and are seen to vary between 0.48 and 0.60. These are nearly equal to the value 0.577 which is the ratio of shear to normal stress to produce the same distortion energy.

The concept of the action of materials being related to the distortion energy as distinct from the energy associated with change of volume is well known in connection with the theories of failure. The theoretical derivation of the ratio between shear and normal stresses on this basis is given by Timoshenko (28). The value 0.577 is independent of Poisson's ratio or any other special property of the material and holds good for all isotropic materials obeying Hooke's law.

The agreement between the experimental stress ratios for equal damping capacity and the stress ratio for equal distortion energy is relatively good, since damping is a sensitive property that cannot be measured with great accuracy. It is therefore deduced that the damping capacity in isotropic materials is associated only with the distortion of the material and not with any change of volume under stress.

A few other experimenters have noted a correlation between damping under shear and normal stresses but have tried to correlate the damping capacity with shear stress and not distortion energy. Under this assumption the ratio K should be 0.500 and not 0.577. Föppl (3) presents data on a steel for which K is 0.570 and states that for other steels it varies between 0.53 and 0.60. These values were arrived at indirectly and are not felt to be conclusive.

The theory that distortion is the cause of inelastic behavior of materials (damping being one phase of inelasticity) is further evidenced by findings in the field of high pressures. Bridgeman (26) see also Nadai (27), has reported little or no yielding or permanent set (an inelastic action) in materials which have been subjected to exceedingly high hydrostatic pressures which cause no distortion energy, even though the acting pressures were many times the intensity of the yield strength observed under unidirectional stressing. If these materials had possessed internal friction of any magnitude under such a stress system, it would have manifested itself in the occurrence of a permanent set.

Conclusions

In the light of the experimental results presented, and the discussion of the results of others, the following conclusions appear to be justified:

Internal friction in materials, as represented by the damping capacity, is independent of the frequency, is proportional to the third power of the stress amplitude, and is due only to the distortion of the material.

Acknowledgment

The various metallic alloys studied were obtained through the co-operation of the following: The International Nickel Company, Inc., the Steel and Tubes Division of the Republic Steel Corporation; and the Dow Chemical Company. The tests were conducted in the Materials Testing Laboratory of the Pennsylvania State College, with equipment developed there by Dr. B. J. Lazan.

Appendix

Equations [3] and [6] by means of which the values of ΔW presented were determined from the experimental measurements are special cases of the relation for the work done by a harmonically varying force upon a harmonic motion of the same frequency. This relation is (29)

$$\text{Work per cycle} = \pi F a \sin \phi \quad [10]$$

where ϕ is the phase angle between the force and displacement.

In the experimental setups used in obtaining the data presented in this paper, mechanical energy was transmitted from the mechanical oscillator to the test specimen which absorbed all or nearly all of it. For the direct-stress-vibration case, the end away from the oscillator (W_1 end) had no energy-feeding device, and hence could only absorb energy. At the oscillator end the displacement was accurately measured and the forces acting were determined as to magnitude and phase relation. It was thus possible to determine accurately the energy supplied to the specimen. The major part of this energy was absorbed by the specimen as damping and the rest passed through the specimen to the support or to W_1.

At the oscillator end of the specimen two forces were acting; an inertia force A, due to the motion of mass W_2 (which included the oscillator and motor), and a force B, due to the rotating eccentrics on the oscillator. Force A was sinusoidal or very nearly so and in phase with the harmonic displacement. The phase angle in Equation [10] for this force was therefore zero, indicating that it did no work on the specimen. Force B was known from the weights and eccentricities of the rotating eccentrics and the oscillator speed. The phase angle between this force and the displacement a was obtained by direct observation, and the dynamics of the system adjusted until the angle was 90 deg. From Equation [10] the work done by this force on the specimen or the energy supplied to the specimen was

$$\text{Work per cycle} = \pi F a \sin 90 \text{ deg} = \pi F a \quad [11]$$

If Equation [11] is divided by the volume of the test specimen Equation [6] results. Equation [3] for the torsional tests is obtained in similar fashion.

It should be noted that in both the torsional- and direct-stress tests the electrical and mechanical losses in the electric motor and the mechanical oscillator in no way entered into the determination of the internal friction ΔW. The total energy absorbed by the system, i.e., the watts input to the electric motor, was considerably larger than the energy loss due to damping in the specimen but in none of the tests was this energy determined or measured.

One possible cause of error in the determinations of ΔW could be in the assumption that all of the energy supplied to the specimen was actually absorbed by damping. Some energy was

transmitted to the foundation of the apparatus. In the case of the tests in the horizontal-direct-stress apparatus there was little loss of energy to the foundation. The vibrating system in this case was free-floating, with the main vibratory forces of the masses not being transmitted to the supporting structure at all. This was because the masses were supported on the lightly loaded, highly polished, hardened rollers and rails. The coefficient of rolling friction for this roller-rails system was very small.

The torsional tests were performed on a system in which one end of the specimen was fixed to a relatively rigid structure. As noted under "Apparatus and Methods," difficulty was experienced in finding a rigid and heavy enough structure to which to attach the equipment. Some vibration was transmitted to this support, and it is believed that an error of significant magnitude could be introduced as a result of this loss, particularly in tests of specimens of low damping capacity.

The method used in measuring damping capacity is relatively new and untried. In order to obtain some idea of its reliability measurements were made on one material using the time-honored method of vibration decay. The tests were made on the $^3/_4$-in. monel tubing as it had one of the lowest damping characteristics of the materials studied and any extraneous losses as just discussed would be relatively more serious for it. The specimen used in the decay tests was cut from the same length of tubing as the specimens used with the oscillator. One end of the specimen was attached to a heavy rigid support with a collet chuck and the other end attached with a collet chuck to a rectangular metal bar having a moment of inertia about the specimen axis of 1340 lb-in.^{2} The specimen was vertical with the bar hanging from it. With a specimen length of 10 in., the natural frequency of the system was 7.6 cps.

The metal bar was first rotated through a certain small angle, so as to subject the specimen to a torsional load. The bar was then released, allowing it to oscillate angularly, subjecting the specimen to torsional oscillations which decayed because of damping in the specimen. The decay in amplitude of this torsional oscillation was measured as a function of the number of cycles. The amplitude a, at various numbers of cycles after the start of the oscillation, was plotted as a function of the number of cycles and the slope of this curve was taken for various values of a. The specific damping capacity was then obtained from the relation

$$\psi = \frac{2}{a}\frac{da}{dn} \qquad [12]$$

The unit shearing strain γ was obtained from the known values of length and diameter of the specimen, and the angular deformation of the bar at the end of the specimen.

The data thus obtained are presented in Fig. 11 together with similar data obtained with the mechanical-oscillator test apparatus at frequencies of 9 and 19 cps. The results seem to agree to a certain extent, although both sets of data show considerable scatter in the range of strains in which the decay data were taken It is probable that if a more refined apparatus had been used for the vibrations-decay method, the two sets of data would have been in closer agreement. This comparison of the data obtained by the two methods indicates that the oscillator method is at least as reliable as the commonly accepted method, and furthermore, that no serious energy losses were ignored in determining the damping capacity from the experimental data taken with the oscillator.

Concentrated-Force Problems in Plane Strain, Plane Stress, and Transverse Bending of Plates[1]

By P. S. SYMONDS,[2] WASHINGTON, D. C.

A general method is described for the solution of problems of transverse bending of thin plates acted on by concentrated normal forces, and of problems of plane stress or plane strain, in which concentrated forces are applied to the boundaries. The solution is taken in two parts: (*a*) The special functions which give the stresses or deflections in the neighborhood of the concentrated forces. (*b*) A complementary function, satisfying the appropriate biharmonic equation, such that the complete solution satisfies the boundary conditions of the problem. For certain types of boundaries, this complementary function can be determined by expanding the concentrated-force functions as infinite trigonometric series. Then by addition of general solutions of the appropriate biharmonic equation, the required boundary conditions may be satisfied. The method is first illustrated by solving the plate-bending problem, for which the solution is known, of a clamped circular disk loaded by a transverse force at any point. It is then applied to the problem of an infinite plate fixed at an inner circular boundary, with outer edge free, and loaded by a transverse force at any point. This solution is obtained in finite form, and typical curves of deflection, bending moments, and shear forces are given in Figs. 3 to 8, inclusive. Using this result, solutions are next obtained for ring-shaped plates of finite outer radius, with the force applied either at the outer edge or at any point between the inner clamped edge and the outer free edge. The former case was previously solved by H. Reissner. Curves comparing the maximum moments and shears in the infinite plate with those of the annular plate with force either at the outer edge, or inside the ring are given in Figs. 9 to 12, inclusive. Finally, a solution is given of the problem in plane stress of a large plate containing an elliptical hole, which is loaded by line forces at the ends of the minor axes of the ellipse. Curves showing results of this solution are given in Figs. 14 and 15.

Introduction

THE subject of this paper is the determination of stresses and displacements due to concentrated forces. The term "concentrated force" is used here in the sense of the mathematical abstraction, in which infinite force intensities acting over infinitesimal areas define finite point or line forces. The stresses and displacements calculated are therefore valid only at sufficiently great distances from the load points, according to Saint Venant's principle. Problems of transverse bending of thin plates loaded by normal point forces, and problems of plane stress or plane strain in which line forces are applied to boundaries may be treated by the method used here, which is of general application when the boundaries consist of concentric or nonconcentric circles, hyperbolas, or ellipses. The method makes use of the known functions which express the required singularities at the load points, appropriate to each of the two classes of problems considered. These functions are discussed briefly as follows:

In the Poisson-Kirchhoff theory of bending of thin plates (1, 2),[3] the stress couples and shears per unit length of arc are obtained in terms of the deflection w of the middle surface of the plate, w being a solution of the equation

$$D\nabla^4 w = p \qquad [1]$$

where $\nabla^4 = \partial^4/\partial x^4 + 2\partial^4/\partial x^2\partial y^2 + \partial^4/\partial y^4$, p is the transverse-load intensity, and $D = Eh^3/12(1 - \nu^2)$ is the plate "flexural rigidity." The following function gives the deflection in the neighborhood of a concentrated transverse force

$$w = \frac{F}{8\pi D} r^2 \log r \qquad [2]$$

This function is the singular part of the Green's function for a thin plate. It represents the deflection due to a transverse force F at the origin of co-ordinates r, θ, since the resultant of the vertical shear forces over any curve enclosing the origin is $-F$. Moments and shears per unit length of arc corresponding to Equation [2] are infinitely large at the origin. When plates of any shape and type of edge support are acted upon by concentrated transverse forces, the solution w consists of the foregoing function together with other functions, which are solutions of $\nabla^4 w = 0$ and are so chosen that the edge conditions of the particular problem are satisfied.

In the case of problems of plane stress or strain, the following stress functions specify the stress in the neighborhood of concentrated forces

$$\chi = -\frac{F}{\pi} r\theta \sin\theta \qquad [3]$$

$$\chi = -\frac{F}{2\pi} r\theta \sin\theta + F\frac{1-\nu}{4\pi} r \log r \cos\theta \qquad [4]$$

Both of these expressions represent the stresses due to a line force F per unit thickness placed at the origin of the polar co-ordinates r, θ, and acting in the positive direction of the initial line, $\theta = 0$. Equation [3] gives Michell's "simple radial distribution" (3) in which

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

$$\sigma_r = -\frac{2F}{\pi}\frac{\cos\theta}{r}$$

$$\sigma_\theta = \tau_{r\theta} = 0$$

All lines passing through the origin are free from stress, while the force resultant of the stresses on any semicircle with its center at the origin is equal to $-F$, in the direction of the initial line. However, the expressions for the displacements contain terms proportional to $\theta \sin\theta$, $\theta\cos\theta$, so that, if the displacements are not to be many-valued, the value of θ must be restricted to an interval, $\alpha \leq \theta \leq 2\pi - \alpha$. Equation [4] defines a stress system such that the force resultant of the stresses on any circle with center at the origin is equal to $-F$ in the direction of the initial line. However, the displacements corresponding to this function are single-valued for any range of θ. Both Equations [3] and [4] lead to infinite values of stress and displacement at the origin. Solutions of plane-strain or plane-stress problems in which concentrated forces act normal to boundaries of any shape must consist of either function, Equation [3] or Equation [4], to give the required singularities at each load point, plus other stress functions chosen so that the particular boundary conditions are satisfied.

One method which has been employed in problems of plane strain or stress, when concentrated forces are applied to boundaries, is that of expressing the stress distribution on the boundaries corresponding to the concentrated force as a Fourier series, in an angular co-ordinate appropriate to the problem. The required stress distributions on all boundaries can then be obtained by applying the known trigonometric series expressing the most general form of stress function in the co-ordinate system used. General stress functions have been developed in polar (4), elliptic (5), and bipolar co-ordinates (6), so that this method could be applied to problems in which boundaries are conveniently expressed by one of these co-ordinate systems.

An example of the application of this method is the solution by Filon (7) of the problem of a thin circular ring with isolated forces applied to the inner and outer edges in several ways. A general difficulty of this method, however, is the slow convergence of the series in the neighborhood of the forces, which makes numerical evaluation tedious if not impossible. This difficulty may be overcome, as was done by Filon in the case of the circular-ring problem, by summation of the slowly convergent part of the solution, but in other than polar co-ordinates this is generally not possible.

The method here presented avoids the difficulties of slow convergence by the use, in finite form, of the concentrated force functions appropriate to either plane problems or plate problems. It is shown how these functions may be readily expanded in the form of trigonometric series in a suitable co-ordinate system. Then by the addition of an auxiliary function, expressed as a trigonometric series in the same co-ordinates, the required values of stress or of displacement on the boundaries may be obtained.

This method is suitable for problems in which the boundary curves are expressed by the constancy of a co-ordinate of one of the three co-ordinate systems: polar, bipolar, or elliptic co-ordinates. The types of boundary curves conveniently expressed by these co-ordinate systems: are, respectively, concentric circles; nonconcentric circles (or a circle near an infinite straight line, or two circles of any radii and center distance); and hyperbolas or ellipses. The reason for the limitation of the method to problems in which one of these systems is employed is that, in each of these systems, the typical potential functions have the form

$$\phi = e^{\pm n\alpha}\cos n\beta$$

$$\phi = e^{\pm n\alpha}\sin n\beta$$

while the rectangular co-ordinates are given by functions of the type

$$x = f_1(\alpha)\cos\beta$$

$$y = f_2(\alpha)\sin\beta$$

Therefore, the typical biharmonic functions in these co-ordinate systems have the form

$$x = x\phi = g_1(\alpha)\cos\beta\begin{matrix}\cos n\beta\\ \sin n\beta\end{matrix}$$

$$X = y\phi = g_2(\alpha)\sin\beta\begin{matrix}\cos n\beta\\ \sin n\beta\end{matrix}$$

Thus, the typical harmonic and biharmonic functions may be easily written as trigonometric series in the curvilinear co-ordinate β.

1—APPLICATION TO TRANSVERSE BENDING OF PLATES

Clamped Circular Plate With Noncentral Force

A plate problem whose solution is known will be solved first as an illustration of the present method. This is the problem of a clamped circular disk loaded by a transverse force at an arbitrary point. The solution was first obtained in series form by Clebsch, and is quoted by Timoshenko (8). The solution was also obtained in finite form by Michell (9).

We write as the general form of solution

$$\frac{8\pi D}{F}w = r_1^2\log r_1 + w'(r,\theta) \qquad [5]$$

Here the term $r_1^2\log r_1$ gives the necessary singularity at the point of application of the force F (see Fig. 1), where r_1 is distance from the load point, while r, θ are polar co-ordinates with origin at the center of the plate. The term $w'(r,\theta)$ is an auxiliary function, satisfying $\nabla^4 w' = 0$, which enables us to obtain the boundary conditions.

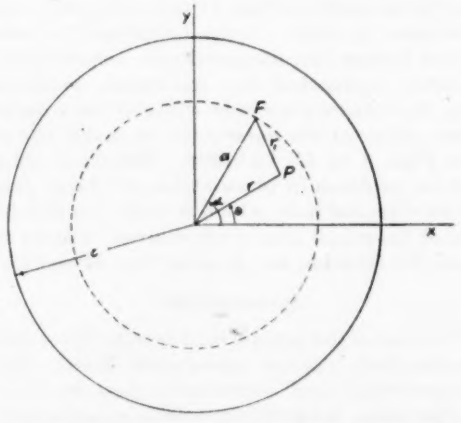

Fig. 1 Clamped Plate Loaded by Noncentral Force

We now write the term $r_1^2\log r_1$ in terms of r, θ, and express our result as an infinite trigonometric series. Two series are required, one valid for $r < a$ and the other for $r > a$. The point $P(a, \alpha)$ denotes the load point, while $P(r, \theta)$ is any point of the plate. We use the relation

$$r_1^2 = r^2 + a^2 - 2ar\cos(\theta - \alpha)$$

Regarding $\overline{OP}$, $\overline{PF}$, $\overline{OF}$ as vectors specified by the complex variable $z = x + iy = re^{i\theta}$

$$\overline{OP} = z = re^{i\theta}$$
$$\overline{OF} = z_0 = ae^{i\alpha}$$
$$\overline{PF} = z_0 - z = r_1 e^{i\phi}$$

It follows that

$$\log r_1 = Re[\log \overline{PF}] = Re[\log (z_0 - z)]$$

where Re denotes the real part of the expression in brackets. To obtain the series for $r < a$, we write

$$\log r_1 = Re\left[\log z_0 \left(1 - \frac{z}{z_0}\right)\right] = Re\left\{\log z_0 - \sum_{1,2..}^{\infty} \frac{1}{n}\left(\frac{z}{z_0}\right)^n\right\}$$

$$= \log a - \sum_{1,2..}^{\infty} \frac{1}{n}\left(\frac{r}{a}\right)^n \cos n\,(\theta - \alpha)$$

$$r_1^2 \log r_1 = [r^2 + a^2 - 2ar\cos(\theta - \alpha)]\left\{\log a - \sum_{1,2..}^{\infty} \frac{1}{n}\left(\frac{r}{a}\right)^n \cos n\,(\theta - \alpha)\right\}$$

We obtain, after reduction, the series
$(r < a)$

$$r_1^2 \log r_1 = (a^2 + r^2)\log a + r^2 + \left[-2ar\log a - \frac{1}{2}\frac{r^3}{a} - ar\right]\cos(\theta - \alpha)$$
$$+ a^2 \sum_{n=2,3..}^{\infty}\left\{\frac{1}{n(n-1)}\left(\frac{r}{a}\right)^n - \frac{1}{n(n+1)}\left(\frac{r}{a}\right)^{n+2}\right\} \cos n\,(\theta - \alpha) \ldots\ldots [6a]$$

The corresponding series for $r > a$ is obtained by writing $z_0 + \overline{FP} = z$, where $\overline{FP} = r_1 e^{i\phi'}$

$$\log r_1 = Re[\log \overline{FP}] = Re\left[\log z\left(1 - \frac{z_0}{z}\right)\right]$$

The following series is obtained
$(r > a)$

$$r_1^2 \log r_1 = a^2 + (a^2 + r^2)\log r + \left[-ar - \frac{1}{2}\frac{a^3}{r} - 2ar\log r\right]\cos(\theta - \alpha) + a^2 \sum_{n=2,3..}^{\infty}\left\{\frac{1}{n(n-1)}\left(\frac{a}{r}\right)^{n-2} - \frac{1}{n(n+1)}\left(\frac{a}{r}\right)^n\right\} \cos n\,(\theta - \alpha) \ldots [6b]$$

We now have to determine the auxiliary function $w'(r, \theta)$. This must be biharmonic, in the form of a trigonometric series in r, θ, which together with the series, Equations [6a] and [6b], satisfies the boundary conditions. These are that at the clamped edge $r = c$, $w = \dfrac{\partial w}{\partial r} = 0$; while at $r = 0$, w and its derivatives must be regular. A suitable function, satisfying $\nabla^4 w' = 0$, is

$$w'(r, \theta) = R_0 + \sum_{n=1,2..}^{\infty} R_n(r) \cos n\,(\theta - \alpha) \ldots\ldots [7]$$

where

$$R_0 = A_0 + B_0 r^2 + C_0 \log r + D_0 r^2 \log r$$
$$R_1 = A_1 r + B_1 r^3 + C_1 r^{-1} + D_1 r \log r$$

For $n \geq 2$

$$R_n = A_n r^n + B_n r^{-n} + C_n r^{n+2} + D_n r^{-n+2}$$

The constants A_n, B_n, etc., are to be determined by the boundary conditions.

To satisfy the conditions at $r = 0$, we must have

$$C_0 = D_0 = C_1 = D_1 = B_n = D_n = 0$$

The conditions at $r = c$ require

$$A_0 = \frac{c^2 - a^2}{2} - a^2 \log c$$

$$B_0 = -\frac{a^2}{2c^2} - \frac{1}{2} - \log c$$

$$A_1 = \frac{a^3}{c^2} + 2a \log c$$

$$B_1 = \frac{a}{c^2} - \frac{a^3}{2c^4}$$

$$A_n = \frac{a^2}{c^n}\left[\frac{1}{n}\left(\frac{a}{c}\right)^n - \frac{1}{n-1}\left(\frac{a}{c}\right)^{n-2}\right]$$

$$C_n = \frac{a^2}{c^{n+2}}\left[\frac{1}{n}\left(\frac{a}{c}\right)^{n-2} - \frac{1}{n+1}\left(\frac{a}{c}\right)^n\right]$$

The complete solution is therefore
$(r < a)$

$$\frac{8\pi D}{F} w = (a^2 + r^2)\log\frac{a}{c} + \frac{(c^2 + r^2)(c^2 - a^2)}{2c^2} - \frac{a^2}{2}\left[\frac{2r(c^2 - a^2)}{a^2 c^2} + \frac{r^3(a^2 - c^2)^2}{a^4 c^4} - \frac{4r}{a^2}\log\frac{c}{a}\right]\cos(\theta - \alpha)$$
$$+ \sum_{n=2,3..}^{\infty} \frac{a^n}{n(n-1)}\left\{\frac{r^n}{c^{2n}}\left[(n-1)a^2 - nc^2 + \frac{c^{2n}}{a^{2n-2}}\right] + (n-1)\frac{r^{n+2}}{c^{2n}}\left[1 - \frac{n}{n+1}\frac{a^2}{c^2} - \frac{1}{n+1}\frac{c^{2n}}{a^{2n}}\right]\right\}\cos n\,(\theta - \alpha) \ldots [8a]$$

$(r > a)$

$$\frac{8\pi D}{F} w = (a^2 + r^2)\log\frac{r}{c} + \frac{(a^2 + c^2)(c^2 - r^2)}{2c^2} - \frac{a^2}{2}\left[\frac{1}{r} - \frac{4}{a^2} r\log\frac{c}{r} + \frac{2r(c^2 - a^2)}{a^2 c^2} - \frac{r^3(2c^2 - a^2)}{a^2 c^4}\right]\cos(\theta - \alpha)$$
$$+ \sum_{n=2,3..}^{\infty} \frac{a^n}{n(n-1)}\left\{\frac{r^n}{c^{2n}}\left[(n-1)a^2 - nc^2 + (n-1)r^2 - \frac{n(n-1)}{n+1}\frac{a^2 r^2}{c^2}\right] + \frac{1}{r^n}\left[r^2 - \frac{n-1}{n+1}a^2\right]\right\}\cos n\,(\theta - \alpha) \ldots [8b]$$

This result is the same as that of Clebsch quoted by Timoshenko (8).[4]

[4] There is a discrepancy which is obviously due to a typographical error. Timoshenko gives $\frac{4r}{a^2}\log\frac{c}{r}\cos(\theta - \alpha)$ in the series for $r < a$ instead of $\frac{4r}{a^2}\log\frac{c}{a}\cos(\theta - \alpha)$. The former would lead to a singularity in $\frac{\partial w}{\partial r}$ at $r = 0$, which is inadmissible.

Large Plate Clamped at Inner Circular Boundary

The solution of the problem of an infinitely large plate clamped at an inner circular edge, with outer edge free, and loaded by a concentrated force at an arbitrary point, will now be obtained. From this result the solutions are found for finite ring-shaped plates, with the concentrated force applied either at the outer edge or at any point between the edges.

Taking first the case of the infinite plate, we write, as in the problem just solved

$$\frac{8\pi D}{F} w = r_1^2 \log r_1 + w'(r, \theta) \quad \ldots\ldots\ldots\ldots [5]$$

where, as before, r_1 is the distance from the load point F, r, θ are polar co-ordinates with origin at the center of the inner circle (see Fig. 2), and w' is a biharmonic function such that the required

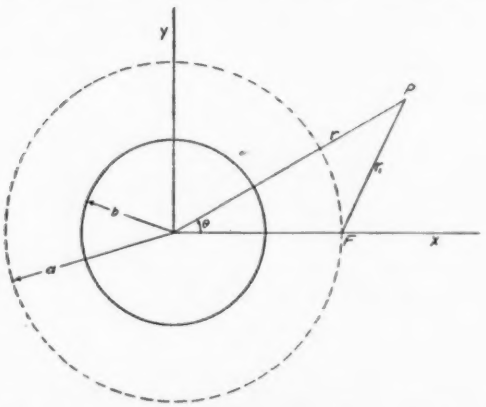

Fig. 2 Infinite Plate Clamped at Circular Edge

edge conditions are obtained. The term $r_1^2 \log r_1$ is taken in the form of Equations [6a], [6b], and the auxiliary function w' as given by Equation [7]. The boundary conditions at the clamped edge ($r = b$) are $w = \dfrac{\partial w}{\partial r} = 0$. At the outer edge ($r \to \infty$) the conditions are

$$V_n = Q_n - \frac{\partial M_{nt}}{\partial s} = 0$$

$$M_n = 0$$

where M_n, M_{nt} are bending and twisting moments, respectively, and Q_n is the shear force, all taken per unit length of arc; the co-ordinate axes n, t being normal and tangential, respectively, to the edge. These conditions are easily obtained in the case of an infinitely large plate, the solution being independent of the particular boundary curve of the outer edge. To satisfy the conditions at the outer edge, we must have $B_0 = B_1 = A_n = C_n = 0$, $D_0 = -1$, $D_1 = 2a$. To satisfy the conditions at the clamped edge we require

$$A_0 = 2b^2 \log b \left(1 + \log \frac{a}{b}\right) - (a^2 + b^2) \log a - b^2$$

$$C_0 = -b^2 \left[1 + 2 \log \frac{a}{b}\right]$$

$$A_1 = \frac{b^2}{a} + 2a \log \frac{a}{b}$$

$$C_1 = ab^2 - \frac{b^4}{2a}$$

$$B_n = b^{n+2} \left[\frac{1}{n}\left(\frac{\ }{a}\right)^{n} - \frac{1}{n+1}\left(\frac{b}{a}\right)^{n}\right]$$

$$D_n = b^n \left[\frac{1}{n}\left(\frac{b}{a}\right)^{n} - \frac{1}{n-1}\left(\frac{b}{a}\right)^{2}\right]$$

Substituting these values in the general solution, and introducing the dimensionless variables

$$\rho = \frac{r}{b}, \qquad q = \frac{a}{b}$$

the following solution is obtained

$(r < a, \rho < q)$

$$\left.\begin{aligned}\frac{8\pi D}{Fb^2} w = {} & (\log q + 1)(\rho^2 - 1) - [\rho^2 + 1 + 2 \log q] \log \rho \\ & + \left[(q^{-1} - q)\rho - \frac{1}{2} q^{-1}\rho^3 + \left(q - \frac{1}{2} q^{-1}\right)\rho^{-1} \right. \\ & \left. + 2q\rho \log \rho \right] \cos\theta + \sum_{n=2,3..}^{\infty} \left\{ \frac{q^{-n+2}}{n(n-1)} \rho^n \right. \\ & - \frac{q^{-n}}{n(n+1)} \rho^{n+2} + \left(\frac{q^{-n+2}}{n} - \frac{q^{-n}}{n+1}\right)\rho^{-n} \\ & \left. + \left(\frac{q^{-n}}{n} - \frac{q^{-n+2}}{n-1}\right)\rho^{-n+2} \right\} \cos n\theta\end{aligned}\right\} \quad \ldots [9a]$$

$(r > a, \rho > q)$

$$\left.\begin{aligned}\frac{8\pi D}{Fb^2} w = {} & q^2 - 1 - (q^2 + 1) \log q + (q^2 - 1 \\ & - 2 \log q) \log \rho + \left[(q^{-1} - q + 2q \log q)\rho \right. \\ & \left. + \left(q - \frac{1}{2} q^3 - \frac{1}{2} q^{-1}\right)\rho^{-1} \right] \cos\theta \\ & + \sum_{n=2,3..}^{\infty} \left\{ \left(\frac{q^n}{n(n-1)} + \frac{q^{-n}}{n} - \frac{q^{-n+2}}{n-1}\right)\rho^{-n+2} \right. \\ & \left. + \left(\frac{q^{-n+2}}{n} - \frac{q^{n+2}}{n(n+1)} - \frac{q^{-n}}{n+1}\right)\rho^{-n} \right\} \cos n\theta\end{aligned}\right\} \quad \ldots [9b]$$

It may be verified that the foregoing result satisfies the boundary conditions and that the two solutions Equations [9a] and [9b] have proper values at the load circle $r = a$. At this circle the functions w, $\dfrac{\partial w}{\partial r}$, M_r are continuous, but the shear resultant

$$V_r = Q_r - \frac{1}{r} \frac{\partial M_{r\theta}}{\partial \theta}$$

is discontinuous due to the presence of the force. It may be checked that the solutions, Equations [9a], [9b] give, in the limit as r approaches a

$$\lim_{r \to a} \left[(V_r)_{r>a} - (V_r)_{r<a} \right] = -\frac{F}{\pi a} \left[\frac{1}{2} + \sum_{1,2..}^{\infty} \cos n\theta \right]$$

This is the Fourier series representing the concentrated force F as a line loading on the circle $r = a$.

The series appearing in Equations [9] may be summed, the series terms all being similar to the following

$$S_1 = \sum_{2,3..}^{\infty} \frac{q^n}{n(n-1)} \frac{\cos n\theta}{\rho^{n-2}} = \rho^2 \sum_{2,3..}^{\infty} \frac{x^n}{n(n-1)} \cos n\theta$$

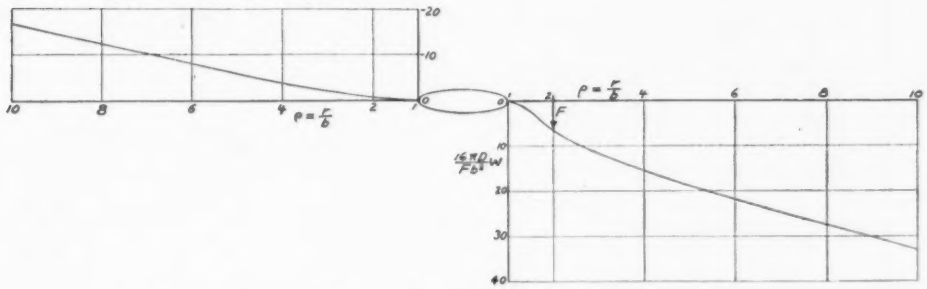

FIG. 3 INFINITE PLATE: DEFLECTION ALONG LINE, $y = 0$; $q = 2$

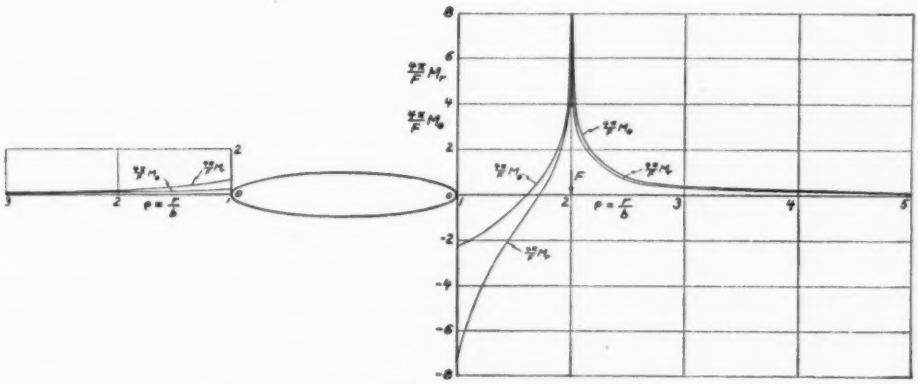

FIG. 4 INFINITE PLATE: BENDING MOMENTS ALONG LINE, $y = 0$; $q = 2$

where $x = \dfrac{a}{r} < 1$. Writing $z = xe^{i\theta}$ this is given by

$$S_1 = \rho^2 Re[(1-z)\log(1-z) + z]$$

where Re denotes "real part of." After summing, by methods similar to this, all the series terms in Equations [9], the following expression is obtained for both Equations [9a] and [9b]

$$\frac{8\pi D}{Fb^2} w = \frac{1}{2}(q^2 + \rho^2 - 2q\rho\cos\theta)\log\frac{q^2+\rho^2-2q\rho\cos\theta}{1+q^2\rho^2-2q\rho\cos\theta} + (q^2-1)\log\rho + (\rho^2-1)\log q - 2\log q\log\rho \quad [10]$$

Curves showing the deflection w along the central line ($\theta = 0$, π) are given in Fig. 3, for $q = \dfrac{a}{b} = 2$. The deflection under the load is given by

$$w(a, 0) = \frac{Fb^2}{4\pi D}\log q(q^2 - 1 - \log q)$$

The slopes at great distances from the clamped edge (neglecting terms in q/ρ compared to unity) are

$$\frac{\partial w}{\partial x} = \frac{Fb}{8\pi D} \times q\left(\log q^2 - 1 + \frac{1}{q^2}\right), \qquad \frac{\partial w}{\partial y} = 0$$

These show that the deflection surface of the plate, far from the clamped circle, is a plane inclined to the undeflected surface. The strain energy of the plate is concentrated in a relatively small region including the clamped edge and the load point.

Curves[5] showing the bending moments M_r, M_θ, on the central line ($\theta = 0, \pi$) are given in Fig. 4, for $q = 2$. Plots of Q_r, V_r on the same line are given in Figs. 5, 6. The variation of M_r, Q_r along the clamped edge ($r = b$) is shown in Figs. 7, 8. The curves of Figs. 9, 10 show the maximum values of the bending moment M_r and shear Q_r (at $r = b$, $\theta = 0$) as functions of $q = a/b$; these are given by the following expressions

$$(M_r)_{max} = (M_r)_{\substack{r=b\\ \theta=0}} = -\frac{F}{2\pi}(1 + q + \log q)$$

$$(Q_r)_{max} = (Q_r)_{\substack{r=b\\ \theta=0}} = \frac{F}{2\pi b}\frac{(1+q)^2}{q-1}$$

The finite form of the solution of this problem suggested that it might be obtainable directly, rather than by the series method. This was found to be the case. In Appendix 1 is outlined a solution of the problem by means of an inversion transformation, making use of the solution of Michell for the problem of a clamped circular plate loaded by a noncentral transverse force.

SOLUTIONS FOR PLATES WITH FINITE OUTER RADIUS

The solution for an infinite plate, Equation [10] can be used to obtain solutions for ring-shaped plates of finite outer radius, with the force applied either at the outer edge or at any point between the inner clamped edge and the outer edge. The first case, in which the force is applied at the outer boundary, was solved by H. Reissner (10). The method used by Reissner was that of applying directly the general series solution, Equation [7], and determining the constants A_n, etc., so as to obtain the required conditions at the inner and outer radii, which are as follows

[5] In all calculations Poisson's ratio ν has been taken as 0.3. Expressions for bending moments and shears are given in reference (2), p. 259.

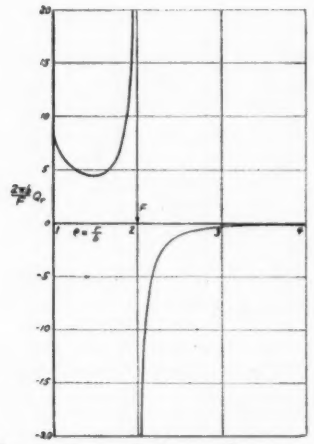

FIG. 5 SHEAR Q_r ALONG LINE $y = 0$
(Infinite plate, $q = 2$.)

$$\left.\begin{aligned} (w)_{r=b} &= \left(\frac{\partial w}{\partial r}\right)_{r=b} = 0 \\ (M_r)_{r=a} &= 0 \\ (V_r)_{r=a} &= \left(Q_r - \frac{1}{r}\frac{\partial M_{r\theta}}{\partial \theta}\right)_{r=a} = \frac{F}{\pi a}\left[\frac{1}{2} + \sum_{n=1,2..}^{\infty} \cos n\theta\right] \end{aligned}\right\} \quad ..[11]$$

where b, a are inner and outer radii, respectively. However, the same results can be obtained by making use of the solution just found for the infinite plate, in closed form (Equation [10]), to express the singularity in V_r at the outer edge. This solution, when evaluated at $r = a$, $(\rho = q)$, leads to shears V_r in addition to those corresponding to the force F, and to a distribution of bending moments M_r. These additional shears and moments

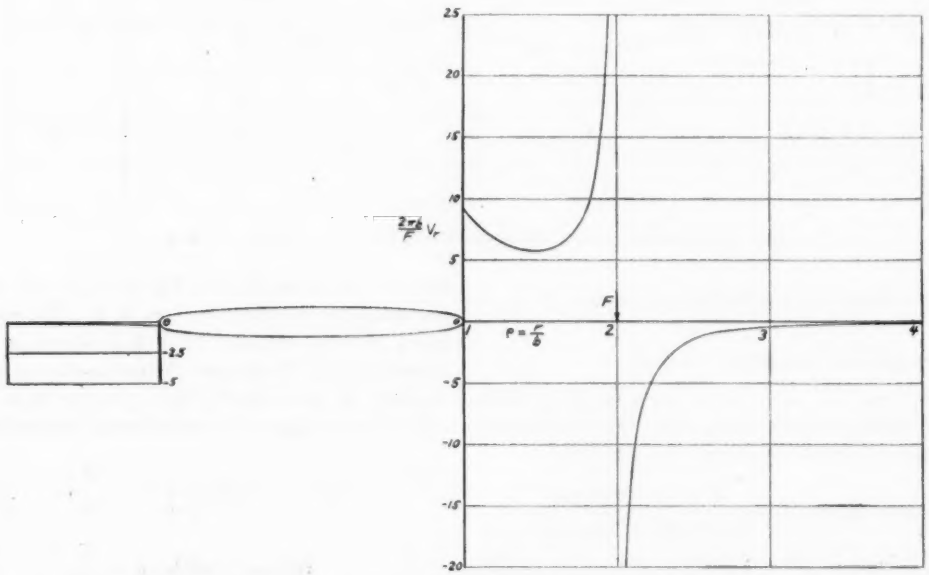

FIG. 6 INFINITE PLATE: RESULTANT SHEAR V_r ALONG LINE $y = 0$; $q = 2$

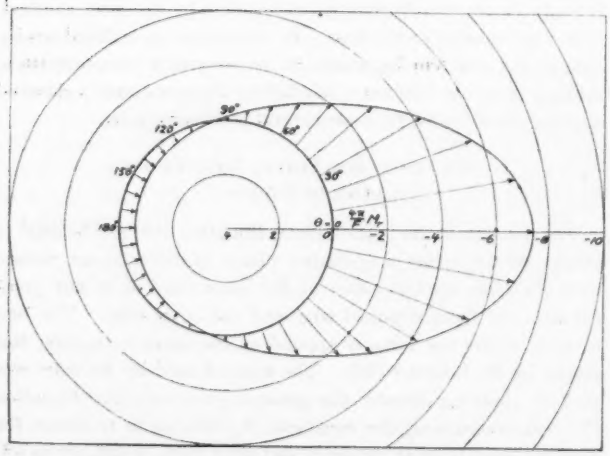

FIG. 7 BENDING MOMENT AT CLAMPED EDGE, $r = b$
(Infinite plate, $q = 2$.)

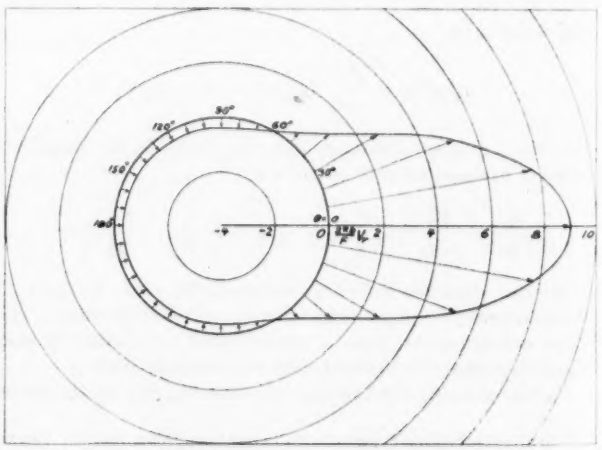

FIG. 8 SHEAR AT CLAMPED EDGE, $r = b$
(Infinite plate, $q = 2$.)

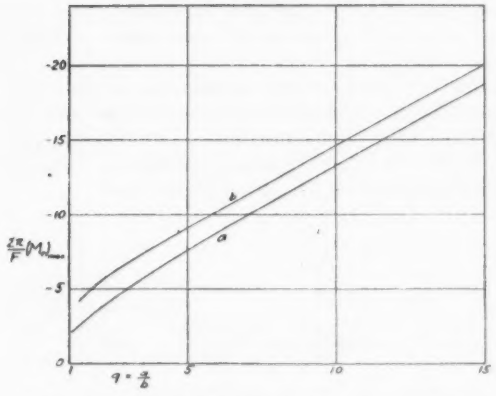

FIG. 9 MAXIMUM BENDING MOMENT (M_r AT $r = b$, $\theta = 0$) AS FUNCTION OF q = Ratio $\frac{\text{Distance of Force From Center of Clamped Circle}}{\text{Radius of Clamped Circle}}$
(Curve *a*, infinite plate; Curve *b*, force applied at edge of plate.)

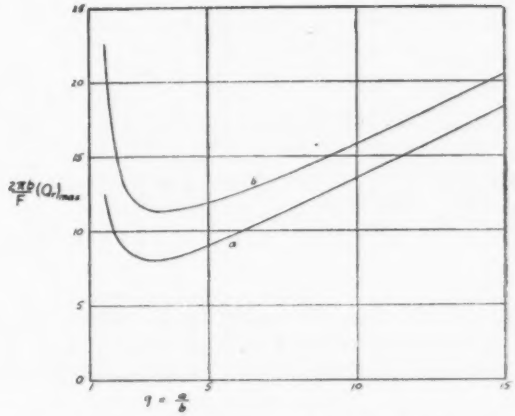

FIG. 10 MAXIMUM SHEAR (Q_r AT $r = b$, $\theta = 0$) AS FUNCTION OF q = Ratio $\frac{\text{Distance of Force From Center of Clamped Circle}}{\text{Radius of Clamped Circle}}$
Curve *a*, infinite plate; Curve *b*, force applied at edge of plate.)

may be expressed as trigonometric series by evaluating the series form of solution of the infinite-plate problem, (obtained for $r < a$), Equation [9a], at $r = a$. They may then be annulled by applying the general series solution in polar co-ordinates, and determining the coefficients A_n, etc., so as to give conditions, Equations [11]. In this method, the shear and moment distributions which must be annulled by the general series solution are small and are rapidly convergent, and the contribution to the moments and shears in the plate of the auxiliary solution is small compared to that of the infinite-plate solution, which is easily calculated since it is given in finite form. Hence the labor of the calculation is probably considerably less than that required in Reissner's method, in which the general series solution is itself employed to obtain the singularity at the outer boundary.

The solution of Reissner's problem, using the present method, is obtained as follows: We take the solution in the form

$$w = 2w_1 + w_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

where w_1 is the solution previously obtained for an infinite plate, given by either Equation [9a] or Equation [10], and w_2 is the general biharmonic solution, Equation [7]. The function $2w_1$ leads to the following expressions for M_r and

$$V_r = Q_r - \frac{1}{r}\frac{\partial M_{r\theta}}{\partial \theta}$$

on the circle $r = a(\rho = q)$

$$(M_{r1})_a = \frac{F}{\pi}\frac{1-\nu}{4}\left\{1 - (1 + 2\log q)q^{-2} + (1 - q^{-2})^2\cos\theta + \sum_{2,3..}^{\infty}\left(2\frac{1+\nu}{1-\nu}\left[\frac{1}{n} + \left(1 - q^2 - \frac{1}{n}\right)q^{-2n}\right] + n(q - q^{-1})^2 q^{-2n}\right)\cos n\theta\right\} \quad [13a]$$

$$(V_{r1})_a = \frac{F}{\pi a}\left\{\frac{1}{2} + \sum_{1,2..}^{\infty}\cos n\theta + \frac{1}{2} + \sum_{1,2..}^{\infty}\left[nq^2 - n + 1 + \frac{1-\nu}{4}n^2(q - q^{-1})^2\right]q^{-2n}\cos n\theta\right\} \quad [13b]$$

The arbitrary constants of the auxiliary solution w_2 are now determined so as to annul the foregoing expression for $(M_{r1})_a$ and to annul all but the first two terms in the expression for $(V_{r1})_a$ which express the required singularity due to the applied force at the outer boundary. In addition, the conditions $(w_2)_{r=b} = \left(\frac{\partial w_2}{\partial r}\right)_{r=b} = 0$ must be satisfied. After solving for the constants A_n, B_n, etc., and substituting in Equation [12], the following complete solution is obtained

$$\left.\begin{aligned}\frac{8\pi D}{Fb^2}w = {} & (q^2 + \rho^2 - 2q\rho\cos\theta)\log\frac{q^2 + \rho^2 - 2q\rho\cos\theta}{1 + q^2\rho^2 - 2q\rho\cos\theta} \\ & + 2(\rho^2 - 1)\log q + 2(q^2 - 1)\log\rho - 4\log q\log\rho \\ & + (\rho^2 - 1)\log\rho + \frac{1}{2} \\ & \times\left\{\frac{1 + 3\nu + 3(1-\nu)q^{-2} + 2\log q[1 + \nu + 2(1-\nu)q^{-2}]}{1 + \nu + (1-\nu)q^{-2}}\right\} \\ & \times(1 - \rho^2 + 2\log\rho) + \left\{\left[\frac{2q^{-1} - (1-\nu)(1-q^{-2})q^{-3}}{3 + \nu + (1-\nu)q^{-4}}\right]\right. \\ & \times(\rho^3 - 2\rho + \rho^{-1}) + q(\rho - \rho^{-1} \\ & \left. - 2\rho\log\rho)\right\}\cos\theta + 8\sum_{n=2,3..}^{\infty}\left\{K_n\left[\frac{\rho^{n+2}}{n+1} - \frac{\rho^n}{n}\right.\right. \\ & \left.\left. + \frac{\rho^{-n}}{n(n+1)}\right] - L_n\left[\frac{\rho^n}{n(n-1)} - \frac{\rho^{-n+2}}{n-1} + \frac{\rho^{-n}}{n}\right]\right\}\cos n\theta\end{aligned}\right\} \quad \ldots\ldots\ldots [14]$$

Here the constants K_n, L_n ($n \geqslant 2$) in the series expression are the solutions of the pairs of simultaneous equations

$$\left.\begin{aligned}f_nK_n + g_nL_n &= \alpha_n \\ h_nK_n + k_nL_n &= \beta_n\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [15]$$

where

$$f_n(q) = -2\frac{1+\nu}{1-\nu} - q^{-2} - n - q^{-2n-2} + nq^{-2}$$

$$g_n(q) = q^{-2} + (n+1)q^{-2n-2} + 2\frac{1+\nu}{1-\nu}q^{-2n} - nq^{-2n}$$

$$h_n(q) = -2\frac{1+\nu}{1-\nu} - 2 + q^{-2} - nq^{-2} - q^{-2n-2} + n$$

$$k_n(q) = -q^{-2} - 2 - n - 2\frac{1+\nu}{1-\nu}q^{-2n} + (n+1)q^{-2n-2}$$

$$\alpha_n(q) = -\frac{1}{2}\frac{1+\nu}{1-\nu}\frac{q^{-n}}{n} + \frac{1}{2}\frac{1+\nu}{1-\nu}\left(q^2 - 1 + \frac{1}{n}\right)q^{-2n} - \left(\frac{q-q^{-1}}{2}\right)^2 nq^{-2n}$$

$$\beta_n(q) = -q^{-1}\left[\frac{1}{1-\nu}\left(q^2 - 1 + \frac{1}{n}\right)nq^{-2n} + \left(\frac{q-q^{-1}}{2}\right)^2 n^2q^{-2n}\right]$$

The maximum values of M_r and Q_r for this problem (occurring at $r = b$, $\theta = 0$) are shown in Figs. 9, 10, as functions of $q = a/b$. These maximum values are given by the following expressions

$$(M_r)_{max} = \frac{F}{\pi}\left\{-(1 + q + \log q) - \frac{1}{2} + \frac{1}{4}\frac{1 + 3\nu + 3(1-\nu)q^{-2} + 2[1 + \nu + 2(1-\nu)q^{-2}]\log q}{1 + \nu + (1-\nu)q^{-2}} + \frac{1}{2}q - \frac{2q^{-1} - (1-\nu)(1-q^{-2})q^{-2}}{3 + \nu + (1-\nu)q^{-4}} - 4\sum_{2,3\ldots}^{\infty}(K_n - L_n)\right\} \quad \ldots\ldots [16]$$

$$(Q_r)_{max} = \frac{F}{\pi b}\left\{\frac{(1+q)^2}{q-1} - \frac{1}{2} - \frac{1}{2}q - \frac{2q^{-1} - (1-\nu)(1-q^{-2})q^{-2}}{3 + \nu + (1-\nu)q^{-4}} - 4\sum_{2,3\ldots}^{\infty} n(K_n + L_n)\right\} \quad \ldots\ldots [17]$$

where the constants K_n, L_n, etc., are determined by Equations [15]. As an example of the relative magnitudes of the contributions from the infinite-plate solution $2w_1$ and from the auxiliary function w_2, the calculation of $(M_r)_{max}$ for the case $q = a/b = 1.5$ gives the following results

$$(M_{r1})_{max} = \frac{F}{2\pi}(-5.8110)$$

$$(M_{r2})_{max} = \frac{F}{2\pi}(0.3629 + 0.7915 + 0.1342) = \frac{F}{2\pi}(1.2887)$$

$$(M_r)_{max} = -4.522\frac{F}{2\pi}$$

(This is the case calculated by Reissner, who gives the value $[M_r]_{max} = -4.45F/2\pi$). The contribution of all the series terms for $n \geq 2$ (0.1342) is less than 3 per cent of the value of $(M_r)_{max}$. It is interesting to note that the maximum bending moment found for the case when the force is applied at the outer edge is considerably greater than that found for the case when the force acts at the same distance from the clamped edge, but the plate extends a large distance beyond the load point (for example, for $a/b = 1.5$, these values are $\frac{2\pi}{F}(M_r)_{max} = -4.522, -2.905$, respectively).

The intermediate cases, when the outer circular edge is at a finite distance from the load point, will be considered below.

The solution of the problem of a ring-shaped plate, clamped at its inner edge $r = b$ and free at the outer edge $r = c$, and loaded by a concentrated force at any point $r = a$, where $b < a < c$, may also be obtained by modifying the solution for the infinite plate previously found. The required solution is the sum of the infinite-plate solution, Equation [10], and the general series solution, Equation [7], where the arbitrary constants of Equation [7], are now determined so as to give the conditions

$$\left.\begin{aligned}(w)_{r=b} &= \left(\frac{\partial w}{\partial r}\right)_{r=b} = 0\\ (M_r)_{r=c} &= 0\\ (V_r)_{r=b} &= \left(Q_r - \frac{1}{r}\frac{\partial M_{r\theta}}{\partial \theta}\right)_{r=b} = 0\end{aligned}\right\} \quad \ldots\ldots [18]$$

The typical curves for M_r, V_r (Figs. 4, 6) from the infinite-plate solution show that these both decrease rapidly to zero beyond the load point. Hence, in the solution for plates with finite outer radius, the contribution from the auxiliary solution, required to annul M_r, V_r on $r = c$, will be small compared to that of the infinite-plate solution, unless the outer edge is very close to the load point.

The complete solution is

$$w = w_1 + w'$$

where w_1 is the infinite-plate solution, given by Equation [10] and w' is taken in the form of Equation [7].

The distributions of M_r, V_r which must be annulled are obtained from the series form of the infinite-plate solution, valid, for $r > a$ ($\rho > q$), Equation [9b]. These are evaluated at $r = c$ ($\rho = c/b = s$), and annulled by means of w'. After calculating the constants A_n, B_n, etc. and simplifying, the complete solution is found to be

$$\left.\begin{aligned}\frac{8\pi D}{Fb^2}w = {} & \frac{1}{2}(q^2 + \rho^2 - 2q\rho\cos\theta)\log\frac{q^2 + \rho^2 - 2q\rho\cos\theta}{1 + q^2\rho^2 - 2q\rho\cos\theta} + (q^2 - 1)\log\rho\\ & + (\rho^2 - 1)\log q - 2\log q\log\rho\\ & + \frac{(q^2 - 1 - 2\log q)(\rho^2 - 1 - 2\log\rho)}{2\frac{1+\nu}{1-\nu}s^2 + 2} + \frac{(q^3 - 2q + q^{-1})(\rho^3 - 2\rho + \rho^{-1})}{2\frac{3+\nu}{1-\nu}s^4 + 2}\cos\theta\\ & + \sum_{n=2,3\ldots}^{\infty}\left\{P_n\left[\frac{\rho^{n+2}}{n+1} - \frac{\rho^n}{n} + \frac{\rho^{-n}}{n(n+1)}\right] - Q_n\left[\frac{\rho^n}{n(n-1)} - \frac{\rho^{-n+2}}{n-1} + \frac{\rho^{-n}}{n}\right]\right\}\cos n\theta\end{aligned}\right\} \quad \ldots [19]$$

where $\rho = r/b$, $q = a/b$, $s = c/b$, and the quantities P_n, Q_n are determined from the simultaneous equations

$$\left.\begin{aligned}f_nP_n + g_nQ_n &= \phi_n\\ h_nP_n + k_nQ_n &= \psi_n\end{aligned}\right\} \quad \ldots\ldots [20]$$

where

$$f_n(s) = -2\frac{1+\nu}{1-\nu} - s^{-2} - n - s^{-2n-2} + ns^{-2}$$

$$g_n(s) = s^{-2} + (n+1)s^{-2n-2} + 2\frac{1+\nu}{1-\nu}s^{-2n} - ns^{-2n}$$

$$h_n(s) = -2\frac{1+\nu}{1-\nu} - 2 + s^{-2} - ns^{-2} - s^{-2n-2} + n$$

$$k_n(s) = -s^{-2} - 2 - n - 2\frac{1+\nu}{1-\nu}s^{-2n} + (n+1)s^{-2n-2}$$

$$\phi_n = s^{-2n}\left\{\left(1 - \frac{2}{n}\frac{1+\nu}{1-\nu}\right)[q^n + (n-1)q^{-n} - nq^{-n+2}] + [(n+1)q^{-n+2} - q^{n+2} - nq^{-n}]\,s^{-2}\right\}$$

$$\psi_n = s^{-2n}\left\{\left(1 + \frac{4}{n(1-\nu)}\right)[q^n + (n-1)q^{-n} - nq^{-n+2}] + [(n+1)q^{-n+2} - q^{n+2} - nq^{-n}]\,s^{-2}\right\}$$

The maximum values of M_r, Q_r (at $r = b$, $\theta = 0$) are given by the following expressions

$$(M_r)_{max} = \frac{F}{2\pi}\left\{-(1 + q + \log q) - \frac{q^3 - 1 - 2\log q}{2\dfrac{1+\nu}{1-\nu}s^2 + 2} - \frac{q^3 - 2q + q^{-1}}{\dfrac{3+\nu}{1-\nu}s^4 + 1} - \sum_{2,3..}^{\infty}(P_n - Q_n)\right\} \quad [21]$$

$$(Q_r)_{max} = \frac{F}{2\pi b}\left\{\frac{(1+q)^2}{q-1} - \frac{q^3 - 2q + q^{-1}}{\dfrac{3+\nu}{1-\nu}s^4 + 1} - \sum_{2,3...}^{\infty} n(P_n + Q_n)\right. \quad [22]$$

The interesting feature of the curves of Figs. 11, 12, which show these maximum values as functions of $s/q = c/a$ for the cases $q = 1.5, 2.0$, is the rapid decrease of $(M_r)_{max}$ and $(Q_r)_{max}$ when the plate extends only slightly beyond the load point. For example, the calculation for $q = a/b = 1.50$, $s = c/b = 1.55$, gives

$$\frac{c}{a} = \frac{1.55}{1.50} = 1.034; \quad \frac{2\pi}{F}(M_r)_{max} = -2.905 - .391 = -3.296$$

so that the maximum bending moment already differs by less than 15 per cent from the value which it would have if the plate extended indefinitely beyond the load point (—2.905); the value of $\frac{2\pi}{F}(M_r)_{max}$ found for the case when the force was applied directly to the outer edge was —4.522.

Ratio $\frac{\text{Radius of Outer Free Edge}}{\text{Distance of Force From Center of Clamped Circle}}$

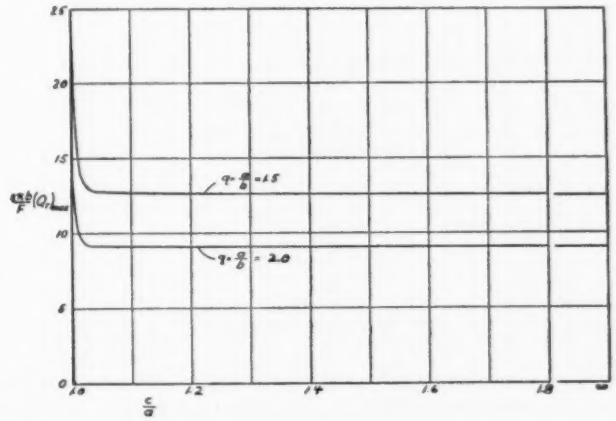

FIG. 12 MAXIMUM SHEAR (Q_r AT $r = b$, $\theta = 0$) AS FUNCTION OF c/a = RATIO $\frac{\text{RADIUS OF OUTER FREE EDGE}}{\text{DISTANCE OF FORCE FROM CENTER OF CLAMPED CIRCLE}}$

2 APPLICATION TO PLANE STRESS AND PLANE STRAIN

The solution will now be given for the problem of determining the stress in an infinite plate containing an elliptical hole, loaded by a pair of concentrated forces acting at the ends of the minor axes of the ellipse.

We require a stress function X which satisfies the equation of plane stress (or plane strain), $\nabla^4 X = 0$, and which leaves the ellipse free from stress everywhere except at the load points, where the normal stress is infinite in such a way that the resultant force over an arc including each load point is equal to $-F$. We write the solution in the form (see Fig. 13)

$$X = -\frac{F}{\pi}x\theta_1 - \frac{F}{\pi}x\theta_2 + X'(x, y) \quad [23]$$

The stress functions $-\frac{F}{\pi}x\theta_1$, $-\frac{F}{\pi}x\theta_2$ are those for concentrated normal forces at $z_1 = ib$, $z_2 = -ib$, while $X'(x, y)$ is an auxiliary biharmonic function, chosen so that the required stress conditions on the ellipse are satisfied. Although the stress function $\frac{F}{\pi}x\theta$ leads to many-valued displacements, it was shown by Michell (3), as a result of a general theory of dislocations, that when these functions are written for several forces acting at a hole in a plate the resultant dislocations vanish, provided the forces are in equilibrium among themselves. In the present case the forces are self-equilibrating, so that the simple radial stress functions are suitable.

In order to determine the function X' the concentrated-force functions are expanded in trigonometric series in elliptic co-ordinates ξ, η, such that η is an angular co-ordinate, while the distribution of stresses over any elliptical contour will be obtained by assigning to the other co-ordinate a constant value, $\xi = \xi_1$. In particular, the stresses on an ellipse $\xi = \xi_0$ passing through the load points $z = \pm ib$ are obtainable. Since the general solution of the biharmonic equation, $\nabla^4 X = 0$, leads to stresses expressible in the same form

$$\sigma_\xi = f(\xi)\begin{Bmatrix}\cos n\eta \\ \sin n\eta\end{Bmatrix}, \quad \tau_{\xi\eta} = g(\xi)\begin{Bmatrix}\cos n\eta \\ \sin n\eta\end{Bmatrix}$$

suitable functions of this type may now be added in order to annul all stresses on the ellipse ξ_0 except those corresponding to concentrated forces normal to the elliptical boundary, at the load points.

In expanding the radial stress functions, we use the conformal transformation

$$z = c\cosh\zeta$$

where

$$z = x + iy = re^{i\theta};\ \zeta = \xi + i\eta$$

Equating real and imaginary parts, we obtain the relations

$$x = c \cosh \xi \cos \eta$$
$$y = c \sinh \xi \sin \eta$$

It is seen that the curves ($\xi = \xi_1 = $ const) transform to ellipses in the x,y-plane with foci at $x = \pm c$, and having major and minor semiaxes a_1, b_1 equal to $c \cosh \xi_1$, $c \sinh \xi_1$, respectively. Angle η is the eccentric angle of any ellipse $\xi = \xi_1$. The curves ($\eta = \eta_1 = $ const) transform to hyperbolas with foci at $x = \pm c$. We arbitrarily restrict η to the range $0 \leqslant \eta < 2\pi$.

Letting X_1 denote the concentrated normal force function, this is (referring to Fig. 13)

$$X_1 = -\frac{F}{\pi} x\ (\theta_1 + \theta_2) = -\frac{F}{\pi} x\ (\phi_2 - \phi_1)$$

dropping the term proportional to x. Now the vector

$$\overline{OP} = z = z_1 + r_1 e^{i\phi_1} = z_2 + r_2 e^{i\phi_2}$$
$$\phi_1 = Im[\log (z - z_1)]$$
$$\phi_2 = Im[\log (z - z_2)]$$

where Im denotes "imaginary part of." Hence

$$X_1 = \frac{F}{\pi} x\, Im[\log (z - z_1) - \log (z - z_2)]$$

$$= \frac{Fc}{\pi} \cosh \xi \cos \eta\, Im[\log c\ (\cosh \zeta - \cosh \zeta_1) - \log c\ (\cosh \zeta - \cosh \zeta_2)]$$

But we can write

$$\cosh \zeta - \cosh \zeta_1 = \frac{1}{2} e^{\zeta}(1 - e^{\zeta_1 - \zeta})(1 - e^{-\zeta_1 - \zeta})$$

$$\log (1 - e^{\zeta_1 - \zeta}) = -\sum_{n=1,\,2\ldots}^{\infty} \frac{1}{n} e^{n(\zeta_1 - \zeta)}, \text{ etc.}$$

Substituting, we obtain

$$X_1 = \frac{Fc}{\pi} \cosh \xi \cos \eta \sum_{n=1,\,2\ldots}^{\infty} \left\{ -\frac{1}{n} e^{n(\xi_1 - \xi)} \sin n(\eta_1 - \eta) + \frac{1}{n} e^{-n(\xi_1 + \xi)} \sin n(\eta_1 + \eta) + \frac{1}{n} e^{n(\xi_2 - \xi)} \sin n(\eta_2 - \eta) - \frac{1}{n} e^{-n(\xi_2 + \xi)} \sin n(\eta_2 + \eta) \right\}$$

After introducing the values

$$\zeta_1 = \xi_0 + i\frac{\pi}{2}$$

$$\zeta_2 = \xi_0 + i\frac{3\pi}{2}$$

the foregoing reduces finally to

$$X_1 = -\frac{2Fc}{\pi} \left\{ \sinh \xi_0 \cosh \xi e^{-\xi} - \cosh \xi \sum_{n=2,\,4\ldots}^{\infty} (-1)^{n/2} \left[\frac{\sinh (n-1)\xi_0 e^{-(n-1)\xi}}{n-1} - \frac{\sinh (n+1)\xi_0 e^{-(n+1)\xi}}{n+1} \right] \cos n\eta \right\} \quad [24]$$

The stresses σ_ξ, $\tau_{\xi\eta}$ are now derived from X_1 and evaluated on the ellipse $\xi = \xi_0$. General expressions for stresses in terms of orthogonal curvilinear co-ordinates are as follows (11)

$$\sigma_\xi = \frac{1}{J^2} \frac{\partial^2 X}{\partial \eta^2} + \frac{1}{J^3} \left(\frac{\partial X}{\partial \xi} \frac{\partial J}{\partial \xi} - \frac{\partial X}{\partial \eta} \frac{\partial J}{\partial \eta} \right)$$

$$\sigma_\eta = \frac{1}{J^2} \frac{\partial^2 X}{\partial \xi^2} + \frac{1}{J^3} \left(\frac{\partial X}{\partial \eta} \frac{\partial J}{\partial \eta} - \frac{\partial X}{\partial \xi} \frac{\partial J}{\partial \xi} \right)$$

$$\tau_{\xi\eta} = -\frac{1}{J^2} \frac{\partial^2 X}{\partial \xi \partial \eta} + \frac{1}{J^3} \left(\frac{\partial X}{\partial \xi} \frac{\partial J}{\partial \eta} + \frac{\partial X}{\partial \eta} \frac{\partial J}{\partial \xi} \right)$$

The quantities J, ϕ are the so-called stretch and rotation factors, defined by the relation

$$dz = \left(\frac{dz}{d\zeta} \right) d\zeta = (Je^{i\phi}) d\zeta$$

In the case of elliptic co-ordinates

$$\frac{dz}{d\zeta} = c \sinh \zeta = c \sinh (\xi + i\eta)$$

$$J^2 = \frac{c^2}{2} (\cosh 2\xi - \cos 2\eta)$$

$$\tan \phi = \tan \eta \cot \xi$$

In elliptic co-ordinates, the stresses are given by

$$\left.\begin{aligned} \frac{2}{c^2} J^4 \sigma_\xi &= (\cosh 2\xi - \cos 2\eta) \frac{\partial^2 X}{\partial \eta^2} + \sinh 2\xi \frac{\partial X}{\partial \xi} - \sin 2\eta \frac{\partial X}{\partial \eta} \\ \frac{2}{c^2} J^4 \sigma_\eta &= (\cosh 2\xi - \cos 2\eta) \frac{\partial^2 X}{\partial \xi^2} - \sinh 2\xi \frac{\partial X}{\partial \xi} + \sin 2\eta \frac{\partial X}{\partial \eta} \\ \frac{2}{c^2} J^4 \tau_{\xi\eta} &= -(\cosh 2\xi - \cos 2\eta) \frac{\partial^2 X}{\partial \xi \partial \eta} + \sinh 2\xi \frac{\partial X}{\partial \eta} + \sin 2\eta \frac{\partial X}{\partial \xi} \end{aligned}\right\} \quad [25]$$

The stresses on the ellipse ξ_0, derived from the concentrated force functions are as follows

$$\frac{2\pi}{Fc^2} J^4 (\sigma_\xi)_{\xi_0} = -\frac{1}{2} (e^{\xi_0} - 2e^{-3\xi_0} + e^{-7\xi_0}) - 4 \cosh^3 \xi_0 \sum_{n=2,\,4\ldots}^{\infty} (-1)^{n/2} \cos n\eta + \sum_{n=2,\,4\ldots}^{\infty} (-1)^{n/2} e^{-2n\xi_0} \left\{ 2 \cosh \xi_0 + 3 \cosh 3\xi_0 - \cosh 7\xi_0 + n \left[-\frac{1}{2} \sinh \xi_0 + \sinh 5\xi_0 + \frac{1}{2} \sinh 7\xi_0 \right] \right\} \cos n\eta \quad [26a]$$

$$\frac{2\pi}{Fc^2} J^4 (\tau_{\xi\eta})_{\xi_0} = -2 \sinh \xi_0 \sinh 2\xi_0 \sin 2\eta$$

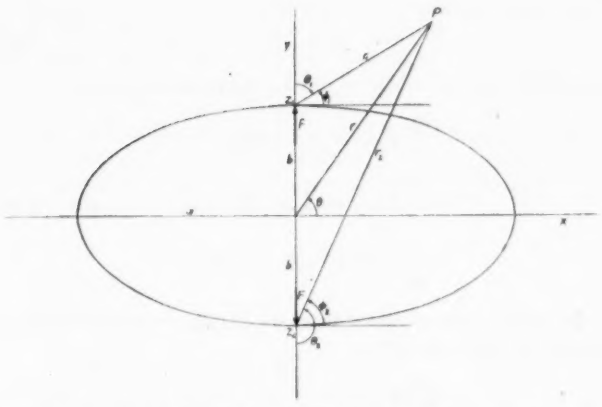

FIG. 13 INFINITE PLATE WITH ELLIPTICAL HOLE, FORCES APPLIED ALONG MINOR AXES OF ELLIPSE

$$+\sum_{n=2,4..}^{\infty}(-1)^{n/2}e^{-2n\xi_0}\left\{3\cosh 3\xi_0-\cosh 5\xi_0-2\cosh 7\xi_0 +n\left[-\frac{1}{2}\sinh\xi_0+\sinh 5\xi_0+\frac{1}{2}\sinh 7\xi_0\right]\right\}\sin n\eta \quad [26b]$$

As a check on these results, we note that in the limit as $\xi_0 \to \infty$, $c \to 0$ so that $a = b = \frac{1}{2}ce^{\xi_0}$, the ellipse reduces to a circle of radius r_0, and the stresses $(\sigma_\xi)_{\xi_0}$, $(\tau_{\xi\eta})_{\xi_0}$ should reduce to those on a circle of radius r_0 produced by a pair of forces at the ends of a diameter. For all points on the circle, except the load points, where the stresses are not defined, these stresses are as follows

$$(\sigma_r)_{r_0} = \frac{F}{\pi}\frac{1}{r_0}$$

$$(\tau_{r\theta})_{r_0} = 0$$

In Equations [26], in the limit as $\xi_0 \to \infty$, $c \to 0$, while $\left(\frac{1}{2}ce^{\xi_0} = r_0 = \text{const.}\right)$, we have first

$$\frac{\pi}{F}r_0^4(\sigma_\xi)_{\xi_0} = \frac{c^3e^{3\xi_0}}{4}\sum_{n=2,4..}^{\infty}(-1)^{n/2}\cos n\eta$$

$$\frac{\pi}{F}r_0^4(\tau_{\xi\eta})_{\xi_0} = 0$$

But it may be shown that for $\eta \neq \pi/2 \neq 3\pi/2$

$$\sum_{n=2,4..}^{\infty}(-1)^{n/2}\cos n\eta = -\frac{1}{2}$$

Hence the stresses on the ellipse ξ_0 reduce to the correct limiting values when the ellipse becomes a circle.

The boundary conditions which must be satisfied are as follows: (*a*) All stresses vanish at infinitely large distances from the hole; (*b*) at the elliptical edge $(\tau_{\xi\eta})_{\xi_0} = 0$ everywhere, while $(\sigma_\xi)_{\xi_0} = 0$ everywhere except at the load points $(\xi_0, \pi/2)$ and $(\xi_0, 3\pi/2)$; here $-(\sigma_\xi)_{\xi_0}$ is infinite in such a way that the resultant normal force on an arc passing through either of the load points is equal to $-F$. The required stress $(\sigma_\xi)_{\xi_0}$ may be expressed as a Fourier series. We obtain the series in the form

$$J^4\sigma_\xi = A_0 + \sum_{n=2,4..}^{\infty}A_n\cos n\eta$$

Using the conditions that $\sigma_\xi = 0$ everywhere except at $\eta = \pi/2$, $3\pi/2$, and that at these points

$$\int_{\pi/2-\epsilon}^{\pi/2+\epsilon}\sigma_\xi ds_\eta = -F, \qquad \int_{3\pi/2-\epsilon}^{3\pi/2+\epsilon}\sigma_\xi ds_\eta = -F$$

where ϵ is an arbitrary small positive number, and ds_η is an element of arc of the ellipse $\xi = \xi_0$

$$ds_\eta = cd\eta\sqrt{\cosh^2\xi_0\sin^2\eta+\sinh^2\xi_0\cos^2\eta}$$

We obtain, finally, for the required stresses on the ellipse ξ_0

$$\frac{2\pi}{Fc^3}J^4\sigma_\xi = -4\cosh^3\xi_0\left[\frac{1}{2}+\sum_{n=2,4..}^{\infty}(-1)^{n/2}\cos n\eta\right] \quad [27a]$$

$$\tau_{\xi\eta} = 0 \quad [27b]$$

These may be checked by evaluating the limiting case $\xi \to \infty$ $c \to 0$ so that $\frac{ce^{\xi_0}}{2} = r_0$. The foregoing reduces to

$$\sigma_\xi \to (\sigma_r)_{r_0} = -\frac{2F}{\pi r_0}\left[\frac{1}{2}+\sum_{2,4..}^{\infty}(-1)^{n/2}\cos n\eta\right]$$

This result, for the normal stresses on a circle of radius r_0 due to concentrated forces F at the ends of a diameter, agrees with that given by Filon (7).

We now have to determine the auxiliary stress function X' so that the complete solution yields the stresses of Equations [27]. Subtracting Equations [27] from [26], the following stresses must be annulled by the stress function X':

$$\left.\begin{aligned}\frac{2\pi}{Fc^3}J^4\sigma_\xi' = &-\frac{1}{2}(e^{\xi_0}-2e^{-3\xi_0}+e^{-7\xi_0})+2\cosh^3\xi_0\\ &+\sum_{n=2,4..}^{\infty}(-1)^{n/2}e^{-2n\xi_0}\left\{2\cosh\xi_0\right.\\ &+3\cosh 3\xi_0-\cosh 7\xi_0+n\left[-\frac{1}{2}\sinh\xi_0+\sinh 5\xi_0\right.\\ &\left.\left.\left.+\frac{1}{2}\sinh 7\xi_0\right]\right\}\cos n\eta\end{aligned}\right\} \quad [28a]$$

$$\left.\begin{aligned}\frac{2\pi}{Fc^3}J^4\tau_{\xi\eta}' = &-2\sinh\xi_0\sinh 2\xi_0\sin 2\eta\\ &+\sum_{n=2,4..}^{\infty}(-1)^{n/2}e^{-2n\xi_0}\left\{3\cosh 3\xi_0-2\cosh 7\xi_0\right.\\ &-\cosh 5\xi_0+n\left[-\frac{1}{2}\sinh\xi_0+\sinh 5\xi_0\right.\\ &\left.\left.\left.+\frac{1}{2}\sinh 7\xi_0\right]\right\}\sin n\eta\end{aligned}\right\} \quad [28b]$$

The typical harmonic solutions, i.e., solutions of

$$\nabla^2\phi = \frac{\partial^2\phi}{\partial\xi^2}+\frac{\partial^2\phi}{\partial\eta^2} = 0$$

are $\phi = e^{\pm a\xi} \cos a\eta$, $e^{\pm a\xi} \sin a\eta$ where a is a constant. The general biharmonic solution is made up of harmonic functions, together with biharmonic functions $x\phi$, $y\phi$. The typical biharmonic solutions in elliptic co-ordinates are easily obtained by substituting the appropriate expressions for x and y (11).

Of the eight characteristic harmonic and biharmonic solutions, only the following yield stresses of proper symmetry in the present problem

$$\phi = Ae^{-n\xi} \cos n\eta \quad \ldots\ldots\ldots\ldots\ldots [29a]$$

$$X = B[e^{-(n+2)\xi} \cos n\eta + e^{-n\xi} \cos (n+2)\eta] \quad \ldots\ldots [29b]$$

where A, B are arbitrary constants, and n is an even integer.

Using Equations [25], these functions yield stresses as follows

$$\left.\begin{aligned}\frac{2}{c^2} J^4 e^{n\xi} \sigma_\xi = &\left[A\frac{n(n-1)}{2} + B\frac{n(n+1)}{2} e^{-2\xi}\right] \cos (n-2)\eta + \left\{-A(n^2 \cosh 2\xi + n \sinh 2\xi)\right. \\ &+ B\left[\frac{(n+2)(n+3)}{2} - e^{-2\xi}(n^2 \cosh 2\xi \right. \\ &\left.\left. + (n+2) \sinh 2\xi)\right]\right\} \cos n\eta + \left\{A\frac{n(n-1)}{2}\right. \\ &+ B\left[\frac{n(n-1)}{2} e^{-2\xi} - (n+2)^2 \cosh 2\xi \right. \\ &\left.\left. - n \sinh 2\xi\right]\right\} \cos (n+2)\eta + B\frac{(n+2)(n+4)}{2} \\ &\cos (n+4)\eta\end{aligned}\right\} [30a]$$

$$\left.\begin{aligned}\frac{2}{c^2} J^4 e^{n\xi} \tau_{\xi\eta} = &\left[A\frac{n(n+1)}{2} + B\frac{(n+2)(n+1)}{2}\right. \\ &\left. e^{-2\xi}\right] \sin (n-2)\eta + \left\{-A(n^2 \cosh 2\xi + n \sinh 2\xi)\right. \\ &+ B\left[\frac{n(n+3)}{2} - e^{-2\xi} n(n+2) \cosh 2\xi \right. \\ &\left.\left. - e^{-2\xi} n \sinh 2\xi\right]\right\} \sin n\eta + \left\{A\frac{n(n-1)}{2}\right. \\ &+ B\left[\frac{(n+2)(n-1)}{2} e^{-2\xi} - n(n+2) \cosh 2\xi \right. \\ &\left.\left. - (n+2) \sinh 2\xi\right]\right\} \sin (n+2)\eta + B\frac{n(n+1)}{2} \\ &\sin (n+4)\eta\end{aligned}\right\} [30b]$$

$$\left.\begin{aligned}\frac{2}{c^2} J^4 e^{n\xi} \sigma_\eta = &\left[-A\frac{n(n+1)}{2} - B\frac{(n+4)(n+1)}{2}\right. \\ &\left. e^{-2\xi}\right] \cos (n-2)\eta + \left\{A(n^2 \cosh 2\xi + n \sinh 2\xi)\right. \\ &+ B\left[-\frac{n^2+n+2}{2} + e^{-2\xi}(n+2) \sinh 2\xi \right. \\ &\left.\left. + e^{-2\xi}(n+2)^2 \cosh 2\xi\right]\right\} \cos n\eta \\ &+ \left\{-A\frac{n(n-1)}{2} + B\left[-\frac{n^2+3n+4}{2} e^{-2\xi}\right.\right. \\ &\left.\left. + n^2 \cosh 2\xi + n \sinh 2\xi\right]\right\} \cos (n+2)\eta \\ &- B\frac{(n-2)(n+1)}{2} \cos (n+4)\eta\end{aligned}\right\} [30c]$$

The special solution

$$X = A_0\xi \quad \ldots\ldots\ldots\ldots\ldots [31]$$

also yields stresses of the required symmetry as follows

$$\left.\begin{aligned}\frac{2}{c^2} J^4 \sigma_\xi &= A_0 \sinh 2\xi \\ \frac{2}{c^2} J^4 \tau_{\xi\eta} &= A_0 \sin 2\eta \\ \frac{2}{c^2} J^4 \sigma_\eta &= -A_0 \sinh 2\xi\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [32]$$

In order to annul the stresses on the ellipse ξ_0 expressed by Equations [28], we take

$$\frac{\pi}{Fc} X' = A_0\xi + \sum_{n=2,4,\ldots}^{\infty} \left\{A_n e^{-n\xi} \cos n\eta + B_n[e^{-n\xi} \cos (n-2)\eta + e^{-(n-2)\xi} \cos n\eta]\right\} [33]$$

The constants A_0, A_n, B_n are determined by solving simultaneously the infinite number of equations which express the conditions that the stresses of Equations [28] are annulled, term by term. These equations are of the type

$$a_n A_{n-2} + b_n A_n + c_n A_{n+2} + d_n B_{n-4} + e_n B_{n-2} + f_n B_n + g_n B_{n+2} = -q_n$$

$$a_n A_{n-2} + b_n A_n + c_n A_{n+2} + d_n' B_{n-4} + e_n' B_{n-2} + f_n' B_n + g_n' B_{n+2} = -q_n'$$

where $a_n \ldots$, $b_n \ldots$, etc., are constants for a given ellipse, i.e. for a given value of ξ_0, while q_n, q_n' are the coefficients of the nth terms in the series for σ_ξ'', $\tau_{\xi\eta}''$ given by Equations [28].

In the numerical evaluation of the constants, the following method of successive approximations has been found successful: The terms for $n = 0, 2$ of Equation [33] are first used as a partial stress function X_1', and evaluated so that the terms in $n = 0, 2$ of Equations [28] are removed. The stress function X_1', containing three constants A_0', A_2', B_2' determined in this way, contributes new stresses proportional to $\cos 4\eta$, $\sin 4\eta$. Next, a partial stress function X_2' is used, consisting of the terms for $n = 4$ of Equation [33], and constants A_4', B_4' evaluated so as to cancel the total stresses proportional to $\cos 4\eta$, $\sin 4\eta$ due both to the original system of stresses to be annulled, and to the partial stress function X_1'. The second stress function X_2', however, contributes new stresses of order $n = 0, 2, 6$. Further partial stress functions X_3', $X_4' \ldots$ are next evaluated so as to cancel, successively, the terms in 6η, 8η, ... The system of functions X_1', $X_2' \ldots$ replaces the original stresses which were to be annulled with a new set of stresses which, because of the numerical relationships of the terms of the general solutions, Equations [30] and [32], are smaller than the original values. By repeating this process, the "residual" stresses may be reduced to any desired values. The required auxiliary stress function is the sum of all the partial stress functions evaluated in this manner.

Calculations have been made for two ellipses, having $\xi_0 = 0.5$, 0.25, respectively (corresponding to minor and major axes in the ratios $b/a = \tanh \xi_0 = 0.462$, 0.245, respectively). The important stresses, (aside from those at the load points, which are not defined in the present analysis), are the tensile stresses σ_η, on the line $y = 0$ (coinciding with the major axis of the ellipse). These stresses are shown in Fig. 14, together with the corresponding stresses for a circle of radius a equal to the semimajor axis of the ellipses.

The complete solution for the case of a circular hole in an infinite plate, loaded by two forces at the ends of a diameter, (or by any number of concentrated forces placed symmetrically around the circle), is given in Appendix 2. It has been verified that the areas under the curves in Fig. 14, converted to proper units, have the value $F/2$, within the accuracy of the plots. The curves indicate that these tensile stresses are sharply localized near the ends of the major axis of the ellipse, and that their maximum value increases rapidly as the ellipse becomes flatter.

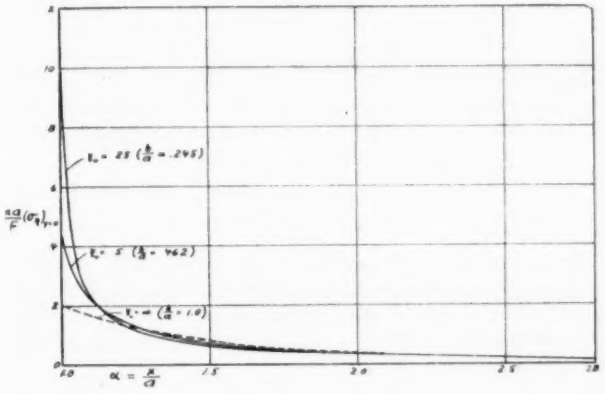

FIG. 14 TENSILE STRESSES $\frac{\pi a}{F}(\sigma_\eta)_{\eta=0}$ ALONG LINE OF MAJOR AXIS OF ELLIPSE
(a = semimajor axis of ellipse.)

Fig. 15 is a plot of the maximum tensile stress as a function of the ratio b/a of the ellipse. However, the present method cannot be applied easily when the ellipse is very flat, corresponding to ξ_0 much less than about 0.25, since the series (Equations [28]), expressing the stresses to be annulled, then decrease very slowly, and the numerical solution becomes extremely laborious. The solution in its present form is therefore not suitable for investigating the limiting case when the ellipse is narrowed to a line or "crack."

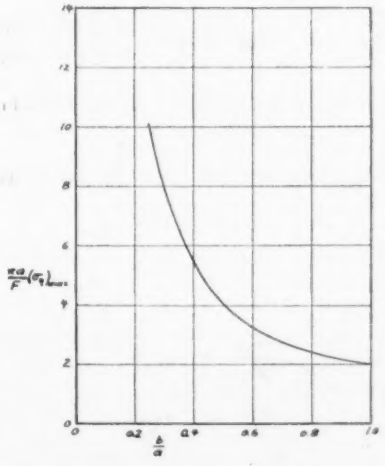

FIG. 15 VARIATION OF MAXIMUM TENSILE STRESS WITH b/a = RATIO OF MAJOR TO MINOR AXIS OF ELLIPSE

In conclusion, it may be noted that problems of concentrated moments could be treated in the same general manner as those of concentrated forces. It may be readily verified that the functions expressing the singularities are

$$\text{(Transverse bending)} \quad w = \frac{M}{4\pi D} r \log r \cos\theta$$

$$\text{(Plane stress or strain)} \quad X = \frac{M}{2\pi}\theta$$

These are analogous to Equations [2] and [3], respectively. Moreover, the solutions obtained for concentrated forces yield those for concentrated moments by differentiation. For example, the solution of the infinite-plate problem, Equation [10], may be written as

$$w = F\phi(a)$$

where a is the radial co-ordinate of the load point. Then the corresponding solution for a moment M is

$$w = \lim_{\substack{\epsilon \to 0 \\ F\epsilon \to M}} \left\{ F\phi(a+\epsilon) - F\phi(a) \right\} = M \frac{\partial \phi}{\partial a}$$

ACKNOWLEDGMENT

The author wishes to express his appreciation to Prof. J. N. Goodier of Cornell University for suggesting these problems and for invaluable aid in their solution.

Appendix 1

The following is a solution, based on the transformation of inversion, of the problem of a large plate clamped at a circular edge and acted on by a concentrated transverse force at any point. The inversion transformation is a conformal transformation defined by the equation

$$z' = \frac{a^2}{z}$$

where

$$z' = x' + iy' = r'e^{i\theta'}, \; z = x + iy = re^{i\theta}$$

and a (the "radius of inversion") is a real number. It is seen that the transformation consists of an "inversion" of the modulus, $r' = a^2/r$, plus a reflection about the real axis.

The properties of this transformation which are useful in the present problem are the following: If X is a biharmonic function in the r,θ-plane, then r'^2X is biharmonic in the r', θ' plane. Thus

w is a deflection function in the r,θ-plane, r'^2w is a deflection function in the r',θ'-plane. The slopes in the r',θ'-plane are equal to

$$\frac{\partial}{\partial r'}(r'^2w) = \frac{2a^2}{r}w - \frac{a^4}{r^4}\frac{\partial w}{\partial r}$$

$$\frac{1}{r'}\frac{\partial}{\partial \theta'}(r'^2w) = \frac{a^2}{r}\frac{\partial w}{\partial \theta}$$

Hence a boundary along which $w = \dfrac{\partial w}{\partial r} = \dfrac{1}{r}\dfrac{\partial w}{\partial \theta} = 0$ (i.e., a clamped edge), in the r,θ-plane, transforms into a clamped edge in the r',θ'-plane.

Another useful property of the transformation is the fact that circles transform into circles. In particular, a circle in the z-plane with center on the real axis, distance c from the origin and having a radius b, transforms into a circle in the z'-plane whose corresponding values are

$$c' = [a^2/(c^2 - b^2)]c,\ b' = [a^2/(c^2 - b^2)]b$$

For example, when the circle passes through the origin ($c = b$), it transforms into a straight line. Again, if $a^2 = c^2 - b^2$, the circle inverts into itself. Michell (9) obtained in this way the solution for the deflection of a clamped circular plate loaded by a concentrated normal force at an arbitrary point. A second inversion leads to the solution of the present problem.

Michell's solution utilizes the following result for the deflection of a clamped circular plate loaded by a central force

$$w = \frac{F}{8\pi D}\left[r^2 \log \frac{r}{b} + \frac{1}{2}(b^2 - r^2)\right]$$

The inversion is performed with respect to a point 0 outside the plate, so that $R' = a^2/R$, where R, R' are distances from 0 to points P, P', respectively (see Fig. 16). Taking $a^2 = b^4/e^2 - b^2$, $c = b^2/e$, the following result is obtained for the deflection of a clamped circular plate loaded by a force F at a distance e from the center of the circle

$$w = \frac{F}{8\pi D}\left[p^2 \log \frac{pb}{R'e} + \frac{1}{2}\left(\frac{R'^2e^2}{b^2} - p^2\right)\right]$$

where the co-ordinates p, R' are as shown in Fig. 16.

If we now perform a second inversion, this time taking the center of the circle 0 as the center of inversion (see Fig. 17), and the radius of inversion equal to the radius b of the circle, then the area within the circle transforms to the infinite area outside the circle. The load point F transforms to F' at distance a from 0, while P transforms to P' at distance r from 0, where $a = b^2/e$, $r = b^2/r'$. Since in the previous transformation c was equal to b^2/e, we have now $a = c$, so that $F'P = R'$. Thus we now have the case of an infinite plate clamped at a circle of radius b and loaded at distance a from the center. Using the relations

$$p^2 = \frac{b^4}{r^2} + \frac{b^4}{a^2} - \frac{2b^4}{ra}\cos\theta$$

$$R'^2 = \frac{b^4}{r^2} + a^2 - \frac{2b^2a}{r}\cos\theta$$

and changing to the dimensionless variables $\rho = r/b$, $q = a/b$

$$w = \frac{Fb^2}{16\pi D}\left[(q^2 + \rho^2 - 2q\rho\cos\theta)\log\frac{q^2 + \rho^2 - 2q\rho\cos\theta}{1 + q^2\rho^2 - 2q\rho\cos\theta} + (q^2 - 1)(\rho^2 - 1)\right]$$

This result satisfies the conditions at the clamped edge, and gives the necessary singularity at the load point. However, the conditions required at the outer free edge are not satisfied, since the foregoing solution leads to a uniform bending moment at large values of ρ, equal to

$$M_r = M_\theta = \frac{F}{8\pi D}(1 + \nu)(q^2 - 1 - 2\log q)$$

This bending moment can be removed by adding a function w' such that

$$\frac{\partial w'}{\partial \rho} = \frac{Fb^2}{16\pi D}\left[-2\rho(q^2 - 1 - 2\log q)\right] + \frac{c_1}{\rho}$$

$$w' = \frac{Fb^2}{16\pi D}\left[-\rho^2(q^2 - 1 - 2\log q) + c_1\log\rho + c_2\right]$$

Evaluating the constants C_1, C_2 so that the conditions at the clamped edge are satisfied, we obtain, finally

$$w = \frac{Fb^2}{8\pi D}\left\{\frac{1}{2}(q^2 + \rho^2 - 2q\rho\cos\theta)\log\frac{q^2 + \rho^2 - 2q\rho\cos\theta}{1 + q^2\rho^2 - 2q\rho\cos\theta} + (q^2 - 1)\log\rho + (\rho^2 - 1)\log q - 2\log q\log\rho\right\}$$

This is the result, Equation [10], found by the series-expansion method.

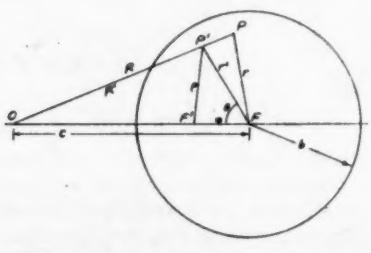

FIG. 16 CIRCULAR PLATE CLAMPED AT $r = b$: INVERSION TO OBTAIN DEFLECTION DUE TO NONCENTRAL FORCE

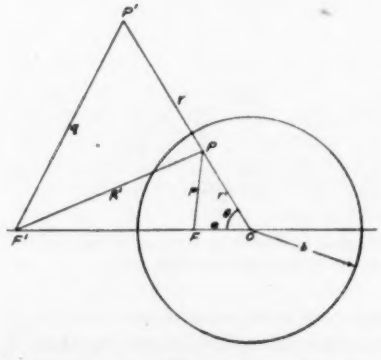

FIG. 17 INFINITE PLATE CLAMPED AT $r = b$: INVERSION TO OBTAIN DEFLECTION DUE TO FORCE AT ARBITRARY POINT OF PLATE

Appendix 2

Problems in which any number of equal concentrated forces are placed symmetrically around the edge of a circular hole in an infinite plate (the forces lying in the plane of the plate and acting normal to the edge) have simple solutions in finite form. If the stress functions for the simple radial stress distribution are added, for the given arrangement of forces, the shear stress on the load circle is found to be zero, owing to the symmetry of loading. The normal stress on the load circle due to the combination of simple radial distributions is easily shown to be given by $\sigma_0 = nF/\pi d$ where n is the number of symmetrically disposed forces each equal to F, and d is the diameter of the hole.

This uniform tensile stress may be annulled by adding the stress distribution corresponding to the stress function $X' = A \log r$, namely

$$\sigma_r' = Ar^{-2} \qquad \tau_{r'\theta} = 0 \qquad \sigma_\theta' = -Ar^{-2}$$

where r is distance measured from the center of the hole. In the case of two forces at the ends of a diameter (a limiting case of the elliptical-hole problem previously solved), we have $\sigma_0 = 2F/\pi d = F/\pi r_0$ (where r_0 is the radius of the hole), and $A = -Fr_0/\pi$. In terms of x, y co-ordinates, taken as shown in Fig. 13 of the paper, the stresses on the line $y = 0$ are given by

$$(\sigma_y)_{y=0} = \frac{4F}{\pi} \frac{r_0^3}{(x^2 + r_0^2)^2} + \frac{Fr_0}{\pi} \frac{1}{x^2}$$

$$(\sigma_x)_{y=0} = \frac{4F}{\pi} \frac{r_0 x^2}{(x^2 + r_0^2)^2} - \frac{Fr_0}{\pi} \frac{1}{x^2}$$

The maximum tensile stress (at $x = r_0$) is $(\sigma_y)_{r_0} = 2F/\pi r_0$. Similar results are easily obtained for any other number of symmetrical forces.

Buckling Under Locally Hydrostatic Pressure

By G. H. HANDELMAN,[1] PROVIDENCE, R. I.

The instability of a simple pin-supported beam when subject to a locally hydrostatic pressure distribution, the intensity of which is a function of distance along the beam only, is discussed in this paper. In particular, the pressure is assumed to follow a polynomial law given by Equation [1]. The problem, basic assumptions, and precise definition of locally hydrostatic pressure are stated in the first section of the paper. The second section contains a discussion of the equations of equilibrium from which the basic differential equation is derived. The solutions of this differential equation satisfy the boundary conditions only for certain discrete values of the parameters involved, and these values in turn define the buckling loads. In the third section the buckling loads are tabulated for several cases in comparison with the buckling loads for the same beam subject only to an end thrust. The appendix contains a mathematical discussion of the solution of the basic differential equation and a derivation of the formula for the buckling loads.

Introduction

AMONG the various types of loading of a simple beam with pin ends which might produce instability, the case of loading by locally hydrostatic pressure does not appear to have been discussed. By a locally hydrostatic pressure distribution is meant one in which the intensity of the pressure is a function of the distance along the center line of the beam only. Such a distribution is a generalization of the linear pressure distribution which arises when a prismatic bar is placed vertically in a heavy liquid. This paper is concerned, then, with the buckling of a thin, uniform, prismatic beam with pin supports under such a loading.

Let the origin of co-ordinates be taken at one of the pin supports, the x-axis directed along the undeformed center line of the beam, and the y-axis vertically upward as shown in Fig. 1. The length of the beam is denoted by l and the area of the cross section is A. The pressure distribution $p(x)$ is assumed to be given by the following law

$$p(x) = p_0\left[1 - k\left(\frac{x}{l}\right)^m\right] \quad \ldots\ldots\ldots\ldots [1]$$

where p_0 is the head pressure, the pressure at $x = 0$, m is non-negative, and k is a constant with values in the range 0 to 1. When $m = 1$, Equation [1] reduces to the linear case mentioned.

As indicated by the choice of co-ordinate axes in Fig. 1, the slider is assumed to be at the high-pressure end of the beam ($x = 0$). It will be shown in a later section that if the role of slider and simple pin support are reversed buckling cannot occur.

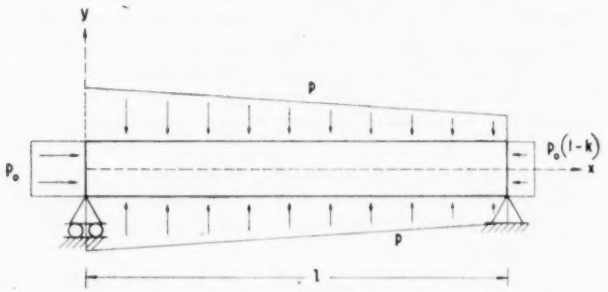

FIG. 1 PRESSURE DISTRIBUTION FOR $m = 1$, $k = \frac{1}{2}$

Equations of Equilibrium

Consider a small element in the deformed state subject only to a pressure distribution of the locally hydrostatic type, Fig. 2. Since the element is small, the variation of the pressure along the portion of the center line considered, ds, can be neglected. The element would be in equilibrium if additional uniform pressure distributions p were added to the faces as shown in Fig. 2. Since these additional pressures are not present, the resultant

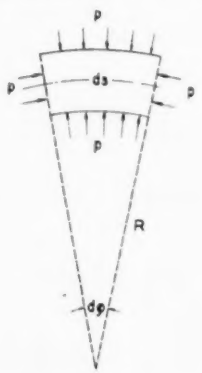

FIG. 2

force produced by the pressure which does occur must be equal in magnitude and opposite in direction to that produced by the added pressure. The face pressures are equivalent to a force pA, acting normal to each of the two cross sections which bound the element; and these forces have a resultant $pAd\varphi = pAds/R$ acting along the normal to the center line in the direction of the convex side (R is the radius of curvature of the center line). Consequently, the pressure distribution which does act on the wedge has a resultant of magnitude $pA\ ds/R$ directed along the normal to the center line pointing toward the concave side.

The equilibrium conditions for an element of the beam under the complete system of forces acting can now be set up under the assumption that the deflection, $y = y(x)$, is small. On the basis of the result just obtained the element is subject to a restoring force $pA\ ds/R = -pA\ d^2y/dx^2$, for small deflections, acting in the negative y-direction as well as internal shear forces, S, pulls P, and bending moments M, as shown in Fig. 3. The equilibrium condition for components in the horizontal direction is

$$dP = 0 \quad \text{or} \quad P = \text{const} \ldots\ldots\ldots\ldots [2]$$

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

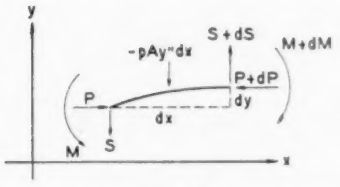

FIG. 3

The components in the vertical direction must satisfy the equation

$$S - pAy''dx = S + dS$$

or

$$S' = -pAy'' \quad \ldots\ldots [3]$$

where $S' = dS/dx$. Finally, the moment equation reduces to

$$Pdy + Sdx = dM$$

provided that terms of higher order are neglected. This last equation may be rewritten as

$$Py' + S = M' \quad \ldots\ldots [4]$$

Equation [4] can be simplified by differentiating with respect to the independent variable x and taking into account Equations [2] and [3], that is

$$M'' - (P - pA)y'' = 0 \quad \ldots\ldots [5]$$

Now the bending moment M and the deflection y are connected by the usual Euler-Bernoulli law for small deflections

$$\frac{M}{EI} = -y''$$

where E is Young's modulus and I is the polar moment of inertia of the cross section taken about an axis passing through the centroid and perpendicular to the plane of bending. Thus Equation [5] can be written in such a way that the bending moment M is the only dependent variable

$$M'' + (P - pA)\frac{M}{EI} = 0 \quad \ldots\ldots [6]$$

In addition, the boundary conditions for pin supports (namely, the vanishing of the bending moment at both ends) must be added, that is

$$M(0) = M(l) = 0 \quad \ldots\ldots [7]$$

The pressure p has been assumed to follow the law given in Equation [1], and this must be inserted in Equation [6]. For the slider at $x = 0$, $P = p_0A$, therefore

$$P - pA = kp_0A\left(\frac{x}{l}\right)^m = kP\left(\frac{x}{l}\right)^m$$

and Equation [6] becomes

$$M'' + \frac{kP}{EI}\left(\frac{x}{l}\right)^m M = 0 \quad \ldots\ldots [8]$$

CALCULATION OF CRITICAL PRESSURE

The differential equation for the bending moment, Equation [8], can be integrated in terms of Bessel functions. Since the equation is homogeneous, solutions cannot be determined which will satisfy the boundary conditions, Equation [7], for all values of the parameter P. The smallest nonvanishing value P for which solutions of the boundary-value problem do exist defines the critical pressure. The general solution of Equation [8] together with a discussion of the boundary conditions is given in the Appendix. It will be shown there that the critical end force P_{cr} is given by the formula

$$P_{cr} = \frac{(m+2)^2\,\xi_m^2}{4k} \cdot \frac{EI}{l^2} \quad \ldots\ldots [9]$$

where ξ_m is the first nonvanishing zero of the Bessel function of first kind of order $1/(m+2)$, $J_{1/(m+2)}(\xi)$.

The critical head pressure, p_{0cr}, can be found by noting that $p_{0cr} = P_{cr}/A$; thus

$$p_{0cr} = \frac{(m+2)^2\xi_m^2}{4k} \cdot \frac{E}{(l/\kappa)^2}$$

where κ is the radius of gyration of the cross section.

In the case of a simply supported beam subject to an end force $\bar{P}$, the first buckling load is known to be given by $\bar{P}_{cr} = \pi^2EI/l^2$. Buckling under locally hydrostatic pressure can be compared with this simple case by means of an equivalence factor e defined as

$$e = \frac{\bar{P}_{cr}}{P_{cr}} = \frac{4k\pi^2}{(m+2)^2\xi_m^2}$$

This factor is plotted in Fig. 4 as a function of m for various values of the parameter k. Since the coefficient of pressure decrease k enters linearly, e can be found for values of k other than those given by multiplying the results for $k = 1$ by the desired value of k. Since $\xi_0 = \pi$, the equivalence factor for $k = 1$

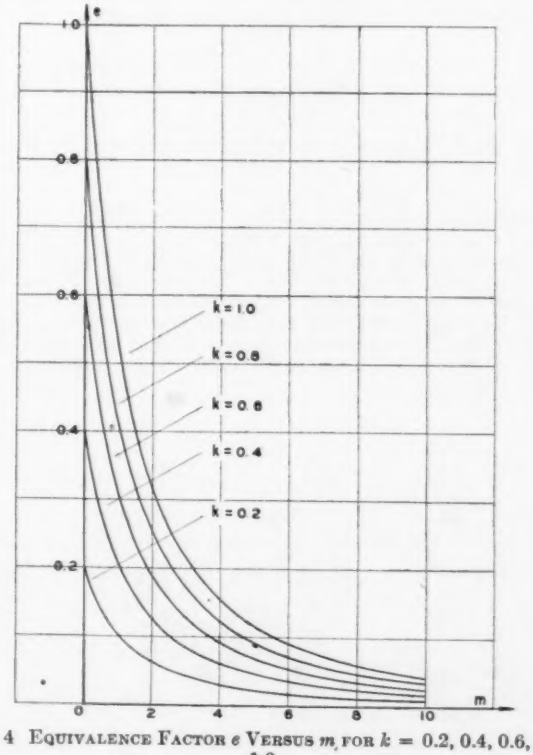

FIG. 4 EQUIVALENCE FACTOR e VERSUS m FOR $k = 0.2, 0.4, 0.6, 0.8, 1.0$

$m = 0$, reduces[2] to 1, that is, for this limiting case the critical end load is simply the classical Euler load as one would expect.

It should be noted that in the case of a constant pressure dis-

[2] "Tables of Functions With Formulas and Curves," by E. Jahnke and F. Emde, Dover Publications, New York, N. Y., 1943, p. 167.

tribution, $k = 0$, the bar cannot buckle. This result may be read from Equation [9] or found directly by considering the differential equation and boundary conditions.

In case the slider is at the low-pressure end of the beam, $x = l$, the condition $P = p_0A$ must be replaced by $P = p_0A(1 - k)$. Then

$$P - pA = p_0Ak\left[\left(\frac{x}{l}\right)^m - 1\right]$$

and the differential Equation [8] must be replaced by

$$M'' + \frac{kAp_0}{EI}\left[\left(\frac{x}{l}\right)^m - 1\right]M = 0 \quad \ldots\ldots\ldots [10]$$

Now the function

$$\frac{kAp_0}{EI}\left[\left(\frac{x}{l}\right)^m - 1\right] \leqq 0$$

for $0 \leqq x \leqq l$. Equation [10] is a special case of the general Sturm-Liouville differential equation, the solutions of which have been studied extensively. In particular, it is known that if the coefficient of M is nonpositive in the interval $0 \leqq x \leqq l$, the solution can have but one zero in that interval.[3] Thus it is impossible to fulfill the boundary conditions $M(0) = M(l) = 0$ and buckling cannot take place.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Prof. W. Prager of Brown University and to Prof. I. S. Sokolnikoff of the University of Wisconsin for many helpful suggestions.

Appendix

The general solution of the differential Equation [8] is of the form[4]

$$M = A\sqrt{x}\,J_{1/(m+2)}\left[\frac{2}{m+2}\sqrt{\frac{kP}{EIl^m}}\,x^{(m+2)/2}\right] + B\sqrt{x}\,J_{-1/(m+2)}\left[\frac{2}{m+2}\sqrt{\frac{kP}{EIl^m}}\,x^{(m+2)/2}\right]. \quad [11]$$

where $J_{1/(m+2)}(\xi)$ is the Bessel function of first kind of order $1/(m+2)$, $J_{-1/(m+2)}(\xi)$ is the Bessel function of first kind of order $-1/(m+2)$, and A and B are constants to be determined from the boundary conditions. Since $J_p(\xi)$ vanishes at $\xi = 0$ for $p > 0$, the first term of Equation [11] automatically fulfills the boundary condition $M(0) = 0$. The Bessel function of negative order $J_{-p}(\xi)$, $p > 0$, has a singularity at $\xi = 0$; it will be necessary to investigate this more closely. The following approximate formula[5] can be used to study the behavior of the Bessel function of negative order for $|\xi| \ll 1$

$$J_{-1/(m+2)}(\xi) = \frac{(1/2\xi)^{-1/(m+2)}}{\Gamma[1 + 1/(m+2)]}$$

where $\Gamma[1 + 1/(m+2)]$ is the gamma function evaluated for the argument $1 + 1/(m+2)$. Since this function does not vanish for $m \geqq 0$, $J_{-1/(m+2)}(\xi)$ behaves like $(2/\xi)^{1/(m+2)}$ near the origin. This result can be applied to the second term of Equation [11] to yield

$$\lim_{x\to 0}\sqrt{x}\,J_{-1/(m+2)}\left[\frac{2}{m+2}\sqrt{\frac{kP}{EIl^m}}\,x^{(m+2)/2}\right] = C\sqrt{x}\left[\frac{2}{x^{(m+2)/2}}\right]^{1/(m+2)} = \text{const} \neq 0$$

where C is a nonvanishing constant. Thus B must vanish if the first boundary condition is to be satisfied.

The second boundary condition $M(l) = 0$, will yield the desired critical value, for it requires that

$$J_{1/(m+2)}\left(\frac{2}{m+2}\,l\sqrt{\frac{kP}{EI}}\right) = 0$$

Let ξ_m be the first nonvanishing zero of $J_{1/(m+2)}(\xi)$, then the critical end force, P_{cr}, will be given by

$$\frac{2}{m+2}\cdot l\cdot\left(\frac{kP_{cr}}{EI}\right)^{1/2} = \xi_m \quad \text{or} \quad P_{cr} = \frac{(m+2)^2\,\xi_m^2}{4k}\cdot\frac{EI}{l^2}$$

[3] "Ordinary Differential Equations," by E. L. Ince, Dover Publications, New York, N. Y., 1944, p. 226.

[4] "Bessel Functions for Engineers," by N. W. McLachlan, Oxford University Press, 1934, ex. 47, p. 39. The solution given in the reference cited is written in terms of Bessel functions of first and second kind. This may be rewritten with Bessel functions of first kind of positive and negative order since $1/(m+2)$ is not an integer (ibid., p. 23). The succeeding argument is somewhat simplified by this substitution.

An Empirical Approach to the Fatigue-Strength Analysis of Structures

By HENRY W. FOSTER[1] and VICTOR SELIGER[1]

A method of fatigue-strength analysis for fabricated structures, based on laboratory fatigue-test data, is proposed in this paper. To this end the nature of structural fatigue strength is discussed with the view of defining the necessary correlating assumptions and the type of experimental data needed.

An example of this method is presented for structures fabricated from Alclad 24S-T aluminum alloy and analysis results are compared with actual test results.

Nomenclature

N = number of cycles of loading required to produce failure.
F_{tu} = ultimate tensile strength of material.
F_{tf} = fatigue strength of material in terms of maximum stress attained during a cycle.
F_{vf} = fatigue strength of material in terms of varying stress attained during a cycle.
f_{tf} = maximum stress in part, based on net area without regard to stress concentrations = average maximum stress.
f_{vf} = varying stress in part, based on net area without regard to stress concentrations = average varying stress.
R = ratio of minimum stress to maximum stress in a loading cycle.
K_t = elastic-stress-concentration factor.
K_f = effective stress-concentration factor in fatigue = F_{tf}/f_{tf}, for constant R on applied external loading.
K_m = ratio of effective maximum stress at stress raiser to average maximum stress across section.
K_v = ratio of effective varying stress at stress raiser to average varying stress across section.
f_t = $K_m f_{tf}$ = effective maximum stress developed at stress raiser.
f_v = $K_v f_{vf}$ = effective varying stress developed at stress raiser.
(g) = all stress values are calculated on the basis of net area except when subscript g is used denoting stress calculation of the basis of gross area.

Introduction

THE analysis of a structure for life expectancy may be divided into three practically independent problems: 1, The determination of the spectrum of external loading to which the structure will be subjected; 2, the determination of the fatigue strength of the structure under any given loading condition; and 3, the correlation of the expected loading with the fatigue strength of the structure. This paper deals with the second problem only, and presents a method for determining the fatigue strength of a fabricated structure from basic data which may be determined experimentally.

The fatigue strength of a structure is often regarded as if it were a quantity entirely separate from the static strength of the same structure. Actually, the strength of a structure is a function of the same variables whether it is defined for static failure in tension, i.e., one-half cycle at a range ratio of 0, or for any other one of the infinite number of ways in which it may be loaded. The importance of each of the variables of course does depend on which one of the ways of loading determines failure, but it should be emphasized that the strength of a structure is just as much an engineering quantity for one type of loading as for any other, and is just as susceptible to rational analysis. The fact that we do not know what causes fatigue failure need worry us no more than the fact that we do not know the mechanism by which static failure operates. We customarily use empirically determined constants as a basis for the design of structures for static strength, and there is no reason why experimentally determined constants cannot be used as the basis for a rational method of design for fatigue strength.

It is the purpose of this paper to discuss structural fatigue strength with the view to defining the nature of the experimental data and of the correlating assumptions which would permit the fatigue analysis of fabricated structures to be based on material properties obtainable in the laboratory.

The Definition of Fatigue Strength

Any fluctuating load possesses both maximum and minimum values, and two loading parameters must be used in combination with a number of cycles to define fatigue strength. These loading parameters must be chosen from among the following: maximum load, minimum load, mean load, or varying load, or any one of these may be combined with the dimensionless ratio of any two. For convenience, R, the ratio of minimum to maximum load in a loading cycle, has been used in combination with

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

the maximum load in presenting a great deal of experimental fatigue-strength data, and must be brought into any review of data. A family of R curves defining the fatigue strength of Alclad 24S-T sheet is shown as Fig. 1. There is, however, an inherent disadvantage in this method of presentation in that it precludes explicit definition of the varying load, the only load which can repeatedly perform work on the material. It tends, upon cursory inspection of data, to lay undue emphasis on the value of the maximum load as it would indicate an increase in allowable maximum load with increasing R even if the fatigue strength of the material were independent of the maximum load. This fact is important since, as will be seen later, it affects certain other parameters which have been defined in terms of R.

A much more direct and descriptive set of parameters for the definition of a repeated loading condition is the combination of varying with maximum load in a loading cycle. In such a way a true physical picture of the loading cycle is presented, for the varying load defines the magnitude of the variation of load in a cycle, and the maximum load defines the level at which the variation of loading takes place. In Fig. 2 the curves of Fig. 1 are replotted to show the fatigue strength of Alclad 24S-T sheet on

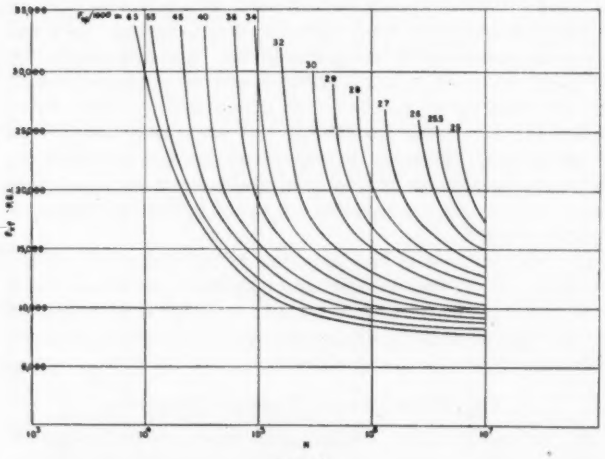

FIG. 2

this basis. This latter method of defining fatigue strength will be used in the subsequent discussion, except where resort must be made to data which are available only in the form of R curves.

VARIABLES INVOLVED IN DEFINING THE FATIGUE STRENGTH OF STRUCTURES

For the purposes of the static-strength analysis of tension structure, it is generally assumed that failure will occur when the most highly stressed portion of the structure reaches the failure stress of the material, the failure stress having been determined in static tests of small test coupons. Similarly, in the fatigue-strength analysis of structures it may be assumed that failure will occur in a given number of cycles when the most highly stressed portion of the structure is subjected to a repeated stressing which would cause failure in the same number of cycles in fatigue tests of the basic material. In other words, in analyses for both static and fatigue strength, the essential problem is to correlate the external loads with the maximum values of internal stress in the structure, since the strength of the basic material may be obtained for any loading. The stress determination for fatigue-strength analysis is, however, usually more complex than the stress determination for static-strength analysis due to the action of the following factors:

1 In the fatigue-strength analysis, two different values of external load must be correlated with internal stress: The peak values of internal stress must be determined from maximum values of external load; and the magnitude of the stress variation in a loading cycle must be determined from the magnitude of the external-load variation.

2 Since the magnitude of the average stress in a structure is usually much lower in fatigue-strength analyses than in static-strength analyses, the usual static-strength assumption that yielding of the material will practically level out the local stress concentrations cannot be made. This means that in correlating external loads with internal stresses the very local stress peaks, which are generally considered to be of minor importance in a static-strength analysis, are usually of considerable importance in a fatigue-strength analysis.

The first of these factors is of course inherent in the definition of fatigue strength; in the second factor lies almost the entire difference between a fatigue-strength analysis and a static-strength analysis, even though its importance is entirely a function of the magnitude of the applied load rather than any peculiar property associated with the fatigue strength of materials. Hence the only new methods needed in the fatigue analysis are those which will define the very local stress values in terms of average stress values, and the remainder of this paper will be concerned with that problem only.

STRESS-CONCENTRATION FACTORS

Any discontinuity in a loaded part will cause a local concentration of stress at the changed section, and the ratio of the peak stress at the discontinuity to the average stress across the section is called the stress-concentration factor. As long as the material is completely elastic, the value of this stress-concentration factor will depend entirely on the geometry of the structure, and is defined as the elastic-stress-concentration factor, K_t. Its value may be determined mathematically by elastic theory, or experimentally by photoelastic measurements, and will vary in practical structure from slightly greater than unity for a very gradual change in section to as high as 10 or 12 for a shear joint which transmits all the load from one sheet to another. This factor is generally considered to be a constant for any particular discontinuity, but in certain cases the geometry of the structure changes sufficiently under load to alter its value. An instance of this which may be important (it has never been evaluated) is a countersunk rivet in single shear, where local bearing pressure varies with load due to rivet rotation.

Fortunately, the true value of this elastic-stress-concentration factor is very rarely realized as a determining factor in the strength of structures, because when the material becomes inelastic at the point of maximum stress, the stress and strain distribution change at that point in a manner which reduces the ratio of peak stress to average stress, i.e., reduces the value of the actual stress-concentration factor. The amount of this alleviation apparently depends almost entirely on the stress-strain characteristics of the material and on the magnitude of the elastic-stress-concentration factor, and thus it appears likely that the alleviation may be evaluated as a basic material property which may be used in determining fatigue strength where discontinuities exist.

Effective Stress-Concentration Factor, K_f: An effective stress-concentration factor, K_f, has been defined (1)[2] as the ratio of the fatigue strength of the basic material to the fatigue strength of a structure at a constant number of cycles to failure and a constant range ratio of applied load. This concentration factor, so defined, is the reciprocal of the structural efficiency factor under repeated loading, since it defines the ratio of structural cross-

[2] Numbers in parentheses refer to table of references at the end of the paper.

sectional area to unnotched-material cross-sectional area necessary to carry a given applied load for a given number of cycles. However, it will relate to the actual stress condition in the structure only when the applied loading is completely reversed, that is, when $R = -1.0$, as will be shown later.

Assumptions for Fatigue Analysis

Since, as we have shown in Fig. 2, fatigue strength is a function of the magnitudes of both the maximum and varying stresses, it is readily apparent that the effect of a discontinuity on both of these stresses must be evaluated for the proper correlation of the fatigue strength of the basic material with the fatigue strength of a structure. In other words, we must be able to define both the true stress level and the true varying stress at a stress raiser in terms of average stresses, before basic-material strength data may be used to determine the fatigue strength of composite structures.

This analysis is founded on the principle of referring to certain constants determined from fatigue tests. The following assumptions are those which will allow us to relate these constants with the alleviation of stress at a stress raiser to provide a general relationship between applied average stress values and the fatigue strength of a structure.

The first assumption is that fatigue life is a function of stress magnitude only, i.e., that failure will occur in a given number of cycles in any part when the highest existing local values of varying stress and maximum stress correspond to the combination necessary to produce failure in the same number of cycles in tests of the basic material.

The second assumption is that for any one material the value of the peak stress at a stress raiser is a function only of the average value of the maximum stress across the pertinent section and the value of the elastic-stress-concentration factor. This seems reasonable since we know that the product of the average maximum stress and the elastic-stress-concentration factor $f_{tf}\ K_t$ is equal to the peak stress f_t in the elastic range for all values of K_t. When the material is locally plastic, however, the amount of alleviation might well be different for different values of K_t, since the stress gradient is increased with increasing values of K_t and hence the restraint offered the most highly stressed locality by the surrounding material would be expected to vary with the value of K_t. This is the reason for assuming that K_t is an independent variable. It will be seen that since $K_t\ f_{tf}$ is linearly related to strain, being the stress value for purely elastic conditions, the curves resulting from a plot of f_t vs. $K_t\ f_{tf}$ must be quite similar in shape to a stress-strain curve for the basic material. It should be particularly noted, however, that the resulting curve or curves obtained from fatigue-test results could not be expected to be identical with a stress-strain curve for the material determined at the same rate of loading, for two reasons: 1 The strain distribution cannot be expected to be the same as under elastic conditions after the material has become plastic locally, due to the support of the surrounding elastic material; and 2 the curves determined from fatigue-test results must include the effect of repeated loading in locally changing the properties of the material through work-hardening. In other words, the peak-stress value found from fatigue-test results must be an effective value only, since it probably would not be actually reached or approximated until the loading had been continued for a number of cycles.

The third assumption is that the value of the varying stress at a stress raiser is a function only of the average value of the varying stress across the pertinent section and the value of K_t. This is similar to assumption 2 for the maximum stress and it should be noted that the value of the local varying stress is assumed to be independent of the value of the local maximum stress, that is, the stress level at which the repeated stressing occurs is *not* assumed to have any effect on the magnitude of the varying stress. We might picture this physically by plotting $f_{vf}\ K_t$ against f_v. Since $f_{vf}\ K_t$ is linearly related to strain (similar to $f_{tf}\ K_t$), a repeated loading would plot as a hysteresis loop whenever the magnitude of the local varying stress was large enough for inelastic action to occur, and under this assumption, the shape of the hysteresis loop is independent of the stress level at which the repeated loading occurs. Fig. 3 illustrates the second and third assumptions, showing plots of f_t and f_v vs. $K_t\ f_{tf}$ and $K_t\ f_{vf}$ for several different loading conditions: Case A shows a loading at which alleviation of maximum stress occurs, but no alleviation of varying stress; Case B shows a loading at which alleviation occurs on both the maximum stress and the varying stress; Case C shows the same value of varying stress as Case B, but occurring at a different stress level; and Case D shows the conditions for completely reversed loading where the stress magnitude is large enough so that inelastic action occurs.

Case D furnishes the correlation between the amount of alleviation of varying stress and the amount of alleviation of maximum stress. Since by definition, the varying stress and the maximum stress are identical when the loading is completely reversed about 0 stress (i.e., when $R = -1.0$), the same function

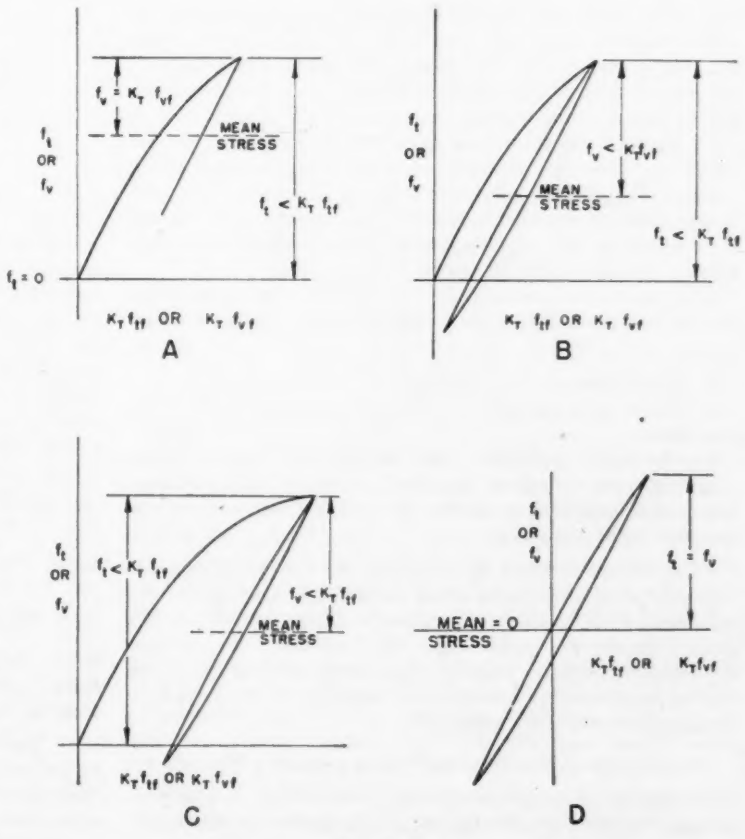

Fig. 3

must necessarily describe the alleviation of both maximum and varying stresses each with respect to its own magnitude.

It will be noted that under these assumptions the true ratio of minimum to maximum stress (the range ratio) may be quite different from the range ratio of applied external loading: The maximum stress is always greater than the varying stress unless the loading is completely reversed; hence the alleviation of maximum stress must always be greater than the alleviation of varying stress unless the external loading is completely reversed. The consequence of this is that the true loading at a stress raiser will always tend toward a completely reversed condition, and the true range ratio will always be less than the nominal range ratio when any alleviation of stress is present at a discontinuity, except when the external loading is completely reversed.

It will also be noted that K_f, the effective stress-concentration factor in fatigue, being defined to represent the over-all change in fatigue strength, does not describe the alleviation due to plastic flow of either the maximum or the varying stress unless the external loading is completely reversed. Instead, it is a measure of the net effect of the magnitude of the elastic-stress-concentration factor, the alleviation of maximum stress by inelastic action, the alleviation of varying stress by inelastic action, and the change in apparent material strength due to change in range ratio. Since K_f is defined on the basis of maximum stress at constant range ratio of external loading, and since, as previously mentioned, constant-range-ratio curves have a defined spacing which is not related to the strength of the material, it may be readily seen that when the true range ratio of a notched part is lower than the nominal range ratio, it is quite possible for K_f to be numerically larger than K_t without the true ratio of peak stress to average stress exceeding K_t.

Therefore in order to evaluate separately the effect of alleviation on the maximum and the varying stress, two other effective stress-concentration factors may be defined; K_m, the ratio of the true maximum stress to the average maximum stress, and K_v, the ratio of the true varying stress to the average varying stress. Under the stated assumptions, these factors will be equal to each other and to K_f when the loading is completely reversed, but not under any other loading condition in which any inelastic action occurs. The essential point here is that K_f is defined in terms of fatigue strength and may be determined experimentally; hence if we determine the fatigue strength of specimens at $R = -1.0$, we may also determine the values of K_m and K_v.

With these assumptions it is now possible to enumerate the information necessary to the fatigue-strength analysis of structures:

1 The geometry of the structure.

2 The fatigue strengths of the basic materials used in the structure.

3 The fatigue strengths under completely reversed loading of several types of idealized "notched" specimens having different values of K_t and fabricated from the same basic materials as the structure to be analyzed.

From the geometry of the structure the correlation between "average" stress or nominal stress and external load may be determined by the usual static analysis methods, and the elastic-stress-concentration factor may be evaluated; the fatigue strengths of the basic materials and of the notched specimens may be determined by test and used to determine the stress alleviation properties of the material.

Hypothetical Example of Fatigue-Analysis Method

An example of the proposed analysis method will now be presented. We shall assume that we have available the completely reversed axial fatigue strength characteristics of several notched specimens made from Alclad 24S-T. These specimens may have included thin strips with circular or elliptical holes, hyperbolic notches, or other types of stress raisers inducing definitely known elastic-stress-concentration factors. Fig. 4 shows such hypothetical data. The upper curve of the same figure represents the completely reversed fatigue-strength characteristics of Alclad 24S-T material, and thus corresponds to a notch possessing an elastic-stress-concentration factor of 1.0.

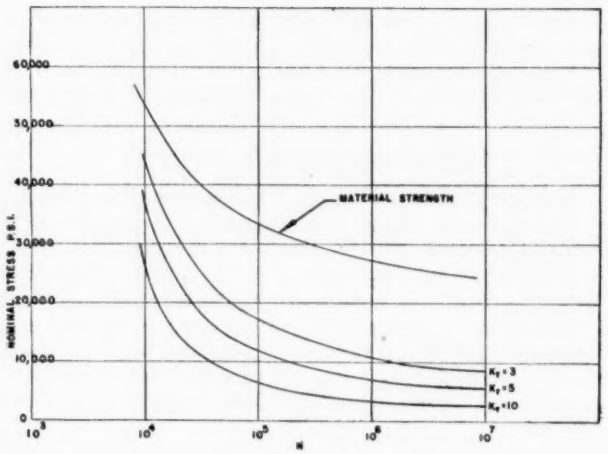

Fig. 4

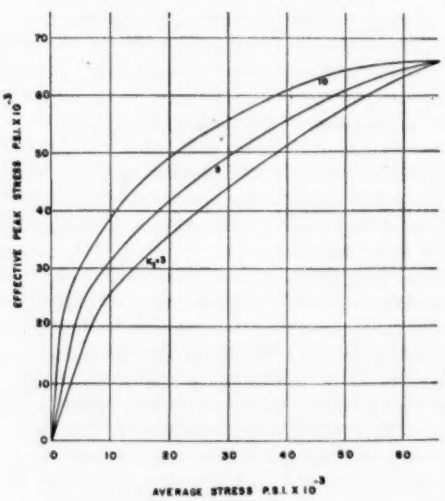

Fig. 5

Since these curves are all representative of the completely reversed stress condition, it follows from the previous discussion that for any particular N and K_t, K_f, K_m, and K_v are equal to the ratio of material strength to notched-specimen strength. Thus for $K_t = 3$ and $N = 10^6$, $K_f = K_m = K_v = \dfrac{27{,}300}{10{,}500} = 2.6$; for $K_t = 10$ and $N = 10^5$, $K_f = K_m = K_v = \dfrac{33{,}500}{6500} = 5.15$, and so forth. In order to obtain from these idealized notched-specimen data the relation between the nominal and the effective or peak stresses, one of two procedures may be followed:

1 Directly from Fig. 4 the notched-specimen strength may be plotted against the material strength for a series of N values. This procedure would, on the basis of our hypothetical data, result in three curves corresponding to K_t's of 3, 5, and 10. These curves, shown in Fig. 5, define the notch sensitivity of a material

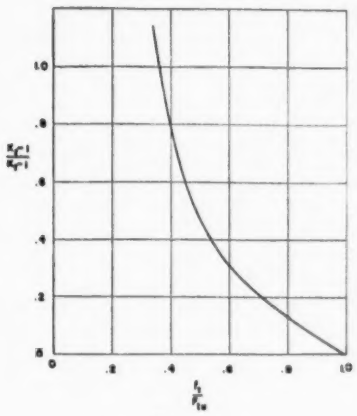

FIG. 6

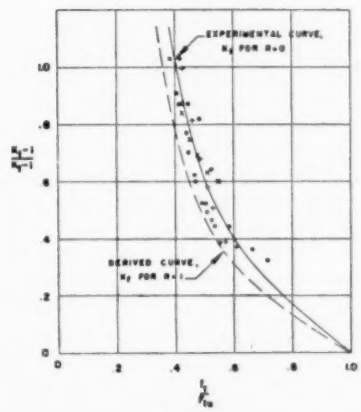

FIG. 7

under any condition of loading, including static, for those three values of K_t, for which Fig. 5 may be used to predict the fatigue strength of a structure fabricated from that material, since the effective values of maximum and varying stress may be determined and used in conjunction with the basic material data, Fig. 2, to determine the life.

2 In order to use the available data to obtain the relationship of Fig. 5 for other values of K_t, an intermediate curve, for the purpose of interpolation and extrapolation, may be plotted from the available data. Such a curve, shown in Fig. 6, relates K_t, K_f, and the peak stress implicit in the form of nondimensional parameters, bringing all the available data together into one curve, which may then be used to plot the relations of Fig. 5 for as many additional values of K_t as may appear necessary. Such a full set of curves is shown in Fig. 8.

With the information of Fig. 8 on hand, an Alclad 24S-T structure may be analyzed for fatigue. Let us suppose, for example, that the structure has at its critical section a notch inducing an elastic-stress-concentration factor of 4, i.e., $K_t = 4$, and that the structure is loaded axially under an alternating nominal stress varying between 20,000 and 30,000 psi. Hence the average maximum stress is 30,000 psi and the average varying stress is ±5000 psi. Going into the $K_t = 4$ curve of Fig. 8 it is found that these stresses correspond to an actual maximum stress of 47,500 psi and an actual varying stress of 20,000 psi. Fig. 2 shows that this combination of stresses corresponds to a life of 32,000 cycles, and the analysis of the structure is complete for that particular loading condition.

In a similar way we may determine the fatigue strength of any structure having a known K_t.

Demonstration of Analysis Method for Alclad 24S-T Structures

The following demonstration of the proposed method does not adhere strictly to the previously outlined procedure, because data on notched specimens under completely reversed loading were not available. By resorting to a tested empirical relationship (2) a large amount of data on various kinds of notched specimens were reduced to the range ratio of 0 (load varying between 0 and maximum.) These data were then plotted as shown in Fig. 7 to show the form of the relationship between K_t, K_f, and the apparent peak stress obtained by multiplying the nominal maximum stress by K_f. Then by trial and error, a law of variation for completely reversed stress ($R = -1$) was determined that would give the experimentally found values of K_f at $R = 0$. This curve is also plotted on Fig. 7 and corresponds to that of Fig. 6 obtained from hypothetical data. This curve was then used to obtain the relation between the average varying and maximum stresses and the effective or peak varying and maximum stresses for constant values of K_t. Fig. 8 is such a plot for several values of K_t. It should be noted that this plot indicates the alleviation of peak stresses at a discontinuity initiates at peak stresses as low as 20,000 psi for 24S-T. This explains why the actual magnitude of the elastic-stress-concentration factor is rarely effective in practice.

Fig. 8 may be used to predict the fatigue strength of a structure fabricated from Alclad 24S-T material.

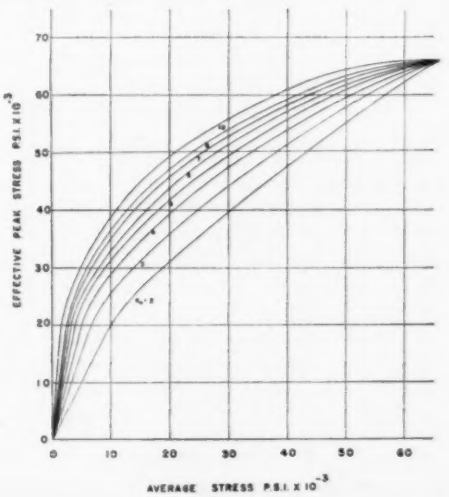

FIG. 8

Figs. 9, 10, and 11 show S-N curves at $R = 0.2$, $R = 0.4$, and $R = 0.6$, respectively for Alclad 24S-T perforated sheet predicted by this method and plotted against the test points. The value of K_t in this case was 2.6. Fig. 12 shows a similar plot for a 24S-T Alclad single-row riveted lap joint having a K_t of 6.1. K_t was determined in this latter case from the values determined photoelastically by Frocht and Hill (3) for pin-loaded double shear joints. Fig. 13 is a similar plot for a 24S-T Alclad double-row riveted joint compared with points obtained from tests of a geometrically identical specimen manufactured from Alclad 24S-T86 material. In the latter case the K_t of 5.0 was obtained by interpolation between the photoelastically determined value for pin-loaded double shear joints (complete shear transfer) and the value for perforated sheet (no shear transfer).

Some of the disparagement between the predicted and actual curves may be attributed to the fact that lack of adequate data led to rather arbitrary methods for the evaluation of constants The accuracy of this evaluation was further detracted from by

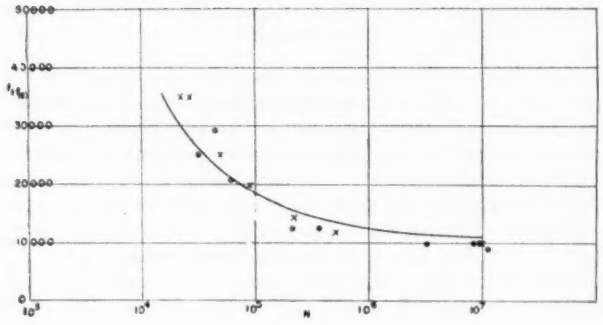

FIG. 9

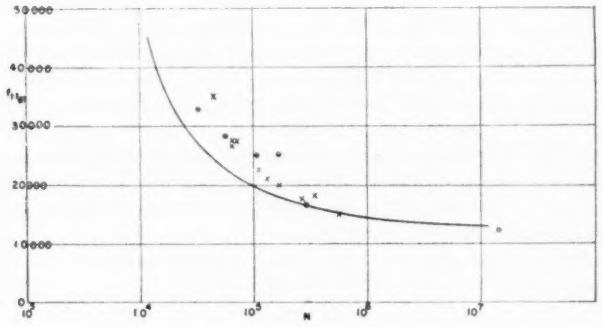

FIG. 10

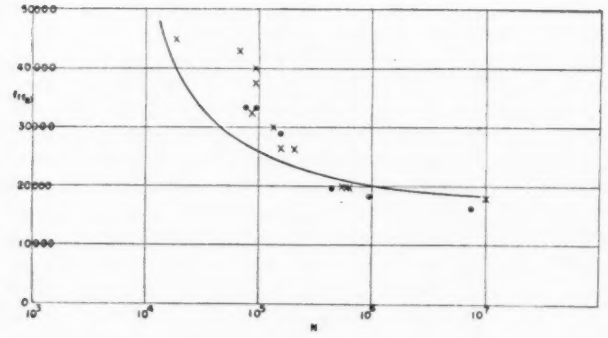

FIG. 11

the fact that specimens made from both the QQA-362 specification material and the ANA-13 specification material were used in conjunction with the known fatigue-strength characteristics only of the former; whereas some recent check tests have shown that the fatigue properties of the two materials diverge considerably, particularly in the low-cycle high stress range.

CONCLUSIONS

This paper has brought out the principal distinction between the problems involved in the development of fatigue and static-strength-analyses methods. This distinction has been shown to lie in the need for evaluating the strictly local stress conditions at stress raisers, whenever the problem of fatigue strength arises, and emphasis has been placed on the nature of the experimental data which would be adequate to determine these conditions.

The lack of complete basic data necessary for the development of the proposed analysis forbids a rigorous proof of the validity of

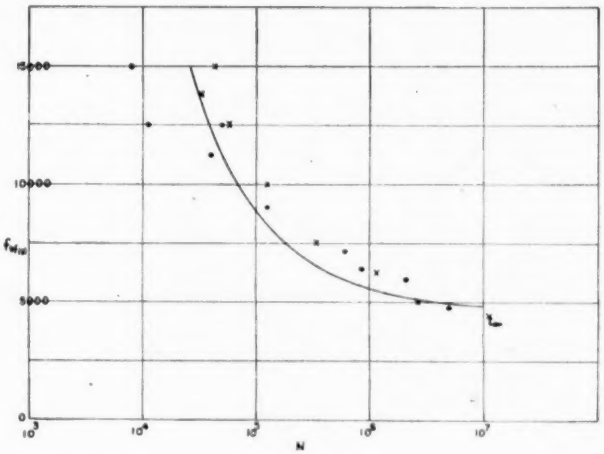

FIG. 12

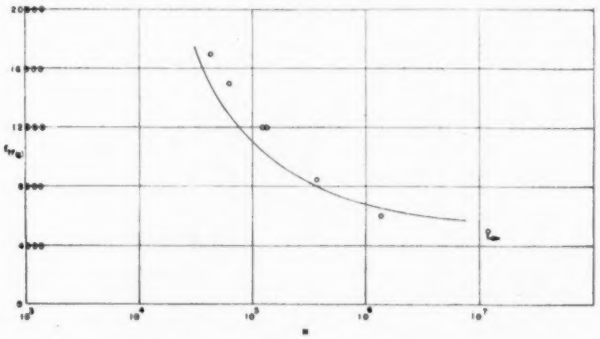

FIG. 13

the assumptions upon which it is based. The real proof must await the time the basic data become available, and the proposed method can be used directly. We feel that in view of the importance to the airframe engineer of a good fatigue-analysis method, the procurement of these data should be placed high on the list of the research laboratories' agenda.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Mr. D. W. Drake for his valuable suggestions.

An Elementary Theory of the Bourdon Gage

By ALFRED WOLF,[1] TULSA, OKLA.

A theory of the Bourdon gage is presented based upon two elements of strain, namely, the bending of the walls in a transverse section through the gage tubing, and a longitudinal extension parallel to the axis of the tubing. Practical formulas are derived for the calculation of the sensitivity and the torque of the Bourdon gage. An estimate is made of the maximum stress. The sensitivity of a very thin-walled gage is shown to be proportional to the inverse first power of the wall thickness. Results of a few measurements show agreement with the theory.

Introduction

A SIMPLE qualitative explanation of the behavior of a Bourdon-gage element was given by Lord Rayleigh (1)[2] on the basis of a theorem of Gauss on the bending of surfaces. Pressure applied internally to a tube of oval section results in a change of shape of the section; the action of the gage then follows from the invariance of the product of the two principal curvatures of the middle surface of the tubing.

Other contributions to the theory of the Bourdon pressure gage were made by E. Hill (2), A. M. Worthington (3), A. G. Greenhill (4), and L. Maurer (5). The only paper in which a definite formula is derived for the sensitivity of the Bourdon gage is that of Chido Sunatani (6).

In the present paper an attempt is made to base the theory on two elements of strain, the bending of the walls in a transverse section through the tubing and a longitudinal extension and contraction parallel to the axis of the tubing; both elements are of equal importance. The procedure may be regarded as an application of the direct methods of the calculus of variations. As expected, maximum stress calculated in this manner is not as close an approximation as the sensitivity and the torque.

The pressure element of a Bourdon gage is made of tubing of oval section, the axis of the tubing being bent into an arc of a circle which lies in a plane of symmetry of the gage element, and has the radius R; the long axis of the oval section of the tubing is perpendicular to the plane of the circle. When pressure is applied the radius of curvature increases by δR: The quantity $\delta R/R$ for unit pressure will be referred to as the sensitivity of the gage. It is postulated in the following that the pressure element is mounted in such manner that only bending moments are applied to its ends; consequently, that δR is always constant along the pressure element.

The torque of the gage is defined in the following manner: Let one end of the gage element be attached to a rigid support and let pressure be applied; the other end of the element will then move a certain distance because of the change in curvature of the axis of the tubing; the external bending moment which must be applied to the free end of the element to restore the deflection to zero will be defined as the torque of the Bourdon gage for any given pressure, and will be denoted T.

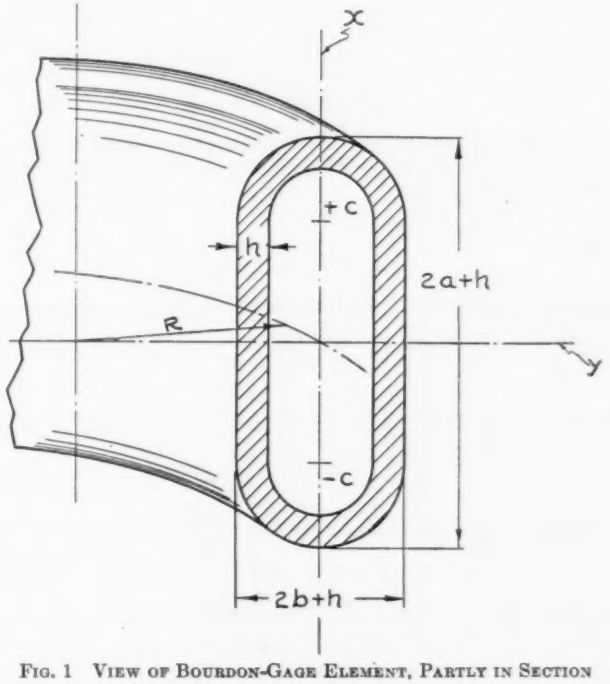

Fig. 1 View of Bourdon-Gage Element, Partly in Section

In the next section an expression will be derived for the potential energy of the gage element under pressure, and from it will be deduced a differential equation for the elastic displacement of the middle surface of the tubing. All subsequent calculations are based upon these two equations. Some of the formulas may, by a slight modification, be applied to tubing of arbitrary cross section but more often the formulas are valid only for sections with two axes of symmetry. In the third section the direct method of the calculus of variations is discussed which constitutes the practical means for the solution of the problem; the same section contains formulas for the sensitivity and the torque in the limiting case $R \rightarrow \infty$.

In the fourth section practical formulas are given for the calculation of torque and sensitivity for a specific shape of cross section of tubing which approaches closely that supplied by manufacturers. In the fifth section the maximum stress in gage elements is dealt with; only approximate results are obtained. In the concluding section a few examples are given of the accuracy to be expected from the formulas.

Potential Energy of the Bourdon Gage

Consider a transverse section through the Bourdon-gage-element tubing, and refer it to a set of rectangular co-ordinate axes x, y; their origin is to be at the center of the oval section, the x-axis is perpendicular to the plane of the circle into which the axis of the tubing is bent, the y-axis points away from the center of the same circle. When pressure is applied, the components of the infinitesimal elastic displacement of the middle line of a transverse section through the walls, relative to the center of the oval, parallel to the x- and y-axes, respectively, will be denoted ξ, η.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

All these variables are regarded as functions of the length of arc s along the middle line of a transverse section of the walls of the tubing. One of the simplifying assumptions introduced is the neglect of any change of length along that line. From this assumption and from

$$x'^2 + y'^2 = 1$$

it follows

$$x'\xi' + y'\eta' = 0 \quad \text{[A1]}$$

in which the primes denote differentiation with respect to s.

Writing ρ for the radius of curvature of the middle line of a transverse wall section,

$$\frac{1}{\rho} = x'y'' - y'x''$$

and the change of curvature resulting from elastic displacement

$$\delta\left(\frac{1}{\rho}\right) = y''\xi' + x'\eta'' - y'\xi'' - x''\eta'$$

which may be transformed with the aid of Equation [A1] into

$$\delta\left(\frac{1}{\rho}\right) = \frac{d}{ds}\left(\frac{\eta'}{x'}\right) \quad \text{[A2]}$$

The change of internal volume per unit length of tubing is

$$\delta V = \delta \int y\,dx = \int ds(y\xi' + x'\eta)$$

Making use of Equation [A1] and employing integration by parts

$$\delta V = \int ds\,\eta\left[x' + \frac{d}{ds}\left(\frac{yy'}{x'}\right)\right] \quad \text{[A3]}$$

The potential energy per unit length of tubing due to the bending of the walls and to the increase in volume is

$$\frac{E_1h^3}{24}\int ds\left[\delta\left(\frac{1}{\rho}\right)\right]^2 - p\,\delta V$$

where

$$E_1 = \frac{E}{1-\sigma^2}$$

E = Young's modulus
σ = Poisson's ratio
h = wall thickness
p = pressure

Besides the potential energy of transverse bending of the walls, the extension of elements parallel to the axis of the tubing will be considered; this is regarded as a function of s only. A simple geometrical consideration of the effect of simultaneous change of the radius of curvature of the axis of the tubing, the length of which remains constant, and of the elastic displacement of the walls, leads to the expression

$$\frac{R + \delta R + y + \eta}{R + \delta R} - \frac{R + y}{R}$$

for the extension of filaments parallel to the axis of the tubing, which, to a sufficient approximation, may be written

$$\frac{\eta}{R} - \frac{y}{R}\frac{\delta R}{R}$$

The total potential energy W per unit length of tubing will be assumed to be the sum of the energies of transverse bending of the walls and of the longitudinal extension parallel to the axis of the tubing; thus

$$W = \int ds\left\{\frac{E_1h^3}{24}\left[\frac{d}{ds}\left(\frac{\eta'}{x'}\right)\right]^2 + \frac{Eh}{2R^2}\left[\eta - y\frac{\delta R}{R}\right]^2 - p\eta\left[x' + \frac{d}{ds}\left(\frac{yy'}{x'}\right)\right]\right\} \quad \text{[1]}$$

There is no rigorous foundation for adding the energies of bending and of longitudinal extension; this step is justified mainly by its success. However, the foregoing procedure can be shown to be correct in the special case of an infinitely long plane strip of moderate thickness, subjected simultaneously to pressure on one side and to uniform longitudinal strain.

Since W is a minimum, it follows by well-known methods

$$\frac{d}{ds}\left[\frac{1}{x'}\frac{d^2}{ds^2}\left(\frac{\eta'}{x'}\right)\right] + \frac{12E}{R^2h^2E_1}\left[\eta - y\frac{\delta R}{R}\right] = \frac{12p}{E_1h^3}\left[x' + \frac{d}{ds}\frac{yy'}{x'}\right] \quad \text{[2]}$$

When $R \to \infty$ Equation [2] reduces to

$$\frac{d}{ds}\left[\frac{1}{x'}\frac{d^2}{ds^2}\left(\frac{\eta'}{x'}\right)\right] = \frac{12p}{E_1h^3}\left[x' + \frac{d}{ds}\left(\frac{yy'}{x'}\right)\right] \quad \text{[2a]}$$

which is clearly solvable by quadratures. Equation [2] can be solved by quadratures in the special case of rectangular cross section, a fact which may be used for an extension of the present theory.

To determine the sensitivity of the Bourdon gage, Equation [2] should be solved with $\delta R/R$ regarded as a parameter; the solution must be substituted in Equation [1] and the value of $\delta R/R$ must be found which makes W a minimum.

The torque of the gage is determined by a similar procedure. Assume $\delta R/R = 0$ in Equation [2] and substitute the solution in Equation [1]. The resulting value W_1 is the potential energy of the gage under pressure when constrained from changing its curvature. The torque of the gage is given by

$$T = \frac{2R(W_1 - W)}{\delta R/R} \quad \text{[3]}$$

which may be verified by considering the work done by external bending moments in reducing the radius of curvature of the gage element from $R + \delta R$ to R, which is $W_1 - W$, and which also is equal to $\frac{1}{2}T$ times the angular deflection of the gage element per unit of its length $\frac{1}{R}\frac{\delta R}{R}$.

Application of Direct Method of Calculus of Variations

The practical method of attack on the Bourdon-gage problem makes use of the minimum property of the energy W. A solution of Equation [2a] or a function proportional to it, is obtained first; it will be denoted $\eta_0(s)$. It is then postulated

$$\eta(s) = B\eta_0(s)$$

where B is an undetermined constant, and this expression is substituted in Equation [1], leading to

$$W = a_{11}B^2 + a_{12}B\frac{\delta R}{R} + a_{22}\left(\frac{\delta R}{R}\right)^2 + a_{23}B \quad \text{[4]}$$

in which the coefficients $a_{11} \ldots a_{23}$ are now known functions of the dimensions of the gage, elastic constants, and pressure. Since W must be a minimum for variations with respect to B and $\delta R/R$, the following results are obtained

$$B = \frac{-2a_{12}a_{33}}{4a_{11}a_{22} - a_{12}^2} \quad [5]$$

$$\frac{\delta R}{R} = \frac{a_{12}a_{33}}{4a_{11}a_{22} - a_{12}^2} \quad [6]$$

The value of W_1 is derived by substituting $\delta R/R = 0$ in Equation [4] and then determining the minimum value of the resulting expression. This procedure leads to

$$T = \frac{Ra_{12}a_{33}}{2a_{11}} \quad [7]$$

It may be of interest at this point to derive some simple formulas applicable to the case $R \to \infty$.

Since Equation [2a] is exact in this case, $B \to 1$; further

$$a_{12}^2/a_{11}a_{22} \to 0$$

It follows

$$\left(\frac{\delta R}{R}\right)_\infty = \frac{\int \eta y \cdot ds}{\int y^2 \cdot ds} \quad [8][3]$$

$$(T)_\infty = \frac{Eh}{R} \int \eta y \cdot ds \quad [9]$$

Explicit formulas for the function η can be deduced easily from Equation [2a]. First, from Equations [A2] and [2a]

$$\delta\left(\frac{1}{\rho}\right) = \frac{6p}{E_1 h^3}(r^2 - \bar{r}^2) \quad [10]$$

where $r^2 = x^2 + y^2$, and $\bar{r}^2$ is the mean value of r^2 on the middle surface of the tubing. Equation [10] will be used in connection with the problem of maximum stress. If the length of arc s is measured from a point at which $x = 0$, the solution of Equation [10] satisfying appropriate periodicity conditions is

$$\eta = \frac{6p}{E_1 h^3}\left\{x\int_0^s r^2 \cdot ds - \int_0^s xr^2 \cdot ds - \frac{sx}{s_0}\int_0^{s_0} r^2 \cdot ds + \bar{r}^2 \int_0^s x \cdot ds\right\} + \text{const.} \quad [11]$$

where s_0 is the total length of the middle line of a transverse section through the gage-element walls. The constant of integration is determined from

$$\int_0^{s_0} \eta \cdot ds = 0$$

It is clear that explicit formulas for sensitivity and torque can be derived from Equations [8], [9], and [11] but the subject will not be pursued any further since it is not important for applications.

Practical Formulas for Sensitivity and Torque of a Bourdon Pressure Gage

A specific shape of cross section of the gage-element tubing will be postulated in what follows. The oval formed by the middle line of the transverse cross section of the walls will be assumed to be made up of two parallel straight-line portions of length $2c$ each, a distance $2b$ apart, and terminated by two half circles of radius b. The straight-line portions of the oval are parallel to the x-axis, and hence perpendicular to the plane of the circle into which the axis of the tubing is bent. The long axis of the oval has the length $2a = 2b + 2c$, the short axis has the length $2b$. The outside dimensions of the tubing are $2a + h \times 2b + h$, h being the wall thickness.

The function $\eta(s)$ which is to be substituted in Equation [1] is chosen as a solution of Equation [2a] multiplied by an indeterminate constant. On the straight-line portions of the oval contour

$$\eta(s) = \alpha + \frac{1}{2}\beta s^2 + \frac{1}{12}\gamma s^4 \quad [12]$$

where s is measured from the respective centers of the straight-line portions, and varies between $-c$ and $+c$. On the half circles terminating the oval contour, it is assumed

$$\frac{d}{d\phi}\left(\frac{1}{x'}\frac{d\eta}{d\phi}\right) = A + B\cos\phi \quad [13]$$

which is a consequence of Equation [2a], and in which the angle ϕ is taken to vary from $-\frac{\pi}{2}$ to $+\frac{\pi}{2}$. The condition of continuity of $\eta, \eta', \eta'', \eta'''$ at the points at which the straight-line portions of the contour meet the half circles $\left(\phi = \pm\frac{\pi}{2},\ s = \pm c\right)$ determines the constants α, β, γ, A in terms of B (refer to Appendix).

The substitution of Equations [12] and [13] in Equation [1] leads to explicit expressions for the coefficients $a_{11} \ldots a_{33}$ which are given in the Appendix. The algebra is very tedious but presents no difficulty, and leads to

$$\frac{\delta R}{R} = \frac{4}{15}\frac{p}{E_1}\frac{a^4}{bh^3}\frac{F}{1 + \frac{4}{35}\frac{E}{E_1}\frac{a^4}{R^2h^2}F_1} \quad [14]$$

$$T = \frac{16}{15}\frac{pE}{E_1}\frac{ba^4\left[a + \left(\frac{\pi}{4} - 1\right)b\right]}{Rh^3}\frac{F}{1 + \frac{8}{21}\frac{E}{E_1}\frac{a^4}{R^2h^2}F_2} \quad [15]$$

The factors F, F_1, F_2, as well as the factor G introduced in the next section, are rational functions of b/a which approach unity as $b/a \to 0$. Their values are derived from the expressions for the coefficients $a_{11} \ldots a_{33}$ and are given in Table 1.

TABLE 1 VALUES OF F AND G FACTORS

b/a	F	F_1	F_2	G
0.0	1.000	1.000	1.000	1.000
0.1	1.273	1.040	1.207	0.934
0.2	1.469	1.059	1.373	0.852
0.3	1.574	1.057	1.498	0.757
0.4	1.574	1.024	1.572	0.652

A consideration of Equations [14] and [15] makes evident the fact that the theory of pure bending of thin shells cannot correctly represent the behavior of the Bourdon pressure gage when the ratio a^4/R^2h^2 is much greater than unity. For sufficiently small values of h the sensitivity of the gage becomes inversely proportional to the first power of the wall thickness; longitudinal extensions parallel to the axis of the tubing are then the predominant factor.

Maximum Stress in a Bourdon Gage

The distribution of stress in a gage element under pressure cannot be derived with any precision from the preceding theory. Approximate results may, however, be attained by postulating the maximum stress to be due to the transverse bending of the walls of the tubing. According to Equation [10] the curvature of the middle line, and hence the stress in this type of deformation is proportional to $r^2 - \bar{r}^2$. Maximum stress is found on one

[3] A similar formula is given by E. Hill (2) who, however, does not attempt to evaluate η. Hill's formula was employed by Sunatani (6) in the special case of elliptic cross section.

of the axes of the oval section of the tubing where r is a maximum or a minimum. In most practical applications, when $b/a < 0.48$, the point of maximum stress is at the intersection of the long axis of the oval and the inner surface of the walls of the tubing. It may be noted that in dealing with a tube which is only slightly elliptical, the maximum stress is on the short axis of the ellipse.

The value of the maximum stress S will be assumed to be given by the simple relation

$$S = \frac{E_1 h}{2} \delta \left(\frac{1}{\rho}\right)$$

The calculations of the preceding section then lead immediately to the formula

$$S = \frac{E_1 h}{2} \frac{A + B}{b^2} = 2p \frac{a^2}{h^2} \frac{G}{1 + \frac{4}{35} \frac{E}{E_1} \frac{a^4}{R^2 h^2} F_1} \quad \ldots\ldots [16]$$

The values of G as a function of b/a are shown in Table 1.

Conclusion

A reasonably good confirmation of Equations [14] and [15] was obtained from some measurements on the Amerada bottom-hole pressure gage, carried out at the laboratory of the Geophysical Research Corporation. No satisfactory method was developed for the measurement of maximum stress, but it is reasonably certain that values of stress furnished by Equation [16] are too great, especially for thick-walled tubing. For illustration of experimental data the examples given in Table 2 may suffice.

The Influence of Oil-Film Journal Bearings on the Stability of Rotating Machines

By A. C. HAGG,[1] EAST PITTSBURGH, PA.

The self-excited vibration caused by the lubricating films of journal bearings and commonly called oil-film whirl or oil whip is discussed. The upper limit of whirling frequency has been found to be one-half rotational frequency in the general case; actually the phenomenon will manifest itself at a frequency which is invariably below this limit. Stability criteria have been developed for certain common systems in terms of bearing and rotor parameters. The tilting-pad bearing of Michell has been established as a so-called "stable" or "nonwhirling" bearing. This bearing and related types are probably the only oil-film journal bearings which are incapable of exciting oil whip, regardless of the system to which they are applied. Qualitatively the results of the paper appear to be in agreement with observations. In certain cases, results have been substantiated experimentally.

Nomenclature

The following nomenclature is used in the paper:

Symbol		Dimensions
a	= radius of journal	L
η	= radial clearance of journal in bearing	L
ϵ	= eccentricity of journal	L
b	$= \frac{\epsilon}{\eta}$	Dimensionless
l	= circumferential length of bearing surface	L
w	= width of bearing surface	L
A	= projected area of journal	L^2
Ω	= angular velocity of journal	T^{-1}
ω	$= \frac{d\theta}{dt}$ = angular velocity of journal center about bearing center	T^{-1}
μ	= viscosity of lubricant	$ML^{-1}T^{-1}$
N	= rpm of journal	T^{-1}
p	= load per unit projected journal area	$ML^{-1}T^{-2}$
B	= bearing-force constant	MT^{-1}
c, D	= bearing-damping constants	MT^{-1}
m	= mass, usually rotor mass	M
ω_n	= natural frequency of rotor in bending or on "spring" of lubricating film	T^{-1}
T	= bearing torque constant	ML^2T^{-1}
I_1	= rotor inertia about rotating axis	ML^2
I_2	= rotor inertia through CG and normal to I_1	ML^2

Introduction

A self-excited vibration known as oil-film whirl or oil whip sometimes occurs in rotating machines employing oil-film journal bearings. Usually the rotor is the major vibrating element, although in some machines the instability may be manifest to the same or greater degree in nonrotating parts; in either case the forces doing work in support of the vibration come from oil-film pressures of the bearings. Oil-film whirl is characterized by relative motion of journal and bearing in an area-enclosing path usually circular or elliptical, and in the direction of machine rotation. The motion of the rotor proper or of the nonrotating elements may or may not be magnified, depending upon the masses and flexibilities of the system. In many cases the vibration frequency may be nearly one-half rotational frequency; however, the frequency of oil-film excited vibration is invariably less than one-half rotational frequency.

It may be mentioned in passing that unbalance vibration, alone or in combination with oil-film excitation, may cause instability at a frequency which is exactly one-half or one-third rotational frequency. This phenomenon has been fully explained by Baker,[2] and can be corrected or reduced to oil-film whirl by sufficiently good rotor balancing.

Instability caused by oil-film journal bearings has been investigated from time to time,[3,4,5] and the phenomenon has been controlled in many cases with success. However, oil-film whirl remains a troublesome vibration problem, especially in the higher-speed machines and in those with vertical shafts.

The present discussion covers some of the rational aspects of this stability problem, and draws attention to certain types of journal bearings which are useful in securing machine stability.

Upper Limit of Whirling Frequency

The upper limit of whirling frequency is determined by the bearing. Robertson[4] has shown by means of hydrodynamical theory that, neglecting friction forces, the resultant film force due to journal rotation in an ideal bearing is at right angles to the eccentricity, and is just balanced by resultant force due to whirling when the whirling frequency is one-half rotational frequency. This result represents the upper limit of whirling frequency for an unloaded ideal bearing. The same result can be deduced more directly by considering the continuity condition that the volume of lubricant passing through the film at some point A, Fig. 1, must equal the volume passing point B plus the volume required to fill the void of the receding journal. In the limiting condition no pressure can exist in the film, hence side leakage is zero, and it follows that

$$\frac{a\Omega}{2}(\eta + \epsilon) = \frac{a\Omega}{2}(\eta - \epsilon) + 2a\omega\epsilon \quad \ldots\ldots\ldots [1]$$

$$\omega = \frac{\Omega}{2} \quad \ldots\ldots [2]$$

The same result is obtained regardless of where points A and B are taken.

The same continuity condition may be applied to the general case given in Fig. 2. Assuming that the pressures due to a steady

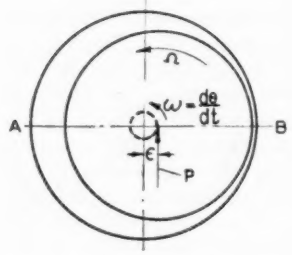

FIG. 1 IDEAL JOURNAL BEARING

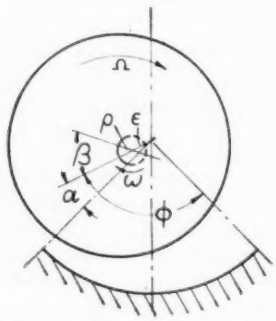

FIG. 2 PARTIAL JOURNAL BEARING

load do not influence the circulation caused by whirling

$$\frac{a\Omega\rho}{2}\cos(\phi+\beta) = -\frac{a\Omega\rho}{2}\cos(\alpha+\beta) + a\omega\rho\cos(\alpha+\beta) - a\omega\rho\cos(\phi+\beta) \quad \ldots\ldots [3]$$

and

$$\omega = \frac{\Omega}{2} \quad \ldots\ldots [2]$$

In reality the upper limit of whirling frequency is reduced more or less from $\frac{\Omega}{2}$ because of fluid friction and bearing leakage.

The actual oil-whirl frequency of a given system is dependent upon other factors besides the bearing; however, it is important to note that whatever its value, it must be less than one half the running frequency of the journals.

IDEAL CASE OF OIL-FILM WHIRL

Referring to Fig. 1, the equations of motion for small oscillations of a journal mass in a fixed ideal bearing are, in polar coordinates

$$\left.\begin{aligned} m\frac{d^2\epsilon}{dt^2} - m\epsilon\left(\frac{d\theta}{dt}\right)^2 &= 0 \\ m\epsilon\frac{d^2\theta}{dt^2} + 2m\frac{d\epsilon}{dt}\frac{d\theta}{dt} &= P \end{aligned}\right\} \quad \ldots\ldots [4]$$

where P can be surmised to be of the form

$$P = B\left(\Omega - 2\frac{d\theta}{dt}\right)\epsilon$$

where B is the bearing characteristic. Its value has been determined by Robertson,[4] and a simplified approximate expression is

$$B = \frac{6\pi\mu w a^2}{\eta^2}$$

Substituting the value of P in Equation [4], assuming a solution of the form $\epsilon = \epsilon_0 e^{\lambda t}$, and remembering that $\frac{d\theta}{dt}$ is a constant for linear systems

$$\lambda^2 + \frac{B}{m}\lambda \pm \frac{B\Omega}{2m} = 0 \quad \ldots\ldots [5]$$

solving for λ

$$\lambda = -\frac{B}{2m} \pm \sqrt{\left(\frac{B}{2m}\right)^2 \mp \frac{B\Omega}{2m}} \quad \ldots\ldots [6]$$

It is evident that a value of λ exists which is real and positive for all values of Ω greater than zero, hence ϵ increases with time and the motion is unstable. From Equation [4]

$$\lambda^2 = \left(\frac{d\theta}{dt}\right)^2$$

and the whirling velocity is

$$\frac{d\theta}{dt} = \omega = -\frac{B}{2m} + \sqrt{\left(\frac{B}{2m}\right)^2 + \frac{B\Omega}{2m}} \quad \ldots\ldots [7]$$

which can be rewritten

$$\omega = -\frac{B}{2m}\left[1 - \sqrt{1 + \frac{2m\Omega}{B}}\right] \quad \ldots\ldots [8]$$

In many cases $\frac{2m\Omega}{B}$ is small compared to unity, and expanding the radical of Equation [8] in a power series and neglecting higher-order terms this equation reduces to

$$\omega \backsimeq \frac{\Omega}{2} \quad \ldots\ldots [9]$$

Hence even though the natural frequency of the system is zero, the driving force is sufficiently strong to give whirling near the upper limit of frequency.

In practical cases with unloaded bearings the amplitude of whirl is limited by the bearing clearance, yet for rigid rotors the conditions with respect to the vibration still correspond closely to the ideal case. Any contact of the journal and bearing effects a tuning of the system so that the frequency may be higher than that indicated in Equation [8].

A vertical pump motor rotor with a self-aligning ball bearing at the top and an 8 × 8-in. full journal bearing at the bottom was observed to whirl in the manner of a pendulum, and from a few revolutions to 1200 rpm the whirling frequency held to slightly less than one-half rotational frequency in accord with calculations based upon the ideal case. Vertical turboblowers and high-speed motors have been observed to exhibit the same characteristics with respect to frequency. The model, Fig. 12, whirled at a frequency slightly less than one-half running frequency when fitted with a full journal bearing as can be noted from records of the vibration Fig. 13 (*a*) and (*b*).

In the lower-speed machines, bearing clearances of about 0.001 in. per in. diam of bearing usually reduces the vibration of rigid rotors to permissible limits. It appears that eccentric running of the journals caused by rotor unbalance may in some cases eliminate whirling of rigid rotors in bearings of small clearance.

DISCUSSION OF THE PROBLEM OF MACHINE STABILITY

The previous example of whirling of a journal mass in a fixed ideal bearing is useful in visualizing the action of the lubricating film in exciting a vibration, and actual cases do occur which can be explained in this simple manner. However, the situation in general is very much more complicated. Formal mathematical consideration of the general case becomes hopelessly complex; however, a qualitative examination can be useful in showing the possible extent of the stability problem and in appraising the

applicability of stability criteria for special cases. For this purpose a dynamical idealization consisting of three spring-damper-mass systems in series, as shown in Fig. 3, is probably sufficiently representative. The parameters k_1, c_1, and m_1 represent the nonrotating parts; k_2 and c_2 represent the lubricating film where c_2 may be positive or negative; and m_2, k_3, c_3, and m_3 represent the rotating element. Of these parameters k_1, c_1, m_1, m_2, and m_3 can be considered as constants and the remaining ones are functions of speed and load, especially k_2 and c_2.

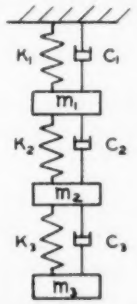

FIG. 3 DYNAMICAL SYSTEM

When the parameters c_1, c_2, and c_3 are positive, i.e., damping elements, it is clear without any analysis that the system is stable for all modes of vibration. In actual cases c_1 is always positive and c_3 can usually be considered negligibly small so that the possibility of self-excited vibration of some natural mode rests with the oil-film parameter c_2. If c_2 is positive the system is stable; if it is negative the system may or may not be unstable. The final answer in this latter case must of course depend upon all parameters of the system. On an energy basis the system is stable when the total damping energy of the system exceeds the total exciting energy for any mode of vibration. This permits the possibility of a negative value of c_2 in a stable system.

Relative motion between the masses m_1 and m_2 is required for the oil film to do work on the system, hence the mode of self-excited oil whirl involves relative motion of journal and bearing. Cases have been observed where the self-excited mode involved considerable motion of both rotating and nonrotating parts; however, the massiveness and the damping of nonrotating parts usually results in small motions of m_1 compared to motions of m_2, and for analysis the bearing may be considered as fixed and the case simplified to a two-mass system. The same situation would occur when the natural frequency of the nonrotating element is high compared to the natural frequency of the rotor.

When the natural frequency of the rotor is somewhat greater than the upper limit of whirling frequency, that is, about one half the running frequency, the rotor behaves as a rigid body so that with fixed bearings the case is a one-mass system, corresponding to the system assumed in the example of the preceding section.

Assumption of fixed bearings is usually essential for a stability analysis, and this assumption is a fairly reasonable one in most cases, and leads to useful results. However, the possibly more complex nature of the stability problem should be kept in mind, in spite of simplifying assumptions for analytical purposes, especially in the diagnosis of a particular case at hand where the mode of vibration can usually be determined. The elimination of oil whip in a particular turbine by a prop under a steam supply pipe becomes less mysterious with the broader view of the problem. It should also become clear that the experimenter must understand his test system if rational results are to be obtained.

SYSTEMS WITH PARTIAL BEARINGS UNDER STEADY LOAD

Partial bearings with clearance are extensively used in the support of horizontal rotors; therefore it is of especial interest to consider systems employing this type of bearing.

The characteristics of the partial bearing can be noted in Fig. 4 which shows the position of the journal center, i.e., the parameters ϵ and γ, as a function of the operating variable $\left(\frac{a}{\eta}\right)^2 \frac{\mu N}{p}$. Naturally the journal locus varies with arc length and width of

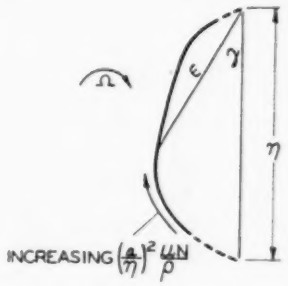

FIG. 4 JOURNAL LOCUS

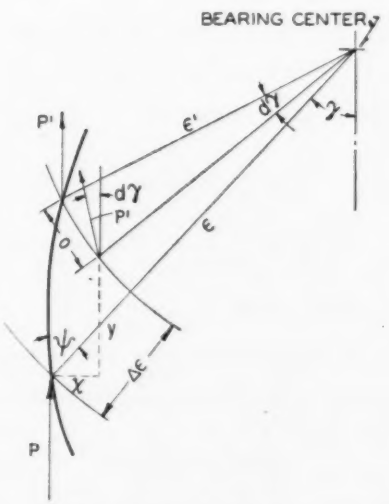

FIG. 5 JOURNAL LOCUS

bearing; however, the loci are similar for the various partial bearings with clearance.

Considering a small angular displacement of a journal $d\gamma$ from some position of equilibrium ϵ and γ, from geometry of the lubricating film, it will be assumed that the resultant film force acting on the journal will not change appreciably in magnitude, but will change its direction by the angle of the displacement. Referring to an enlarged section of the journal locus, Fig. 5, the forces F_x and F_y on the journal for the small displacement (x, y) are

$$\left.\begin{aligned} F_x = P'\frac{o}{\epsilon} &= \frac{P}{\epsilon}\Big[x(\sin\gamma\tan\psi + \cos\gamma) \\ &\qquad - y(\sin\gamma - \cos\gamma\tan\psi)\Big] \\ F_y = \frac{\partial P}{\partial \epsilon}\Delta\epsilon &= \frac{\partial P}{\partial \epsilon}(x\sin\gamma + y\cos\gamma) \end{aligned}\right\} \quad [10]$$

(a) *Rigid Rotor in Fixed Bearings.* If we let

$$\left.\begin{aligned} k_1 &= \frac{P}{\epsilon}(\sin\gamma\tan\psi + \cos\gamma) \\ D_1 &= \frac{P}{\epsilon}(\sin\gamma - \cos\gamma\tan\psi) \\ k_2 &= \frac{\partial P}{\partial\epsilon}\cos\gamma \\ D_2 &= \frac{\partial P}{\partial\epsilon}\sin\gamma \end{aligned}\right\} \quad \ldots\ldots\ldots [11]$$

and assume for the moment that the rotor mass is supported by a single bearing, the equations of motion of the rotor which partakes of the same motion as the journal are[6]

$$\left.\begin{aligned} m\frac{d^2x}{dt^2} + c\frac{dx}{dt} + k_1x - D_1y &= 0 \\ m\frac{d^2y}{dt^2} + c\frac{dy}{dt} + k_2y + D_2x &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots [12]$$

where m is the mass of the rotor and c is the bearing damping constant taken to be approximately the same in the x- and y-directions.

Assuming a solution of Equation [12] of the form

$$x = A_1e^{\lambda t}, \quad y = A_2e^{\lambda t}$$

the characteristic equation is obtained

$$\lambda^4 + 2\left(\frac{c}{m}\right)\lambda^3 + \left(\frac{k_1}{m} + \frac{k_2}{m} + \frac{c^2}{m^2}\right)\lambda^2 + \left(\frac{k_1c}{m^2} + \frac{k_2c}{m^2}\right)\lambda + \frac{k_1k_2}{m^2} + \frac{D_1D_2}{m^2} = 0 \ldots\ldots [13]$$

This equation is of the form

$$\lambda^4 + a_3\lambda^3 + a_2\lambda^2 + a_1\lambda + a_0 = 0$$

and for stability, by Routh's criteria, the coefficients $a_3 \ldots . a_0$ must be positive, and

$$a_1a_2a_3 > a_1^2 + a_3^2a_0$$

The first requirement is always satisfied and the second requirement yields the condition for stability

$$(k_1 - k_2)^2 + 2c^2\left(\frac{k_1}{m} + \frac{k_2}{m}\right) > 4D_1D_2 \ldots\ldots [14]$$

Solution of Equations [12], assuming zero damping, gives the stability criterion

$$(k_1 - k_2)^2 > 4D_1D_2 \ldots\ldots\ldots\ldots [15]$$

which is, as expected, simply condition [14] without the damping term. This result corresponds to Stodola's criterion, and it may be quite pessimistic because the damping term

$$2c^2\left(\frac{k_1}{m} + \frac{k_2}{m}\right)$$

in the condition, Equation [14], is seldom negligibly small, and in many cases it may be larger than

$$(k_1 - k_2)^2$$

Criterion [14] is applicable to the usual approximately symmetrical system in which the rotor mass is contained between the bearings, and the average film pressure is about the same in each bearing, because in this case the mode of vibration yielding the lower frequency will correspond to the conditions for which Equations [12] are written, namely, that the journals and rotor partake of the same motion. Naturally the various bearing constants in criterion [14] will be the sums of the individual bearing constants.

The constants in criterion [14] can be evaluated for systems employing the 120-deg bearing from the curves, Figs. 6 and 7, and with the following formulas[7]

$$\frac{\partial P}{\partial\epsilon} = \left(\frac{a}{\eta}\right)^2\frac{\mu N}{\eta(b_1 - b_2)}\left(\frac{1}{G_1} - \frac{1}{G_2}\right)A \ldots\ldots [16]$$

where G_1 and G_2 are two values of the operating variable corresponding to b_1 and b_2 taken from the curve Fig. 6(b), in the immediate vicinity of the operating point

$$\tan\psi = \frac{b'(\gamma' - \gamma)}{b - b'} \ldots\ldots\ldots\ldots [17]$$

where b and γ specify the journal position under operating conditions, and b' and γ' define a point at slightly increased value of the operating variable, that is to the left of the operating journal position in Fig. 7.

The damping constant c can be extracted from a later development Equation [43] and is

$$c = \frac{\mu}{2\eta^3}\left(\frac{l^2w^2}{l^2 + w^2}\right) \ldots\ldots\ldots\ldots [18]$$

where the quantities are as defined in the nomenclature.

Criterion [14] indicates, not quite directly, that decreasing values of $\left(\frac{a}{\eta}\right)^2\frac{\mu}{p}$ gives increasing stable speed limits; however, the damping term permits the possibility of a stable system even though the journals are running nearly concentrically. These indications have not as yet been substantiated by systematic tests, but qualitatively the criterion appears to follow field observations.

By considering possible modes of rotor vibration, equivalent systems can be constructed for overhung rotors and for special bearing loadings so that criterion [14] may be applied in these cases.

(b) *Flexible Rotor in Fixed Bearings.* A system in which the lowest natural frequency of the rotor in bending is less than the upper limit of whirling frequency is usually unstable. With lightly loaded bearings this upper limit is a maximum of $\frac{\Omega}{2}$, as established in the section, "Upper Limit of Whirling Frequency," and the stability criterion may be expressed as

$$\omega_n > \frac{\Omega}{2} \ldots\ldots\ldots\ldots [19]$$

which may also be interpreted as the condition for which criterion

[6] "Kritische Wellenstörung Infolge der Nachgiebigheit des Oelpolsters im Lager," by A. Stodola, *Schweizerische Bauzietung*, vol. 85, 1925, p. 265; also "Kritische Drehzahlen als Folge der Nachgiebigheit des Schmiermittels im Lager," by C. Hummel, *Forschungsarbeiten*, V. D. I., Heft 287, 1926. Stodola's equations written specifically for the half-bearings are similar to Equation [12] except the damping term is omitted.

[7] Curves are plotted for real bearings from data in "Effects of Side-Leakage in 120-Degree Centrally Supported Journal Bearings," by S. J. Needs, Trans. A.S.M.E., vol. 56, 1934, table 2, p. 726. Data on other bearings are contained in the paper, "Characteristics of Centrally Supported Journal Bearings," by E. O. Waters, Trans. A.S.M.E., vol. 64, 1942, pp. 711–719.

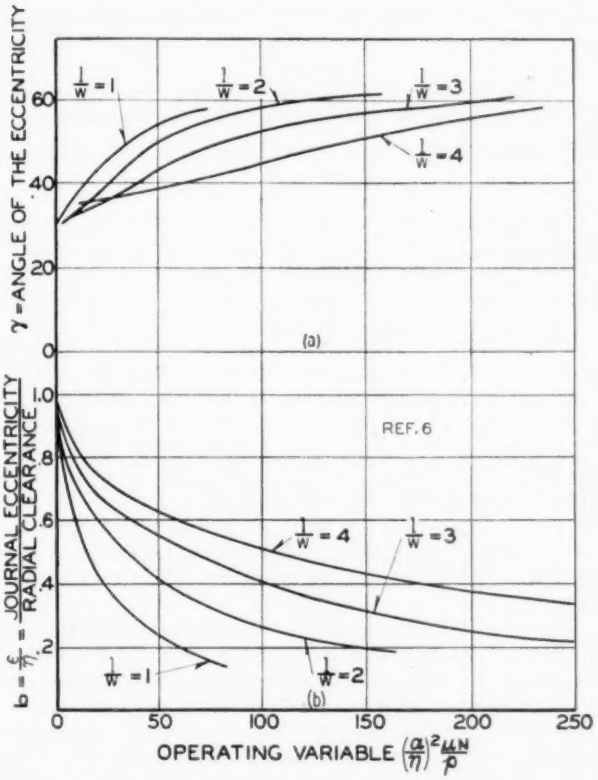

FIG. 6 CHARACTERISTICS OF 120-DEG-CLEARANCE BEARINGS

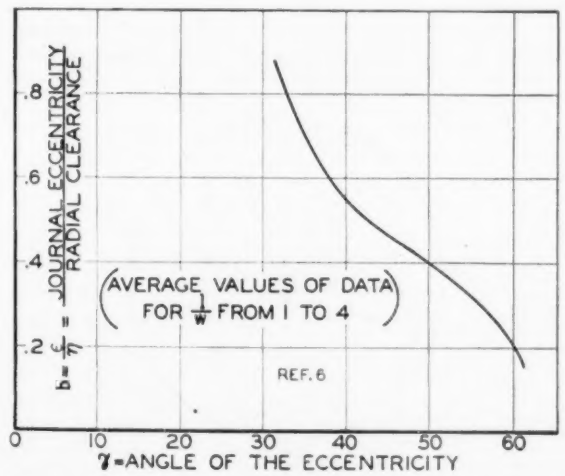

FIG. 7 CHARACTERISTICS OF 120-DEG-CLEARANCE BEARINGS

[14] applies. With heavily loaded bearings the factor $1/2$ in criterion [19] may be replaced by a smaller one, perhaps $1/3$, because the upper limit of whirling frequency is reduced by the increased side leakage which accompanies high film pressures.

Sometimes the mode of vibration may involve small relative motion of journal and bearing so that the energy input to the system is not sufficient to overcome whatever damping exists, and the speed at which instability occurs may be appreciably higher than that indicated by criterion [19]. Heavy and asymmetrical loading of the bearings and possibly imperfect lubrication may occur with bending vibration of the rotor, and doubtless these effects influence the stability characteristics of a system. On these bases it seems plausible that rotors whose mass is contained between bearings may have a higher stable speed than overhung rotors, even though the lowest natural frequencies are the same.

It is desirable to keep the lowest natural frequency of the rotor greater than one-half rotational speed of the machine; however, observance of this rule alone does not preclude the possibility of oil whirl of the rotor as a rigid body, and hence criterion [14] should also be satisfied.

In some designs observance of one or both of the stability criteria for partial bearings may be very difficult or even impossible, and in these cases it may be necessary to employ special damping devices or to substitute other type bearings which are discussed later.

FIXED-PAD BEARINGS

A fixed-pad bearing is a multiple-film type (see Fig. 8) consisting of a series of tapered pads over the bearing surface, each pad being separated by a longitudinal groove. These bearings are especially useful from a stability standpoint for rigid rotors in which the bearing load might be in any direction or for vertical guide purposes.

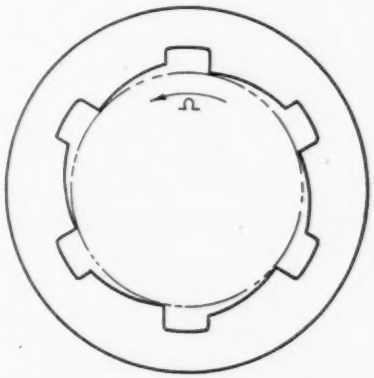

FIG. 8 FIXED-PAD BEARING

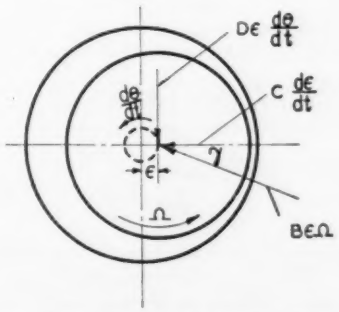

FIG. 9 FORCE SYSTEM, FIXED-PAD BEARING

The characteristics of this bearing are similar to a full sleeve bearing except the resultant film force acting on the journal for eccentricities up to about one half the radial clearance is at some smaller angle to the line connecting journal and bearing centers, as indicated in Fig. 9.

Considering a symmetrical system in which the bearings are lightly loaded, as, for example, a vertical rotor, the equations of motion for the rotor mass which executes the same motion as the journals are

$$\left.\begin{aligned} m\frac{d^2\epsilon}{dt^2} - m\epsilon\left(\frac{d\theta}{dt}\right)^2 + B\Omega\epsilon\cos\gamma + c\frac{d\epsilon}{dt} = 0 \\ m\epsilon\frac{d^2\theta}{dt^2} + 2m\frac{d\epsilon}{dt}\frac{d\theta}{dt} + D\epsilon\frac{d\theta}{dt} - B\Omega\epsilon\sin\gamma = 0 \end{aligned}\right\} \quad \ldots [20]$$

assuming $\epsilon = \epsilon_0 e^{\lambda t}$ in Equation [20] and remembering that $\frac{d\theta}{dt}$ is a constant for oscillations of linear systems, the characteristic equation is

$$\lambda^4 + \left(\frac{D}{m} + \frac{c}{m}\right)\lambda^3 + \left(\frac{D^2}{4m^2} + \frac{B\Omega\cos\gamma}{m} + \frac{cD}{m^2}\right)\lambda^2 + \left(\frac{DB\Omega\cos\gamma}{m^2} + \frac{cD^2}{4m^3}\right) + \left(\frac{D^2B\Omega\cos\gamma}{4m^3} - \frac{B^2\Omega^2\sin^2\gamma}{4m^2}\right) = 0 \quad [21]$$

and the criterion for stability becomes

$$\frac{D^2B\Omega\cos\gamma}{4m^3} > \frac{B^2\Omega^2\sin^2\gamma}{4m^2} \quad [22]$$

which if $B\Omega > 0$ simplifies to

$$\frac{D^2\cos\gamma}{mB\sin^2\gamma} > \Omega \quad [23]$$

Referring again to Fig. 9, at the threshold condition the forces at right angles to the displacement ϵ yield

$$D = \frac{\Omega}{\left(\frac{d\theta}{dt}\right)} B\sin\gamma \quad [24]$$

Substituting Equation [24] into criterion [23] and taking the upper limit of frequency

$$\omega = \frac{d\theta}{dt} = \frac{\Omega}{2}$$

a further simplification of criterion [23] is obtained

$$\frac{4B\cos\gamma}{m} > \Omega \quad [25]$$

This condition for stability is equivalent to criterion [14] where $k_1 = k_2$.

The corresponding criterion for the angular mode in which gyroscopic effect must be taken into account is

$$\frac{4T\cos\gamma}{I_2 - 2I_1} > \Omega \quad [26]$$

where the quantities are as defined in the nomenclature.

Criteria [25] and [26] as previously mentioned apply to the symmetrical case, i.e., where the resultant of bearing forces, for a given rotor translation is directed approximately through the center of gravity of the rotor. Criterion [26] can also be applied to any known angular mode by taking the bearing moments and rotor inertia about the nodal point.

If we multiply criterion [25] by Ω we get a familiar looking form

$$\omega_n > \frac{\Omega}{2} \quad [25a]$$

since $B\Omega\cos\gamma$ is the "spring constant" of the bearing. This suggests that asymmetrical systems can be considered by calculating the natural frequency of the rotor on the "springs" of the lubricating films and then testing for stability using Criterion [25a].

A series of experiments, the details of which cannot be revealed at this time, were carried out to test the validity of criteria [25] and [26] and the results were in good agreement with predictions, utilizing measured load-deflection characteristics of the test bearings.

A recent article[8] in the German literature gives some characteristics of the multiple-pad bearing which may prove useful in stability studies.

Tilting-Pad Bearings

The stability aspects of the tilting-pad journal bearing seem to have been neglected in the literature. This is quite unusual because it has most interesting and useful characteristics; indeed the tilting-pad bearing can be rightly classified as a so-called "stable" or "nonwhirling" bearing.[9]

The stability of dynamical systems considered in previous sections was indicated from the character of the solution of the equations of motion. For the case of the tilting-pad bearing, an energy consideration appears attractive because it leads to a more complete result. Evidently if the exciting energy or work done per cycle of displacement, by the oil-film pressures generated by journal rotation, is less than the damping energy or work done per cycle on the oil film as a result of machine vibration, the system is stable. Conversely, an excess of exciting energy for some mode of vibration indicates the possibility of self-induced vibration.

In the development which follows it is assumed that the bearing-pad arrangement satisfies conditions for the static stability of the rotor; that the flow of lubricant is laminar in character; that each pad is mounted at a point which can be called the pad pivot point, and that this point is fixed relative to the bearing assembly; that the pad-pivot-point friction is small compared to other forces and can properly be neglected, and that thus a pad adjusts its position about the pivot point under the action of the oil-film pressures alone.

(a) *Exciting Energy.* Considering a single pad of the bearing assembly, the lubricating-film forces caused by journal rotation are, Fig. 10, the resultant P of the film pressures acting on the journal through its center, a reaction of the film pressures P' equal to P and acting along a line through the center of pad curvature, a fluid friction force F acting on the journal and a reaction F' acting on the pad. If d is the moment arm of P' about the pad

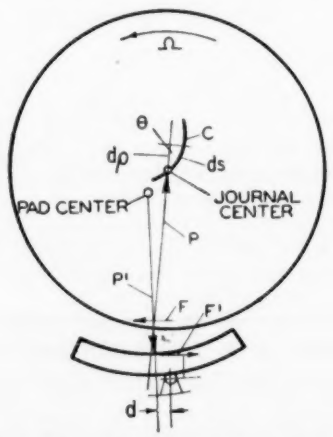

Fig. 10 Force System of Tilting-Pad Journal Bearing

[8] "Reibungswiderstand und Tragkraft eines Gleitschuhes endlicher Breite," by W. Frossel, *Forschung auf dem Gebiete des Ingenieurwesens*, vol. 13, No. 2, March and April, 1942.

[9] The Nomy-pad bearing is also a "stable" type although it may not be particularly applicable to the higher-speed machines where stability becomes a problem.

pivot point, and g is the moment arm of F' about the same point, by equilibrium of the pad

$$d = \frac{F'}{P'} g$$

The moment arm g is small (possibly zero) compared to other pad dimensions, and since the quantity $\frac{F'}{P'}$ the coefficient of friction is very small compared to unity, the moment arm d becomes so extremely small that P' can be considered as always acting through the pad pivot point. Further, the center of pad curvature and the journal center are separated by a small distance compared to the bearing radius, and it follows that the lubricating force P acting on the journal through its center is directed through the pad pivot point.

Because the bearing pad is pivoted and free to rotate, not only is the direction of P from pivot point to journal center, but the magnitude of P is a single-valued function of the distance ρ separating the pivot point and journal center.

$$P = f(\rho) \ldots\ldots\ldots\ldots\ldots\ldots [27]$$

where $f(\rho)$ is a single-valued function of the magnitude of ρ only. The work done on the journal and its counterparts by P for a displacement of the journal center along any curve c is expressed by the line integral

$$\text{Work} = \int_c f(\rho) \cos\theta ds \ldots\ldots\ldots\ldots [28]$$

where θ is the angle between the direction of the force P, that is the direction of ρ, and the direction of the displacement ds on the curve c.

But $\cos\theta = \frac{\partial\rho}{\partial s}$, so that Equation [28] becomes

$$\text{Work} = \int_c f(\rho) d\rho \ldots\ldots\ldots\ldots\ldots [29]$$

If c is a closed curve, the important result is obtained that the work W_P done by the principal force P during one complete cycle is

$$W_P = \oint_c f(\rho) d\rho = 0 \ldots\ldots\ldots\ldots [30]$$

because the integration is carried out over a range of ρ first in one sense and then in the opposite sense. It follows that zero work is done on the rotor by the film pressures of a plurality of pads making up the bearing without stipulation as to number or arrangement, and that this result is not altered by the effect of a steady bearing load or by machine characteristics as for example critical speeds.[10]

The result Equation [30] does not hold true for the plain journal bearing or a fixed-pad bearing previously considered because in these cases the direction of P is not always through a fixed point in the bearing, so that for these we do not have $\cos\theta = \frac{\partial\rho}{\partial s}$, and hence we may not pass from Equation [28] to Equations [29] and [30].

The friction force F acting on the journal does positive work on the rotor if the journal center moves along some area-enclosing path in a direction opposite to the journal rotation. However, it can be judged that this effect is negligibly small, and rightly so because calculations indicate that the rotational frequency would have to be several hundred times the lowest natural frequency of the system before the friction energy could overcome damping in the bearing which will now be considered.

[10] It is obvious that similar conclusions apply to any motion of the bearing and associated parts considering the journal as fixed.

(*b*) *Damping Energy.* In the previous part of this section the forces considered were generated by rotation of the journal about its center; in this part the forces considered are generated by motion of the journal center along some curve as may be effected by machine vibration. It is assumed that the force functions are approximately linear for eccentricities of the journal center up to about one half the radial clearance η, and so for the purpose at hand the effect of journal rotation on the force component caused by journal center motion can be neglected.

A given displacement of the journal toward a particular pad results in a decrease in the film thickness h, and during the displacement lubricant is "squeezed" out of the decreasing clearance volume; conversely, if the displacement is away from the pad the lubricant is "drawn" into the increasing clearance volume.

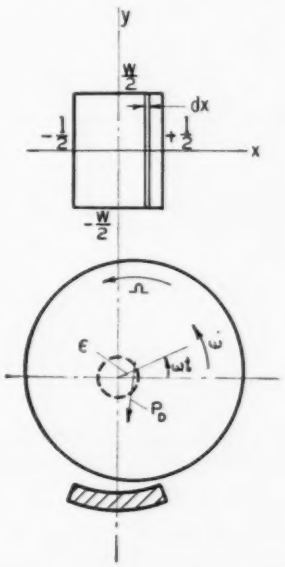

FIG. 11 DAMPING FORCE-ENERGY SYSTEM

In either case the resulting force is in opposition to the journal center velocity during the displacement and thus the motion is damped.

Neglecting inertia forces, the equation of laminar flow of fluid between two planes is

$$\frac{dp}{dx} + \frac{12 Q_x \mu}{h^3} = 0 \ldots\ldots\ldots\ldots [31]$$

where $\frac{dp}{dx}$ is the pressure gradient, Q_x is the flow in the x-direction, μ is the viscosity of the fluid, and h is the distance separating the planes. For the present case, Fig. 11, where the journal center is executing a circular motion about the bearing center, that is a harmonic vibration, and assuming flow in the x-direction only

$$\left.\begin{aligned} Q_x &= \epsilon\omega x \cos\omega t \\ h_0 &= \eta + \epsilon \sin\omega t \end{aligned}\right\} \ldots\ldots\ldots\ldots [32]$$

where h_0 is the film thickness at the pivot point and is taken to represent the average h over the pad; the pivot is assumed to be approximately in the center of the pad. Letting

$$\Phi = \frac{\epsilon\omega \cos\omega t}{(\eta + \epsilon \sin\omega t)^3}$$

Equation [31] becomes

$$\frac{dp}{dx} + 12\mu\Phi x = 0 \quad \ldots\ldots [33]$$

Integrating Equation [33] and using the boundary conditions at $x = \pm \frac{l}{2}$, $p = 0$, the pressure p is

$$p = 6\mu\Phi\left[\left(\frac{l}{2}\right)^2 - x^2\right] \quad \ldots\ldots [34]$$

The total force P_x over the area of the pad of width w for flow in the x-direction is

$$P_x = 6\mu\Phi w \int_{-l/2}^{+l/2}\left[\left(\frac{l}{2}\right)^2 - x^2\right] dx$$

or

$$P_x = \mu\Phi w l^3 \quad \ldots\ldots [35]$$

Similarly if flow occurs in the y-direction only

$$P_y = \mu\Phi l w^3 \quad \ldots\ldots [36]$$

Actually flow occurs in both x- and y-directions, i.e., the flow is in parallel, and the resisting or damping force P_D is

$$P_D = \frac{P_x P_y}{P_x + P_y} \quad \ldots\ldots [37]$$

or

$$P_D = \mu\Phi\left(\frac{l^3 w^3}{l^2 + w^2}\right) \quad \ldots\ldots [38]$$

The work done per cycle W by the rotor on the oil film (period = T) for a circular oscillation of the journal center about the bearing center is

$$W = \int_0^T P_D v dt \quad \ldots\ldots [39]$$

The force P_D is given by Equation [38], v is $\epsilon\omega \cos \omega t$, substituting $d(\omega t)$ for dt, and changing the upper limit to 2π

$$W = \mu\omega\epsilon^2\left(\frac{l^3 w^3}{l^2 + w^2}\right)\int_0^{2\pi} \frac{\cos^2 \omega t d(\omega t)}{(\eta + \epsilon \sin \omega t)^3} \quad \ldots\ldots [40]$$

The definite integral in Equation [40] can be evaluated to a good approximation by substituting η^3 for the denominator of the function under the integral sign, and W for n pads becomes

$$W = \frac{n\pi\mu\omega\epsilon^2 l^3 w^3}{\eta^3(l^2 + w^2)} \quad \ldots\ldots [41]$$

For square pads of side s Equation [41] becomes

$$W = \frac{n\pi\mu\omega\epsilon^2 s^4}{2\eta^3} \quad \ldots\ldots [42]$$

Equation [41] is damping energy per cycle of journal oscillation, whether the oscillation is forward or backward with respect to journal rotation, because the forces in either case oppose journal center motion.

The damping constant c for a tilting-pad bearing can be readily determined from Equation [41] by dividing by $2\pi\epsilon^2\omega$

$$c = \frac{n\mu}{2\eta^3}\left(\frac{l^3 w^3}{l^2 + w^2}\right) \quad \ldots\ldots [43]$$

The damping of the tilting-pad bearing, as indicated by the foregoing formulas, is of the same order of magnitude as the damping in other types of journal bearings; however, in contradistinction to the more conventional types, the tilting-pad bearing is incapable of doing work on the journal regardless of the mode of machine vibration. Hence not only is the bearing incapable of exciting or sustaining a vibration, but the bearing damping is effective in overcoming rotor frictional effects which sometimes lead to instability.[11,12,13]

(*c*) *Experiments.* A simple experimental model, shown in cross section in Fig. 12, was improvised to check qualitatively the

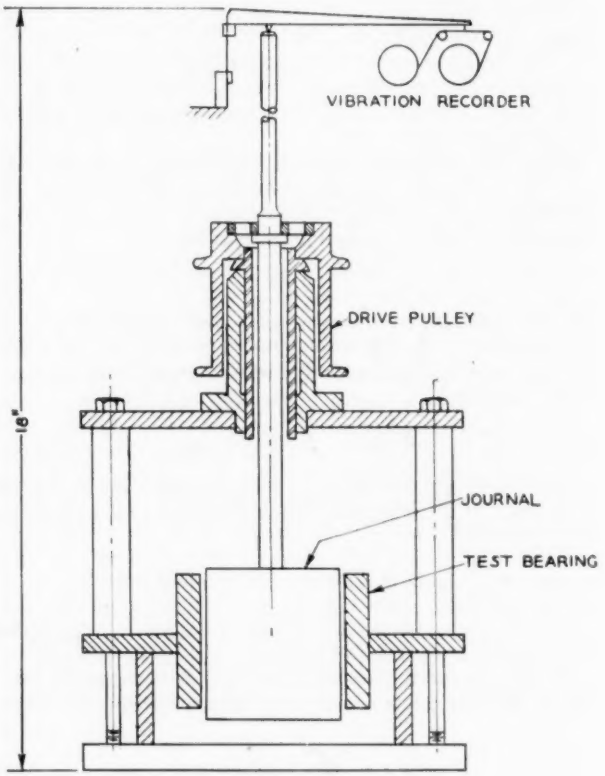

FIG. 12 TEST MODEL

results of the analysis. The journal consisted of a brass plug about 2.7 in. diam and 3 in. long, and was supported through a spindle by means of a metal disk attached to a drive pulley. The drive pulley in turn was supported by close-fitting guide bearings and a thrust surface. The metal disk acted as a spring hinge and the rotor vibration was about this hinge in the manner of a pendulum. The natural frequency of this system was very low; about 3 cycles per sec. The upper extension of the spindle was utilized with a stylus and recorder to secure records of a lateral component of the journal center motion.

A plain guide bearing was installed in the model initially to check whether damping in the model other than that in the test bearing could obscure the results, and also to secure oil-whirl records for comparative purposes. Two tests were carried out with a plain bearing using light mineral oil for the lubricant; the viscosity of the oil was 18 centipoises at the operating temperature. The first test was made with a bearing clearance of 0.005

[13] "Influence of Friction Forces on the Stability of High-Speed Rotors," by P. Kapitza, *Journal of Physics*, Institute for Physical Problems, Moscow, U.S.S.R., vol. 1, 1939, no. 1, pp. 29–50.

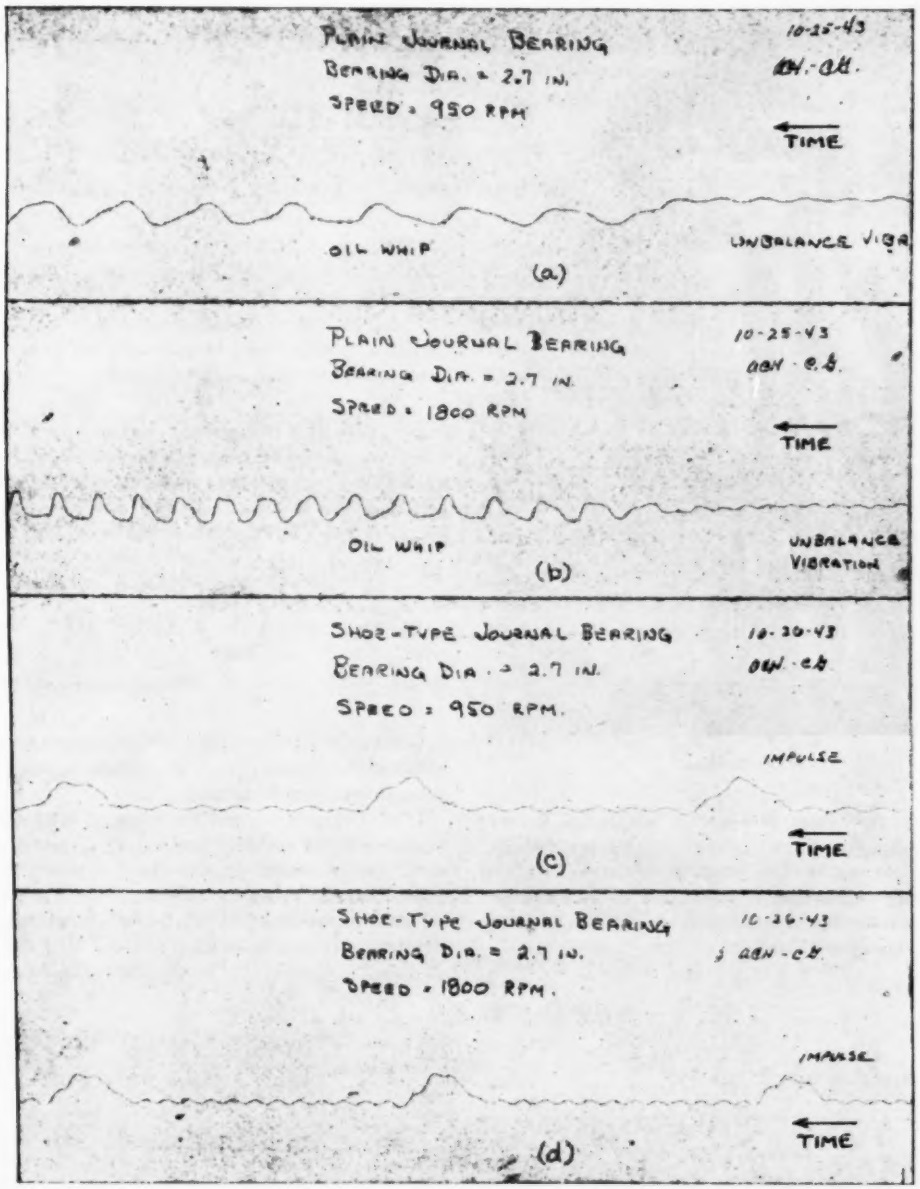

FIG. 13 VIBRATION RECORDS

in. on the diameter, and in the second test the clearance was increased to 0.030 in. on the diameter. In both cases violent whirling occurred at a frequency of slightly less than one-half rotational frequency; the amplitude of vibration was, of course, considerably greater in the second test. Records of this vibration at 950 rpm and 1800 rpm are shown in Fig. 13(*a*) and (*b*). The right-hand part of the record in which only unbalance vibration is shown was obtained by damping the rotor by hand; it can be noticed that upon release the whipping starts within 1 revolution of the journal.

The tilting-pad bearing tested consisted of six segmental pads which were supported radially through pivot buttons by a steel ring, and were held in position by flat steel strips. The flat strips, besides providing axial and tangential support for the pads, also provide a slight spring action which holds the pads against the steel ring. One or more pads could be readily removed from the bearing assembly and thus the effect of number and arrangements of pads on stability could be checked. The model with the pad bearing installed is shown in Fig. 14.

Two sets of tests were carried out with various numbers and arrangements of the bearing pads as identified in Fig. 15. The lubricant was the same as previously used. As indicated in the table, the model was stable in all cases. Records of the journal vibration operating with a six-pad arrangement and 0.030 in. diametral clearance are shown in Fig. 13(*c*) and (*d*). The jumps in the records were caused by load impulses applied to the journal by hand in an effort to excite vibration. It can be noted that the journal motion caused by the impulse is damped out within about 2 revolutions of the journal, and all that remains is the forced vibration caused by unbalance.

SUMMARY AND CONCLUSION

The self-excited vibration commonly called oil-film whirl or oil whip has been discussed and methods of approaching this in-

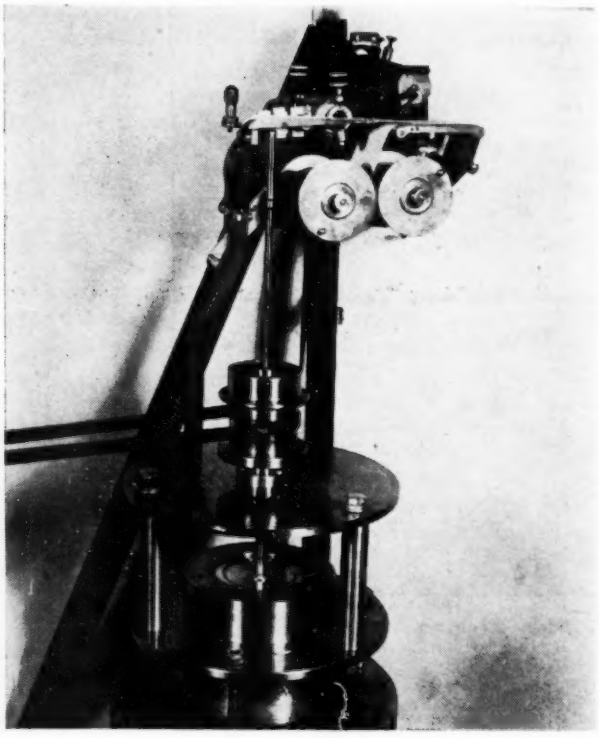

FIG. 14 TEST MODEL

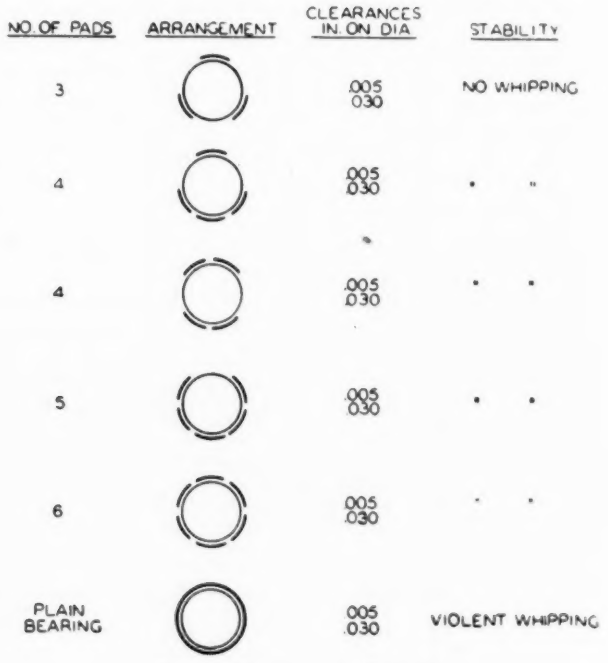

FIG. 15 STABILITY OF BEARINGS

creasingly important vibration problem in a rational manner have been indicated. For certain common systems stability criteria have been developed. The tilting-pad bearing has been found to be incapable of exciting or sustaining a vibration and hence appears very promising in application to high-speed rotors where stability is sometimes difficult to achieve.

Qualitatively, the results of this paper appear to be in agreement with observations. In certain cases criteria have been substantiated experimentally.

It is obviously beyond the scope of this paper to classify and pigeon-hole the stability problem in terms of the many possible variations in conditions and types of machines; however, it is hoped that the methods and results are a step toward the establishment of rational and practicable design criteria for achieving stability of rotating machinery.

Analytical Expressions for Principal Strains

By W. T. THOMSON,[1] MADISON. WIS.

Recent methods by G. Murphy (1)[2] and N. J. Hoff (2) enable the graphical evaluation of principal strains from strains measured along any three intersecting lines. When the two angles between gage lines are equal, the principal strains may be determined from simple analytical expressions without reference to the graphical solution.

STRAIN rosettes are generally constructed with equal angles between gages, the common rosettes having gages oriented at 45 or 60 deg with each other. When gage 1 and 3 are symmetrically oriented with respect to gage 2, as shown in Fig. 1, the principal strains may be evaluated from the following equations

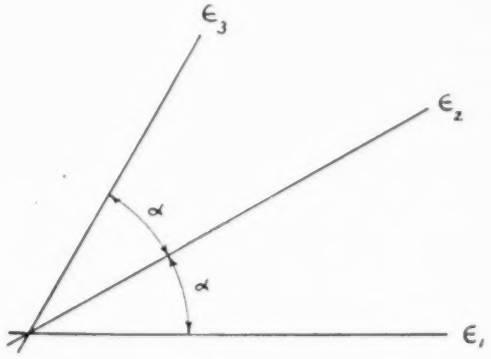

FIG. 1

$$\tan[2(\alpha + \theta) - 90] = \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{(\epsilon_1 - \epsilon_3)\tan\alpha} \quad \ldots\ldots [1]$$

$$\epsilon_{\substack{\max \\ \min}} = \epsilon_2 + \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{2\sin 2\alpha \tan\alpha} \pm \frac{(\epsilon_1 - \epsilon_3)}{2\sin 2\alpha \cos[2(\alpha + \theta) - 90]} \quad \ldots\ldots [2]$$

$$\lambda_{\max} = \frac{(\epsilon_1 - \epsilon_3)}{\sin 2\alpha \cos[2(\alpha + \theta) - 90]} \quad \ldots\ldots [3]$$

where

θ = angle measured from principal strain to ϵ_1 (positive counterclockwise)

α = angle between gages

Proof. Construct Mohr's circle, Fig. 2, as outlined by G. Murphy (1). The construction is started by scaling ϵ_1, ϵ_2, ϵ_3, horizontally from an arbitrary vertical axis. Lines, each making the angle α with the vertical, are then drawn through an arbitrary point D on the vertical through ϵ_2. The intersection of these lines with verticals through ϵ_1 and ϵ_3 determines the circle ACD. The center of the circle O is now determined and the line OA then makes an angle 2θ and the graphical solution is complete.

To develop the analytical expressions for the principal strains, continue with the following construction. Draw a perpendicular bisector to line AC. It will pass through the center of the circle and point B, and the triangle ABC will be isosceles with the two equal angles equal to α. Triangles ABO, ABD, and ABC all subtend the same arc, and hence angle $BCA = \alpha$ and angle $BOA = 2\alpha$. The other angles are then obvious from the diagram.

The angle θ between the principal strain and ϵ_1 is determined from the right triangle ACE, from which the following equation is obtained

$$\tan[2(\alpha + \theta) - 90] = \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{(\epsilon_1 - \epsilon_3)\tan\alpha} \quad \ldots\ldots [1]$$

For the magnitudes of the principal strains, the co-ordinate of the center of the circle is determined and the radius R of the circle is added or subtracted. The co-ordinate of the center of the circle is

$$O'O = \epsilon_2 + R\sin[2(\alpha + \theta) - 90] \quad \ldots\ldots [a]$$

From triangle ACE

$$AC = \frac{(\epsilon_1 - \epsilon_3)}{\cos[2(\alpha + \theta) - 90]} \quad \ldots\ldots [b]$$

From triangle AFO

$$R = \frac{AC}{2\sin 2\alpha} = \frac{(\epsilon_1 - \epsilon_3)}{2\sin 2\alpha \cos[2(\alpha + \theta) - 90]} \quad \ldots\ldots [c]$$

Substituting for R in [a]

$$O'O = \epsilon_2 + \frac{(\epsilon_1 - \epsilon_3)}{2\sin 2\alpha} \cdot \tan[2(\alpha + \theta) - 90]$$

$$= \epsilon_2 + \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{2\sin 2\alpha \tan\alpha} \quad \ldots\ldots [d]$$

Adding or subtracting R, the principal strains become

$$\epsilon_{\substack{\max \\ \min}} = \epsilon_2 + \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{2\sin 2\alpha \tan\alpha} \pm \frac{(\epsilon_1 - \epsilon_3)}{2\sin 2\alpha \cos[2(\alpha + \theta) - 90]} \quad \ldots\ldots [2]$$

The maximum shear strain is the difference of the principal strains, which from Equation [2] becomes

$$\lambda_{\max} = \epsilon_{\max} - \epsilon_{\min} = \frac{(\epsilon_1 - \epsilon_3)}{\sin 2\alpha \cos[2(\alpha + \theta) - 90]} \quad \ldots [3]$$

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

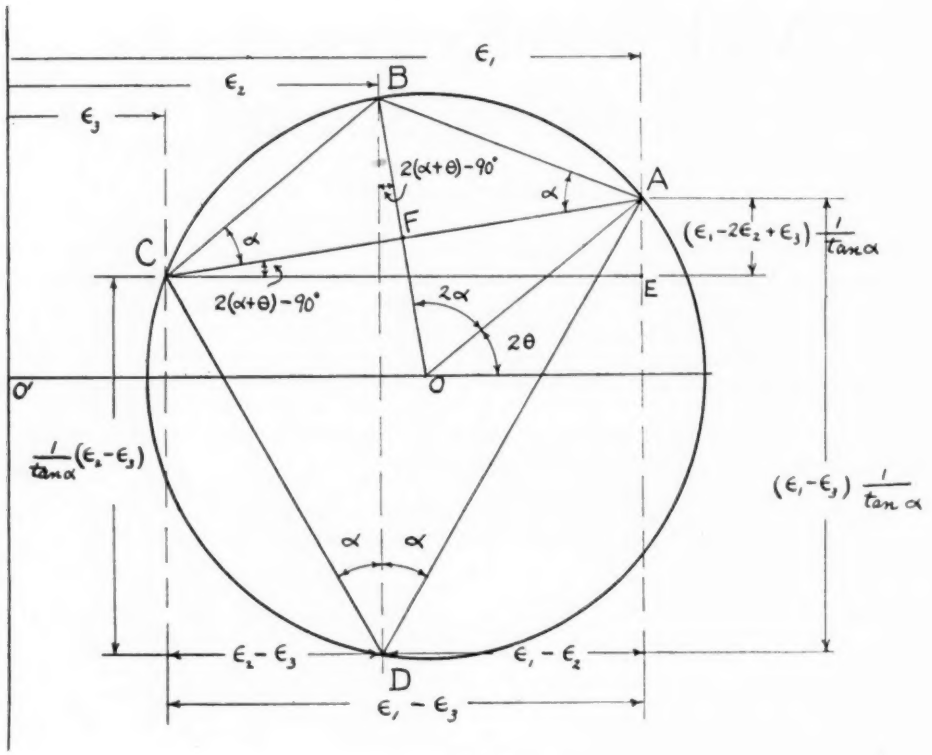

FIG. 2

Special Case for $\alpha = 45$ Deg. When $\alpha = 45$ deg, the line AC becomes the diameter of the circle. The substitution of $\alpha = 45$ deg into the general equations results in the following special equations

$$\tan 2\theta = \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{(\epsilon_1 - \epsilon_3)}$$

$$\epsilon_{\substack{\max \\ \min}} = \frac{\epsilon_1 + \epsilon_3}{2} \pm \frac{(\epsilon_1 - \epsilon_3)}{2 \cos 2\theta}$$

$$\lambda_{\max} = \frac{\epsilon_1 - \epsilon_3}{\cos 2\theta}$$

Special Case for $\alpha = 60$ Deg. Substituting $\alpha = 60$ deg, the special equations for the 60-deg rosettes become

$$\tan (30 + 2\theta) = \frac{(\epsilon_1 - 2\epsilon_2 + \epsilon_3)}{\sqrt{3}(\epsilon_1 - \epsilon_3)}$$

$$\epsilon_{\substack{\max \\ \min}} = \frac{1}{3}(\epsilon_1 + \epsilon_2 + \epsilon_3) \pm \frac{(\epsilon_1 - \epsilon_3)}{\sqrt{3} \cos (30 + 2\theta)}$$

$$\lambda_{\max} = \frac{2(\epsilon_1 - \epsilon_3)}{\sqrt{3} \cos (30 + 2\theta)}$$

Flat Spring With Large Deflections

By F. HYMANS,[1] NEW YORK, N. Y.

This paper gives an analysis of a flat spring initially curved and inserted in the apparatus of which it is an element in a buckled condition. The unstressed spring is shaped in the arc of a circle, and it is shown that then, and only then, the problem may be reduced to that of an initially straight bar by adding to the actually impressed force a couple which, if acting alone, produces the initial curved shape. On this basis the paper ascertains the various possible shapes of the buckled spring and the forces associated with them. It is shown that these must have at least one point of inflection of the elastic line. More particularly, there are two shapes, each with a single point of inflection, yet differing widely in their properties. In one of them there is a range of instability while the other is stable throughout. Finally, it is shown how by a suitable variation of parameter shapes two or more points of inflection may be obtained.

THIS paper is concerned with a rather unusual case of a flat spring which has been proposed as an element in one of the designs of the author's company. In its initial and unstressed shape, as shown in dotted lines in Fig. 1, it is formed in the arc of a circle of radius R. The spring is then buckled inward by hand, its ends fitted between two supports B and B_1, whereupon the spring when freed of constraint assumes some shape as BAB_1 shown in full lines in Fig. 1. In this shape the spring is equilibrated by two equal and opposite forces Q, and the problem is to determine shape and properties of the buckled spring under the action of various forces Q.

One of these properties is that the curvature at B and B_1 remains unaltered at the initial value $1/R$ inasmuch as at the said points the forces Q have no bending moment. On account of symmetry it is also clear that only one half of the spring, say, the half AB, need be considered with the end A appearing as clamped or fixed, as shown in Fig. 2(*a*).

The initial curvature at any point of the spring as for example at C is $1/R$. If then ρ is the radius of curvature at C in the stressed configuration, the change in curvature in the present case will be expressed by

$$1/\rho + 1/R$$

The + sign here is used because of the fact that in the stressed condition the curvature of the element under consideration is the reverse of the initial curvature.

According to the theory of flexure, the change in curvature must equal the bending moment divided by the flexural rigidity EI, and with spring referred to axes AX and AY in Fig. 2*a*, this leads to the equation

$$1/\rho + 1/R = Q(y_B - y)/EI \quad \ldots\ldots\ldots\ldots [1]$$

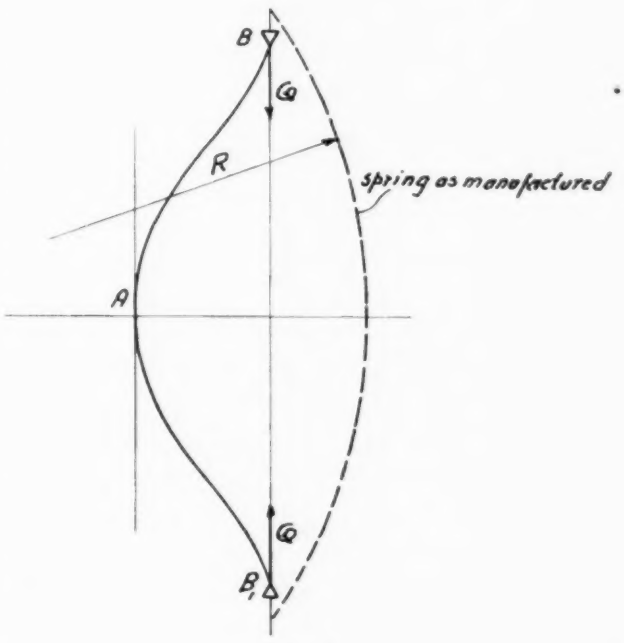

FIG. 1

Placing

$$1/R = M/EI \quad \ldots\ldots\ldots\ldots\ldots\ldots [1a]$$

M has the meaning that it is the couple which if acting at the free end of an initially straight spring will bend it into the arc of a circle of radius R and so will produce its initial curved shape.

Substituting for R in Equation [1] gives

$$1/\rho = \{-M + Q(y_B - y)\}/EI$$

This, however, is the equation of a bar, initially straight, subject at its free end B to a force Q and a couple M, as shown in Fig. 2(*b*). Thus the problem can be reduced to that of an initially straight spring by adding to the force Q a couple M, a simplification possible only when the initial shape is the arc of a circle.

We proceed then on the basis of a straight spring clamped at A and subject at B to a force Q and couple M, both shown dotted in Fig. 2(*c*). These, as is known, may be replaced by a single force Q shown in full lines and acting at a distance h from A, given by

$$h = M/Q \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Thus the problem can further be conceived as that of an initially straight spring fixed at A, provided at B with a rigid arm h, subject at its free end to a force Q. As the actually applied force Q (dotted vector in Fig. 2*c*) remains vertical in all configurations of the spring, the equivalent force Q at the free end of lever h also remains vertical and the arm h in each configuration of the spring must be conceived as so attached as to remain horizontal.

While dealing with the present problem in this manner it must be understood that M as related to the initial curvature by (*1a*) is a constant. Varying the loading of the spring requires then the simultaneous varying of both the magnitude of Q at the end of

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

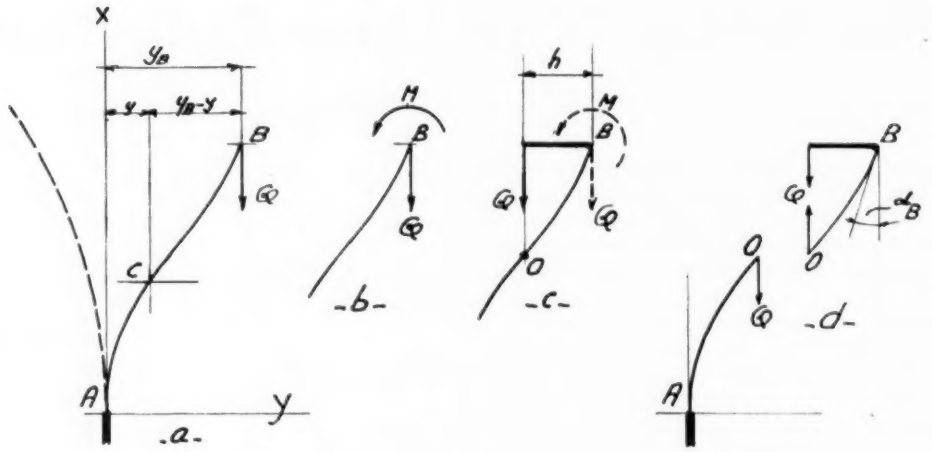

FIG. 2

lever h and the length of h, so as to satisfy the relation of Equation [2] in every instance. An increase in Q is then associated with a decrease of h and vice versa. In view of the sense of rotation of M in connection with the permanently downward direction of the actually applied force Q at B, it is clear that the free end of lever h always lies to the left of B. Therefore h remains a positive quantity under all conditions of loading.

In replacing the dotted vectors Q and M in Fig. 2(*c*) by a single force Q, it is immediately apparent that a point O in the line of action of Q is a point of inflection of the elastic line inasmuch as the bending moment at that point is zero. Shapes with more than one point of inflection, if they exist, must have all such points on the line of action of Q. Shapes with points of inflection outside this line cannot occur. Furthermore, if the spring be cut at its point of inflection O, as in Fig. 2(*d*), the mutual action of one portion on the other at O can only be a force. Therefore branch OA presents the well-known case of a column[1] fixed at A and subject to a force Q at O. The upper branch OB is also a column loaded at O by a force Q but fixed at B under an angle α_B with the vertical.

Since in the loaded spring the curvature at B remains the initial curvature, as there must be at least one point of inflection somewhere between A and B, and inasmuch as the elastic line at A must be tangent to the vertical, it is easy to draw some plausible characteristic shape for the spring. One such shape is shown in Fig. 3 on the basis of which the analysis proceeds.

The origin of axes is most conveniently taken at the point of inflection O, and branch OB of the elastic line is referred to vertical and horizontal axes OX and OY drawn in full lines, while for branch OA the axes are reversed as shown by the dotted lines OX' and OY'. In this arrangement of axes, general equations developed for one branch also apply to the other.

Taking a point E on branch OB or E' on OA the bending moment with due respect to their respective system of axes is

$$M_b = +Qy$$

and hence the rigorous equation of the elastic line is

$$d\alpha/ds = -Qy/EI \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where $d\alpha/ds$ is the curvature at E, respectively E', α the slope of the elastic line at these points, and (ds) is an element of the arc.

Substituting

$$ds = dy/\sin \alpha$$

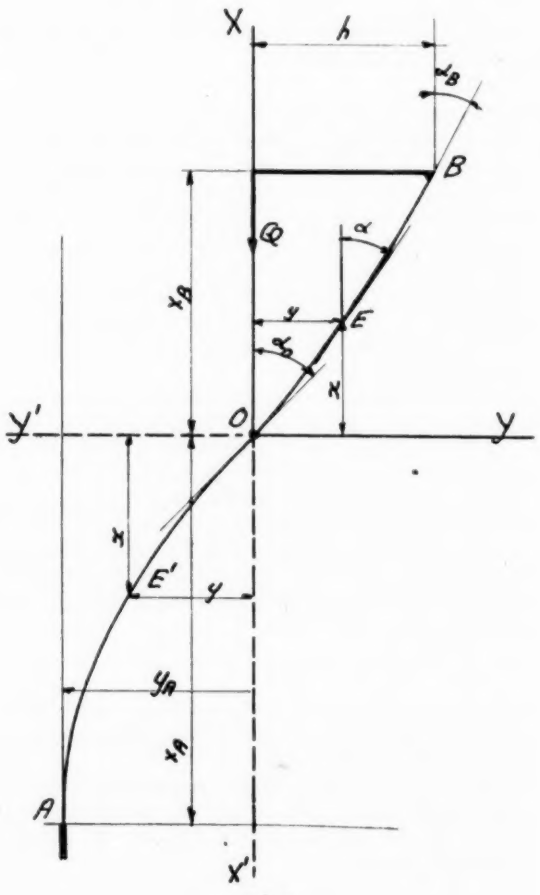

FIG. 3

we obtain

$$\sin \alpha d\alpha = -Qydy/EI$$

Noting that at O the slope of the elastic line is α_0 and $y = 0$, we have by integration

$$\left[\cos \alpha\right]_{\alpha_0}^{\alpha} = \frac{Q}{2EI}\left[y^2\right]_0^y$$

whence

$$y\sqrt{Q/2EI} = \pm\sqrt{\cos \alpha - \cos \alpha_0} \quad \ldots\ldots\ldots [4]$$

[1] "Der belastete stab", by L. Saalschuetz. Published by B. G. Teubner, Leipzig, Germany, 1880.

Leaving it for the present undecided whether the + or — sign must be used in the foregoing, one requirement is that y must be real and the term under the radical on the right must therefore be positive. Now α_0 is the slope of the elastic line at O, and in the present problem the only slopes possible at that point may be expressed as $0 \leqq \alpha_0 \leqq \pi$. While thus the slope at O with respect to the system of axes is limited to a positive angle not greater than π, we may without loss of generality specify slopes at other points as either positive or negative angles limited to $0 \leqq \alpha \leqq +\pi$ in the first case and to $0 \geqq \alpha \geqq -\pi$ in the second.

With slopes so limited the expression under the radical in Equation [4] is positive only when α, whether positive or negative, is numerically smaller or at most numerically equal to α_0.

Should the elastic line have more than one point of inflection, all such points as already stated must lie on the line of action of Q. With the system of axes as in Fig. 3, y for all such points is zero, and thus we derive from Equation [4]

$$\cos \alpha = \cos \alpha_0$$

$$\alpha = \pm \alpha_0$$

Hence it is one property of the elastic line in the present problem that at points of inflection the slopes are numerically equal and greater than at other points.

Writing Equation [4] in the form

$$y = \pm 2 \sqrt{EI/Q} \sin \frac{\alpha_0}{2} \sqrt{1 - \frac{\sin^2 \alpha/2}{\sin^2 \alpha_0/2}} \quad \ldots\ldots [4a]$$

we introduce at this point a new variable φ, expressed by

$$\frac{\sin \alpha/2}{\sin \alpha_0/2} = \sin \varphi \quad \ldots\ldots [5]$$

Therein φ is a parameter of the elastic line specifying its slope in function of the slope at O. All quantities related to the configuration of the elastic line will be expressed in function of φ which so becomes the independent variable.

From Equation [5] we derive for future use by differentiation

$$d\alpha = \frac{2 \sin \frac{\alpha_0}{2} \cos \varphi d\varphi}{\sqrt{1 - \sin^2 \frac{\alpha_0}{2} \sin^2 \varphi}} \quad \ldots\ldots [5a]$$

With the new variable according to Equation [5], Equation [4a] becomes

$$y = \pm 2 \sqrt{EI/Q} \sin \frac{\alpha_0}{2} \cos \varphi \quad \ldots\ldots [6]$$

In this equation $\sin \alpha_0/2$ is always positive in view of an earlier conclusion that α_0 is a positive angle not greater than π. To φ, however, we can always assign such values that make $\cos \varphi$ either positive or negative as may suit the problem. It appears therefore to be only a matter of convenience to use the + or — sign in Equation [6]. Deciding to use the former, we write

$$y = 2 \sqrt{EI/Q} \sin \frac{\alpha_0}{2} \cos \varphi \quad \ldots\ldots [6a]$$

According to Equation [6a], shapes as in Fig. 3 with positive ordinates only with respect to the chosen system of axes will be obtained where $\cos \varphi$ is positive for all points of the elastic line. For such shapes, then, φ must be an angle in the first or fourth quadrants, and without loss of generality we may limit φ in the case first named to angles expressed by $0 \leqq \varphi \leqq +\pi/2$ and in the latter case to angles $0 \geqq \varphi \geqq -\pi/2$. The next step is to determine for immediate and future use the value of the parameter φ at the terminals of branches OA and OB, Fig. 3.

These are obtained from Equation [5], and with the object of developing the equations for shapes with positive ordinates, as in Fig. 3, the values to be assigned to φ must comply with the conclusions previously reached. Thus we have

$$\left.\begin{array}{l} \text{At } A;\ \alpha = 0; \text{ whence according to Equation [5] } \sin \varphi = 0; \\ \qquad\qquad \text{and } \varphi = 0 \\ \text{At } O;\ \alpha = \alpha_0; \text{ whence according to Equation [5] } \sin \varphi = \\ \qquad\qquad +1; \text{ and } \varphi = \pi/2 \end{array}\right\} \quad [7]$$

At B, Fig. 3, the slope $\alpha = \alpha_B$ and denoting by φ_B the corresponding value of φ, we further obtain from Equation [5]

$$\sin \frac{\alpha_B}{2} = \sin \frac{\alpha_0}{2} \sin \varphi_B \quad \ldots\ldots [7a]$$

with the understanding that the value to be assigned to φ_B is not greater than $\pi/2$ nor smaller than $-\pi/2$.

The ordinates at B and A are obtained from Equation [6a]. For the former, substitute $y = h$ and $\varphi = \varphi_B$ and for the latter $y = y_A$ and $\varphi = 0$ to obtain

$$h = 2 \sqrt{EI/Q} \sin \frac{\alpha_0}{2} \cos \varphi_B \quad \ldots\ldots [8]$$

$$y_A = 2 \sqrt{EI/Q} \sin \frac{\alpha_0}{2} \quad \ldots\ldots [8a]$$

whence

$$y_A = h/\cos \varphi_B \quad \ldots\ldots [8b]$$

For the purpose of numerical calculations we modify Equation [8] by eliminating Q from it by means of the relation $Qh = M$, which results in

$$\sqrt{h} = 2 \sqrt{EI/M} \sin \frac{\alpha_0}{2} \cos \varphi_B$$

Herein EI/M is the initial radius of curvature R of the spring, whence

$$h = 4R \sin^2 \frac{\alpha_0}{2} \cos^2 \varphi_B \quad \ldots\ldots [9]$$

Another and necessary relation between the variables is obtained by determining the length of branches OB and OA. Denoting the first by S_{OB}, the latter by S_{OA} and by l, the length of the spring from A to B we have

$$l = S_{OB} + S_{OA}$$

For the determination of S_{OB} and S_{OA} we return to general Equation [3]

$$d\alpha/ds = -Qy/EI$$

and substitute therein for $d\alpha$ from Equation [5a] and y from Equation [6a]. This gives

$$\sqrt{Q/EI}\, ds = -\frac{d\varphi}{\sqrt{1 - \sin^2 \frac{\alpha_0}{2} \sin^2 \varphi}} \quad \ldots\ldots [10]$$

Its integration from O to B where according to Equations [7] and [7a], the corresponding values of φ are $\pi/2$ at O and φ_B at B gives S_{OB}. Similarly S_{OA} is obtained by integration from O to A with $\varphi = 0$ at A and $\varphi = \pi/2$ at O. Hence

$$\left.\begin{aligned}\sqrt{Q/EI}\,S_{OB} &= -\int_{\varphi=\pi/2}^{\varphi=\varphi_B}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}\\ &= \int_0^{\pi/2}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}} - \int_0^{\varphi_B}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}\end{aligned}\right\}\quad[11]$$

and

$$\left.\begin{aligned}\sqrt{Q/EI}\,S_{OA} &= -\int_{\varphi=\pi/2}^{\varphi=0}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}\\ &= \int_0^{\pi/2}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}\end{aligned}\right\}$$

or, in the usual notation of elliptic integrals

$$\sqrt{Q/EI}\,S_{OB} = K - F\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)\quad[12a]$$

$$\sqrt{Q/EI}\,S_{OA} = K\quad[12b]$$

Adding these we obtain

$$l\sqrt{Q/EI} = 2K - F\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)$$

or with $Q = M/h$ and $M/EI = 1/R$

$$l\sqrt{1/R} = \left\{2K - F\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)\right\}\sqrt{h}$$

and eliminating h between this equation and Equation [9]

$$\frac{l}{2R} = \sin\frac{\alpha_0}{2}\cos\varphi_B\left\{2K - F\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)\right\}\quad[13]$$

There remains now the determination of the abscissas of the elastic line. For an arbitrary point E on OB or E' on OA we have

$$ds = \frac{dx}{\cos\alpha} = \frac{dx}{1-2\sin^2\frac{\alpha}{2}}$$

or according to Equation [5]

$$ds = \frac{dx}{1-2\sin^2\frac{\alpha_0}{2}\sin^2\varphi}$$

Substituting for ds in Equation [10] we obtain

$$\sqrt{Q/EI}\,dx = -\frac{\left(1-2\sin^2\frac{\alpha_0}{2}\sin^2\varphi\right)d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}$$

$$= -2\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}\,d\varphi + \frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}$$

Noting that $x = 0$ at O where, according to Equations [7], the corresponding value of φ is $\pi/2$ we obtain by integration

$$\sqrt{Q/EI}\left[x\right]_0^x = -2\int_{\pi/2}^{\varphi}\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}\,d\varphi + \int_{\pi/2}^{\varphi}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}\quad[14]$$

or

$$x\sqrt{Q/EI} = 2\int_0^{\pi/2}\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}\,d\varphi - 2\int_0^{\varphi}\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}\,d\varphi - \int_0^{\pi/2}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}} + \int_0^{\varphi}\frac{d\varphi}{\sqrt{1-\sin^2\frac{\alpha_0}{2}\sin^2\varphi}}$$

which in the usual notations for elliptic integrals assumes the form

$$x\sqrt{Q/EI} = 2\left\{E - E\left(\frac{\alpha_0}{2}\cdot\varphi\right)\right\} - K + F\left(\frac{\alpha_0}{2}\cdot\varphi\right)\quad[14a]$$

The abscissas x_B and x_A of the end points of the elastic line, Fig. 3, are obtained from Equation [14a] by substituting x_B and x_A for x and $\varphi = \varphi_B$, respectively, $\varphi = 0$, the latter according to Equations [7] and [7a] being the values of φ for the points B and A. Hence

$$x_B\sqrt{Q/EI} = 2\left\{E - E\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)\right\} - K + F\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)\quad[14b]$$

and

$$x_A\sqrt{Q/EI} = 2E - K\quad[14c]$$

In view of Equations [12a] and [12b] these can be written

$$x_B = 2\sqrt{EI/Q}\left\{E - E\left(\frac{\alpha_0}{2}\cdot\varphi_B\right)\right\} - S_{OB}\quad[15a]$$

and

$$x_A = 2\sqrt{EI/Q}\,E - S_{OA}\quad[15b]$$

As stated in connection with the derivation of Equation [7a], φ_B in the foregoing equations must either be a positive or negative angle numerically smaller than $\pi/2$ for shapes as in Fig. 3, with positive ordinates only. However, for a negative φ_B, numerical calculations require some modification of these equations and for that reason that case will be considered later.

An example is here worked out for a spring according to the following data

Initial radius of curvature $R = 11.25$ in.; length of spring A to B, $l = 6.75$ in.; $EI = 540$ lb $\times$ in.^{2}; $M = EI/R = 540/11.25 = 48$ in. $\times$ lb; $EI/M = R = 11.25$ in.

$$l/2R = \frac{6.75}{2\times 11.25} = 0.3$$

The limiting case where equilibrium is possible occurs for $\alpha_B = 0$ and in that case the tangent at B, Fig. 3, becomes parallel to the tangent to the elastic line at A. In the absence of an ex-

ternal force between A and B it can be concluded without mathematics that the point of inflection then lies midway between A and B, that the two branches of the elastic line must be identical in shape, of equal lengths and so positioned as to be diametrically symmetrical with respect to O.

With $\alpha_B = 0$ in Equation [7a], $\varphi_B = 0$ and therewith we obtain from Equation [13]

$$l/2R = 2K \sin \alpha_0/2$$

or numerically

$$K \sin \alpha_0/2 = 0.15$$

for the calculation of α_0. By the use of a table of elliptical integrals it will be found that $\alpha_0/2 = 5° -28'$, $K = 1.5744$ and $K \sin \alpha_0/2 = 1.499$ which is close enough to the desired value of 0.15. Similarly with $\varphi_B = 0$, we obtain as expected from Equations [8b] and [9]

$$y_A = h = 4R \sin^2 \alpha_0/2 = 45 \sin^2 5° - 28' = 0.410 \text{ in.}$$

and thence from Equation [2]

$$Q = M/h = 48/0.410 = 116.96 \text{ lb}$$

Also as expected $\varphi_B = 0$ in Equations [12a] and [12b] results in $S_{OB} = S_{OA}$ so that

$$S_{OB} = S_{OA} = l/2 = 6.75/2 = 3.375 \text{ in.}$$

With $S_{OB} = S_{OA}$ and $\varphi_B = 0$ in Equations [15a] and [15b], we obtain

$$x_B = x_A = 2\sqrt{EI/Q}\, E - l/2$$

E for a modulus of $5° -28'$ is 1.5672 and thus

$$x_B = x_A = 2 \times 1.5672 \sqrt{540/116.96} - 3.375 = 3.360 \text{ in.}$$

In Fig. 5 the shape of the spring for $\alpha_B = 0$ is given by curve 1. By assuming various values for α_B, other shapes of the same general type may be obtained in the manner just followed for $\alpha_B = 0$. It is, however, simpler to assume various values of α_0 and to obtain from Equation [13] the corresponding values of φ_B for each of them. To facilitate these calculations we have plotted in Fig. 4 the values of

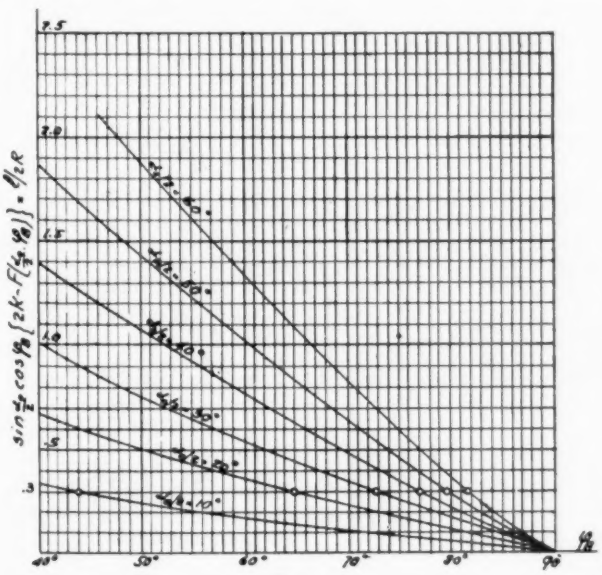

FIG. 4

$$\sin \frac{\alpha_0}{2} \cos \varphi_B \left\{2K - F\left(\frac{\alpha_0}{2} \cdot \varphi_B\right)\right\},$$

as ordinates against φ_B as abscissas for an assumed $\alpha_0/2 = 10°$, 20°, 30°, 40°, etc. According to Equation [13] the ordinates of these curves represent the corresponding values of $l/2R$ which in this example is 0.3. Thus, drawing a horizontal at 0.3 from the axis of φ_B, the intersections with the curves for $\alpha_0/2 = 10°$, 20°, etc., give the values of φ_B which are solutions of Equation [13] for the selected values of $\alpha_0/2$, subject to the accuracy obtainable in the preparation of such curves. Each of these determines a shape of the elastic line of the general type of Fig. 3, as well as of the load Q associated with it.

For example for $\alpha_0/2 = 10°$, the graph gives a value of $\varphi_B = 44°$ which, according to accurate calculations happens to be true within a few seconds. From tables of elliptic integrals we then obtain for $\alpha_0/2 = 10°$ and $\varphi_B = 44°$: $K = 1.5828$; $F(10°, 44°) = 0.7700$; $E = 1.5589$; $E(10°, 44°) = 0.7659$, and the calculations proceed as follows

From Equation [7a]

$$\alpha_B/2 = 6° - 56'$$
$$\alpha_B = 13° - 52'$$

From Equation [9]

$$h = 0.702 \text{ in.}$$

From Equation [2]

$$Q = M/h = 48/0.702 = 68.36 \text{ lb}$$

From Equation [8b]

$$y_A = 0.971 \text{ in.}$$

From Equations [12a] and [12b]

$$S_{OB} = 2.301 \text{ in.}; \quad S_{OA} = 4.459 \text{ in.}$$

From Equations [15a] and [15b]

$$x_B = 2.151 \text{ in.}; \quad x_A = 4.314 \text{ in.}$$

A check on the accuracy of these results may be obtained by adding S_{OB} and S_{OA} which should give $l = 6.75$ in.

Results of these and similar calculations are given in Table 1 and the corresponding shapes of the spring are shown in Fig. 5.

With reference to Fig. 5, the properties of the spring for a positive φ_B are the following:

1 The loads Q to produce increasing deformations first diminish and then increase, whereby the point of inflection O steadily moves upward.

2 For the same load Q there are two different shapes with different deformations as, for example, shapes 3 and 5. For shapes between these the load Q is less and if, after having the spring in equilibrium in shape 3, it is given a slight displacement to the right it will not return to 3 but will assume shape 5. In fact shapes 1, 2, 3, 4 are unstable. Stable shapes are 5 and 6 where Q increases with increasing deformation.

3 Assuming that the spring is in equilibrium in shape 5 with $Q = 51.02$ lb, if then Q be suddenly reduced to, say, 48 lb, slightly below the apparent minimum of 49.2 lb in shape 4, the spring will snap back over center toward its initial unstressed shape. In this manner vigorous snap action can be obtained by slight reduction of the load.

A second set of shapes, also with all ordinates positive with respect to the chosen system of axes, is associated with a negative φ_B, provided that φ_B according to what was said in connection with the derivation of Equation [7a] is an angle not smaller than $-\pi/2$. As the sine of such an angle is negative it follows from Equation [7a] that the slope of the elastic line at B is also a negative angle. For a general discussion, one such shape is shown in

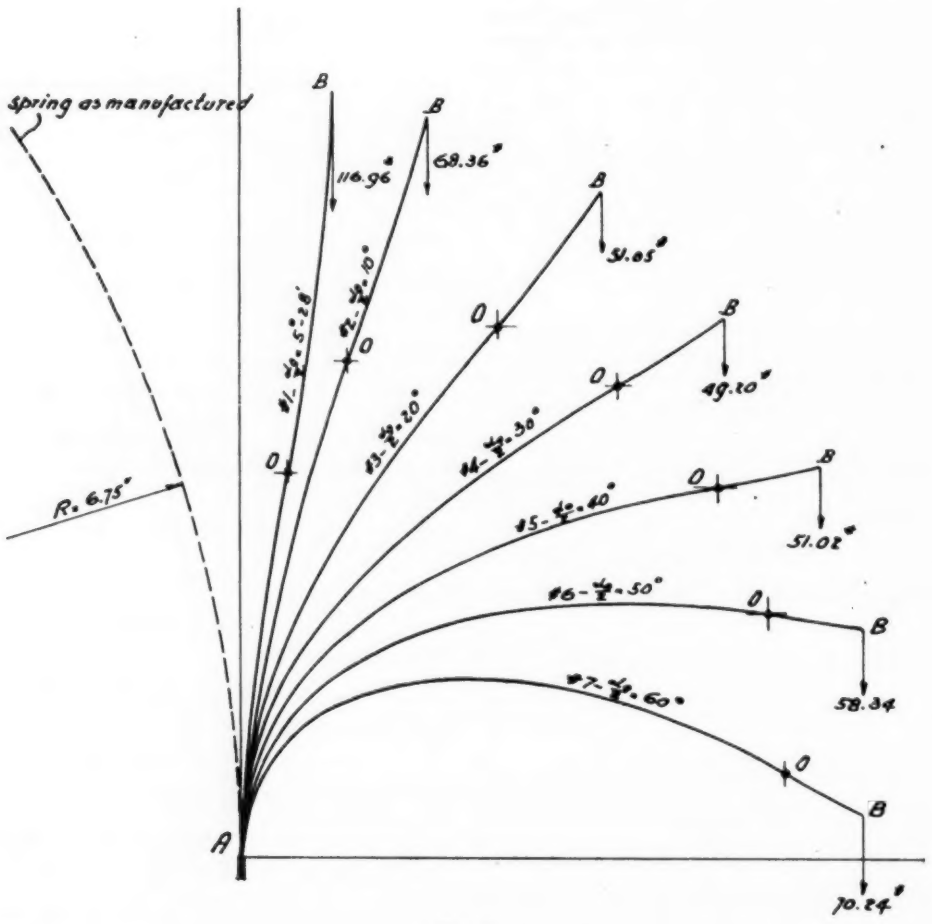

FIG. 5

Fig. 6, referred to the same system of axes adopted before, and various facts become evident without recourse to mathematics.

If we produce BB_1 parallel to OX and CD normal to and bisecting BB_1 it will be seen that the bending moment is the same for all points of arc BCB_1 located symmetrically with respect to CD. In the absence of an external force between B and B_1 it follows that arc BC is the same as B_1C and that both are positioned symmetrically with CD. At C then the ordinate is a maximum and the slope zero. Furthermore, at B as at B_1 the bending moment is $Qh = M$, and the curvature at these points is the initial curvature. Because of symmetry with respect to CD the slopes at the said points are equal in magnitude, negative at B and positive at B_1. Thus at B in Fig. 3 and B_1 in Fig. 6 the curvatures are the initial curvature and the slopes are both positive, from which follows that arc AOB_1 in Fig. 6 and AOB in Fig. 3 are similar as to shape.

Next, at A and C the tangents to the elastic line are parallel, from which we conclude that arcs OA and OC are identical as to shape, of equal lengths and positioned diagonally symmetrical with respect to O. From this follows that $y_C = y_A$ and $x_C = x_A$. With reference to a negative φ_B, the complete elliptic integrals K and E being independent of φ_B remain unchanged. For the incomplete elliptic integrals, however, we have

$$F\left(\frac{\alpha_0}{2} \cdot -\varphi_B\right) = -F\left(\frac{\alpha_0}{2} \cdot \varphi_B\right)$$

and

$$E\left(\frac{\alpha_0}{2} \cdot -\varphi_B\right) = -E\left(\frac{\alpha_0}{2} \cdot \varphi_B\right)$$

Thus of the previous equations only Equation [7a] and those comprising incomplete elliptic integrals experience changes in sign and in sign only. However, for the sake of completeness the equations which follow comprise all of the equations used in the present numerical computations, including those not affected by a negative φ_B

$$\left.\begin{aligned}
&\sin(-\alpha_B/2) = \sin\frac{\alpha_0}{2}\sin\varphi_B \text{ changed from Equation [7}a\text{]}\\
&\sqrt{Q/EI}\,S_{OB} = K + F\left(\frac{\alpha_0}{2}\cdot\varphi_B\right) \text{ changed from Equation [12}a\text{]}\\

which is the function on the right of the fourth of Equations [16] against φ_B as abscissas for several values of $\alpha_0/2$. Drawing as before a line parallel to the axis of φ_B at a distance 0.3 from it, the intersections with the curves for $\alpha_0/2 = 10°, 20°, 30°$, etc., disclose the corresponding values of φ_B that satisfy the fourth of Equation [16]. The process of calculation is otherwise the same as employed earlier and the results are given in Table 2.

The corresponding shapes are drawn in Fig. 8 and it will be seen that the properties of shapes associated with a negative φ_B are radically different. All of the present shapes are stable and by increasing or decreasing the load the spring can be brought from one shape into another.

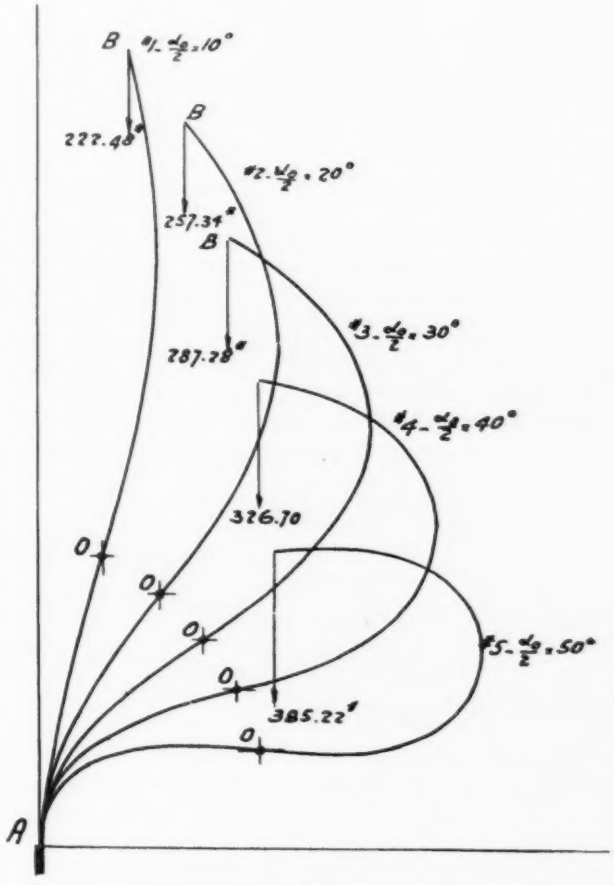

FIG. 8

It will have been noted in the foregoing that shapes according to Fig. 3 and Fig. 6 are associated with the particular values assigned to the parameter φ at the ends of branches OA and OB. With these assigned the values of φ at other points become intermediate between the terminal values.

As there is no restriction in the values that may suitably be assigned to φ at the terminals so long as they satisfy Equation [5], there are, in addition to the shapes discussed before, an infinity of others although none of them is of practical value. To be noted is that in the shapes of Fig. 3 and Fig. 6 the value of φ at A and B are smaller than at O and this rule must be observed to obtain other shapes. One example may suffice.

With reference to Fig. 9 which shows one of the shapes referred to with two points of inflection, let us assign to φ the same values at O and B as in Equations [7] and [7a] so that branch OB will be the same as to shape as in Fig. 3. At A, Fig. 9, $\alpha = 0$ and according to Equation [5] $\sin \varphi = 0$. However, instead of taking $\varphi = 0$ as in Equations [7], we shall now take $\varphi = -\pi$ with the result, as explained later, that we obtain arc $OCO'A$ of Fig. 9 instead of OA of Fig. 3.

While the first of Equations [11] remains undisturbed, the limit $\varphi = 0$ in the second must be replaced by $\varphi = -\pi$, whence

$$\sqrt{Q/EI}\, S_{OA} = \int_{-\pi}^{\pi/2} \frac{d\varphi}{\sqrt{1 - \sin^2 \frac{\alpha_0}{2} \sin^2 \varphi}} = 3K$$

Instead of Equation [13] we then have

$$l/2R = \sin \frac{\alpha_0}{2} \cos \varphi_B \left\{ 4K - F\left(\frac{\alpha_0}{2} \cdot \varphi_B \right) \right\}$$

For slopes and ordinates Equations [5] and [6] remain valid. As to the abscissas, Equation [14b] for x_B remains unaltered, and Equation [14a] applies to that portion of branch OA where φ is positive. Where φ is negative we have to replace φ in Equation [14a] by $-\varphi$ which results in

$$x \sqrt{Q/EI} = 2 \left\{ E + E\left(\frac{\alpha_0}{2} \cdot \varphi \right) \right\} - K - F\left(\frac{\alpha_0}{2} \cdot \varphi \right)$$

Now the general character of the curve is sufficiently disclosed by considering the terminal values $\varphi = \pi/2$ at O and $\varphi = -\pi$ at A, together with the more significant intermediate values $\varphi = 0$ and $\varphi = -\pi/2$. The corresponding slopes are obtained from (5), the ordinates will be given by Equation [6a], and the abscissas determined for positive values of φ by means of Equation [14a] or the foregoing equation for negative values.

In this manner we obtain the following

For $\varphi = \pi/2$; $\alpha = \alpha_0$; $y = 0$; $x = 0$. . . . point O in Fig. 9

For $\varphi = 0$; $\alpha = 0$; $y = 2\sqrt{EI/Q} \sin \alpha_0/2$; $x = \dfrac{2E - K}{\sqrt{Q/EI}}$

. . . . . point C in Fig. 9

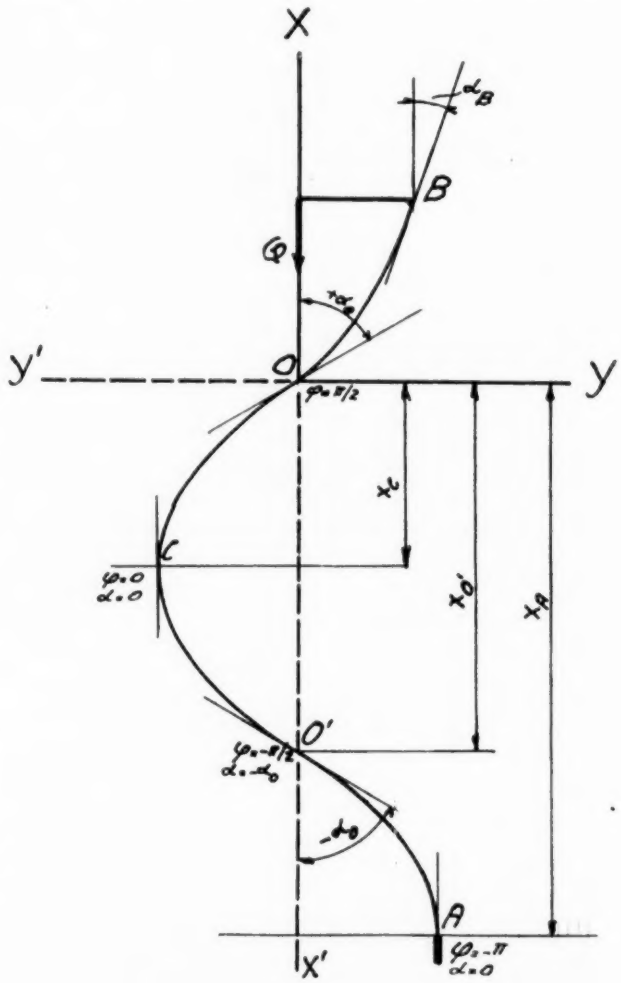

FIG. 9

For $\varphi = -\pi/2$; $\alpha = -\alpha_0$; $y = 0$; $x = \dfrac{4E - 2K}{\sqrt{Q/EI}}$

. . . . . point O' in Fig. 9

For $\varphi = -\pi$; $\alpha = 0$; $y = -2\sqrt{EI/Q} \sin \alpha_0/2$;

$x = \dfrac{6E - 3K}{\sqrt{Q/EI}}$ . . . . . point A in Fig. 9

To be noted is that $x_{O'} = 2x_C$, $x_A = 3x_C$, that arcs OC, CO', $O'A$ are of equal lengths and identical as to shape.

Steady Turbulent-Flow Equations of Continuity, Momentum, and Energy for Finite Systems

By E. R. VAN DRIEST,[1] CAMBRIDGE, MASS.

The steady turbulent-flow equations for continuity, momentum, and energy were derived for certain finite systems. It was found that for an incompressible fluid the continuity relation contained neither nonuniform velocity-distribution correction terms nor turbulence terms, that the momentum equation involved velocity-distribution corrections and mean-square velocity fluctuations, and that the energy relation contained not only velocity-distribution corrections and mean-square terms but in addition mean-cube and double- and triple-correlation terms. The correction factors for nonuniform velocity distribution were evaluated for fully developed open channel and pipe flow. Through the momentum law the effect of turbulence was shown quantitatively in the case of the hydraulic jump in open channels and the sudden expansion in closed conduits.

Introduction

ALTHOUGH the conventional steady-flow momentum and energy equations as used by civil and mechanical engineers have proved to be sufficiently accurate in most cases of application, it will be of interest to derive the more complete equations involving the turbulence terms and the nonuniformity of velocity distribution, and to point out the effect of such factors in some problems.

The steady turbulent-flow equations for continuity, momentum, and energy are derived by first writing the fundamental equations for conservation of mass, the second law of motion, and the first law of thermodynamics, respectively, and then averaging these over time according to the method of Osborne Reynolds. The relations derived are not differential equations[2] but are instead equations that apply to finite systems of matter. Moreover, the equations are by their very nature macroscopic in that they do not involve the inner mechanism of the turbulence but pertain only to mean values at the statistical boundaries of the system.

Continuity

A definite system to be considered will be that of an expanding conduit, as shown in Fig. 1. A more general system could be chosen, but the resulting equations would not be any more instructive.

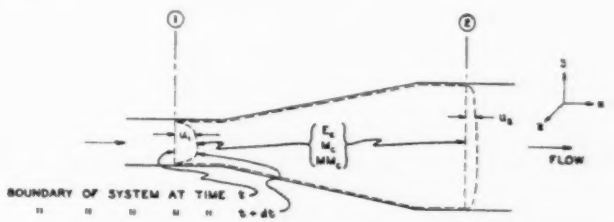

FIG. 1 FLOW THROUGH AN EXPANDING CONDUIT

The law of conservation of matter states that for any system of mass M, $\frac{dM}{dt} = 0$. Then for the system of Fig. 1 there follows

$$\int^{A_1} \rho_1 u_1 dA dt + M_{c/t} = M_{c/t+dt} + \int^{A_2} \rho_2 u_2 dA dt \quad [1]$$

in which ρ and u are the density and instantaneous axial velocity at a point of a section, respectively, and M_c is the matter in the volume common to the initial and final boundaries as indicated in the figure.

Averaging Equation [1] over the time T yields

$$\frac{1}{T}\int_{t-T/2}^{t+T/2}\int^{A_1} \rho_1 u_1 dA dt dt + \frac{1}{T}\int_{t-T/2}^{t+T/2} M_{c/t}\,dt = \frac{1}{T}\int_{t-T/2}^{t+T/2} M_{c/t+dt}\,dt + \frac{1}{T}\int_{-T/2}^{t+T/2}\int^{A_2} \rho_2 u_2\,dA\,dt\,dt$$

or

$$\int^{A_1} \overline{\rho_1 u_1}\,dA = \int^{A_2} \overline{\rho_2 u_2}\,dA \quad [2]$$

where

$$\overline{\rho u} = \frac{1}{T}\int_{t-T/2}^{t+T/2} \rho u dt$$

and

$$\frac{1}{T}\int_{t-T/2}^{t+T/2} M_{c/t}\,dt = \frac{1}{T}\int_{t-T/2}^{t+T/2} M_{c/t+dt}\,dt$$

in the steady state. If the fluid is incompressible and $u_1 = \overline{u_1} + u_1'$, $u_2 = \overline{u_2} + u_2'$ where the bar denotes the mean at a point and the prime the turbulent fluctuation, Equation [2] becomes

$$\int^{A_1} \overline{\overline{u_1} + u_1'}\,dA = \int^{A_2} \overline{\overline{u_2} + u_2'}\,dA$$

or

"Pressure Flow of a Turbulent Fluid Between Two Infinite Parallel Planes," by P. Y. Chou, *Quarterly of Applied Mathematics*, vol. 3, 1945, pp. 198–209.

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

$$\int^{A_1} \bar{u}_1 dA = \int^{A_2} \bar{u}_2 \, dA \quad \ldots\ldots\ldots\ldots [3]$$

since $\int^{A} \overline{u'} dA = 0$. Equation [3] can now be written in terms of the mean for the section, thus

$$U_1 A_1 = U_2 A_2 \quad \ldots\ldots\ldots\ldots [4]$$

where $U = \dfrac{1}{A} \int^{A} \bar{u} \, dA$

It is seen that Equation [4], the familiar equation of continuity, is unaffected by turbulence terms for the flow of an incompressible fluid.

Momentum

Application of Newton's second law of motion to a system, such as in Fig. 1, yields

$$F_x = \frac{d}{dt} \int^{M} u dM =$$

$$\frac{\left(\int^{A_2} \rho_2 u_2^2 dA dt + MM_{c/t+dt}\right) - \left(\int^{A_1} \rho_1 u_1^2 dA dt + MM_{c/t}\right)}{dt}$$

$$= \int^{A_2} \rho_2 u_2^2 \, dA - \int^{A_1} \rho_1 u_1^2 dA + \frac{d(MM_c)}{dt}$$

where MM_c is now the momentum in the volume common to the two positions of the boundaries, and F_x is the resultant of the forces acting on the boundaries in the x-direction. When this equation is averaged over the time T there results in the steady state

$$\bar{F}_x = \int^{A_2} \overline{\rho_2 u_2^2} \, dA - \int^{A_1} \overline{\rho_1 u_1^2} \, dA \quad \ldots\ldots\ldots [5]$$

since $\dfrac{\overline{d(MM_c)}}{dt} = \dfrac{d(\overline{MM_c})}{dt} = 0$

If the fluid is incompressible, Equation [5] becomes

$$\bar{F}_x = \rho \int^{A_2} \overline{u_2^2} \, dA - \rho \int^{A_1} \overline{u_1^2} \, dA$$

$$= \rho \int^{A_2} \overline{(\bar{u}_2 + u_2')^2} \, dA - \rho \int^{A_1} \overline{(\bar{u}_1 + u_1')^2} \, dA$$

$$= \rho \left(\int^{A_2} \bar{u}_2^2 \, dA - \int^{A_1} \bar{u}_1^2 \, dA + \int^{A_2} \overline{u_2'^2} \, dA - \int^{A_1} \overline{u_1'^2} \, dA \right)$$

$$\ldots\ldots\ldots\ldots [6]$$

The last two terms on the right-hand side of Equation [6] are the turbulence terms which must be taken into account in any exact treatment of a flow problem using the momentum law.

The Hydraulic Jump. The hydraulic jump, which is a gravity shock wave in an open channel, will now be considered in detail. The profile of such a shock is shown in Fig. 2.

For the system bounded by sections 1 and 2, Equation [6] becomes

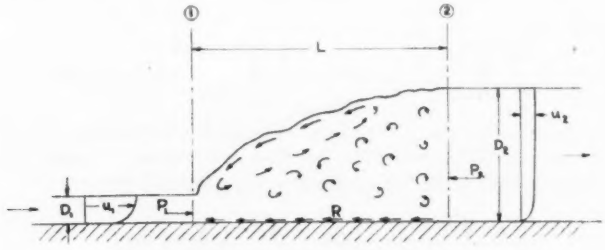

Fig. 2 The Hydraulic Jump

$$P_1 - P_2 - R = \frac{\gamma b D_1^2}{2} - \frac{\gamma b D_2^2}{2} - R =$$

$$\frac{\gamma}{g} \left(\int^{A_2} \bar{u}_2^2 \, dA - \int^{A_1} \bar{u}_1^2 \, dA + \int^{A_2} \overline{u_2'^2} \, dA - \int^{A_1} \overline{u_1'^2} \, dA \right) \quad [7]$$

in which P_1 and P_2 are the hydrostatic forces before and after the jump, D_1 and D_2 are the corresponding depths, R is the skin friction between 1 and 2, γ is the unit weight of the fluid, and b is the width of the channel.

Introducing the coefficients

$$\alpha_1 = \frac{\int^{A_1} \bar{u}_1^2 \, dA}{U_1^2 A_1} = \frac{\int^{A_1} \bar{u}_1^2 \, dA}{U_1^2 b D_1}$$

$$\alpha_2 = \frac{\int^{A_2} \bar{u}_2^2 \, dA}{U_2^2 A_2} = \frac{\int^{A_2} \bar{u}_2^2 \, dA}{U_2^2 b D_2}$$

$$I_1 = \frac{\int^{A_1} \overline{u_1'^2} \, dA}{U_1^2 A_1} = \frac{\int^{A_1} \overline{u_1'^2} \, dA}{U_1^2 b D_1}$$

$$I_2 = \frac{\int^{A_2} \overline{u_2'^2} \, dA}{U_2^2 A_2} = \frac{\int^{A_2} \overline{u_2'^2} \, dA}{U_2^2 b D_2}$$

it follows that

$$D_1^2 - D_2^2 - \frac{2R}{b\gamma} = \frac{2}{g} [(\alpha_2 + I_2) U_2^2 D_2 - (\alpha_1 + I_1) U_1^2 D_1] \quad [8]$$

It is seen that α_1 and α_2 are the correction factors for nonuniform velocity distribution and I_1 and I_2 are the turbulence-correction terms.

Since by Equation [4] $U_1 D_1 = U_2 D_2$, Equation [8] may be written

$$D_1^2 - D_2^2 - \frac{2R}{b\gamma} = \frac{2U_1^2 D_1}{g} [(\alpha_2 + I_2) D_1/D_2 - (\alpha_1 + I_1)]$$

whence upon rearrangement

$$\frac{D_2}{D_1} \left[\left(1 + \frac{D_2}{D_1}\right) \left(1 - \frac{D_2}{D_1}\right) - \frac{2R}{\gamma b D_1^2} \right] = \frac{2U_1^2}{gD_1} \left[(\alpha_2 + I_2) - (\alpha_1 + I_1) \frac{D_2}{D_1} \right]$$

or

$$J \left[(J + 1)(J - 1) + \frac{R}{P_1} \right] = 2\mathbf{F}^2 [(\alpha_1 + I_1) J - (\alpha_2 + I_2)] \quad \ldots\ldots [9]$$

where $J = \dfrac{D_2}{D_1}$, $P_1 = \dfrac{\gamma}{2} b D_1^2$, $\mathbf{F} = \dfrac{U_1}{\sqrt{gD_1}}$

$\mathbf{F}$ being called the Froude number.

Equation [9], or rather,

$$\mathbf{F}^2 = \frac{J \left[(J + 1)(J - 1) + \dfrac{R}{P_1} \right]}{2[(\alpha_1 + I_1) J - (\alpha_2 + I_2)]} \quad \ldots\ldots [10]$$

will now be used to study the effects of the velocity profile, skin friction, and turbulence upon calculations ignoring these factors.

In the case of a uniform velocity profile, and in the absence of skin friction and turbulence, Equation [10] reduces to

$$\mathbf{F}^2 = \frac{1}{2} J(J + 1) \quad \ldots\ldots [11]$$

which is plotted as the heavy line in Fig. 3.

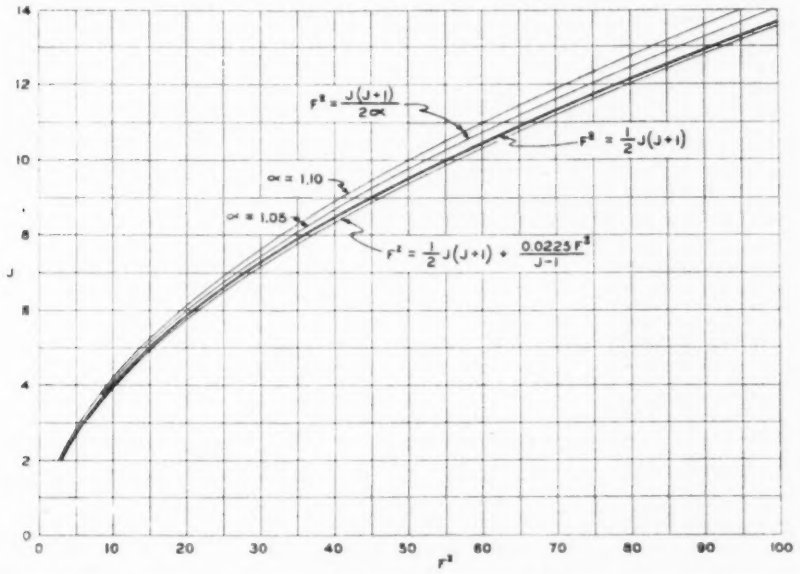

FIG. 3 EFFECT OF VELOCITY DISTRIBUTION AND SKIN FRICTION ON DEPTH AFTER THE HYDRAULIC JUMP

(*a*) *Effect of Velocity Distribution.* Considering only the velocity-distribution factors, Equation [10] becomes

$$F^2 = \frac{J(J+1)(J-1)}{2(\alpha_1 J - \alpha_2)} \quad [12]$$

It is seen at once that if $\alpha_2 = 1$ and $\alpha_1 > 1$, the effect is to shift the curve in Fig. 3 to the left, whereas if $\alpha_1 = 1$ and $\alpha_2 > 1$, the effect is to shift the curve to the right. Since the effect of α_1 compared to α_2 is magnified by the value J, the net tendency is toward the left. For the case when $\alpha_1 = \alpha_2$, a set of curves is plotted in Fig. 3.

It will now be of interest to determine values of α for infinitely wide open channels with known velocity-distribution functions. In the case of laminar flow,

$$u = \frac{3}{2} U \left(2\frac{y}{D} - \frac{y^2}{D^2} \right) \quad [13]$$

where y is measured from the bottom of the channel, so that

$$\alpha = \frac{\int_0^D u^2 dy}{U^2 D} = \frac{6}{5} = 1.20$$

In the case of fully developed turbulent flow, the von Kármán velocity-defect law is used, namely

$$\bar{u} = \bar{u}_{max} + \frac{1}{\kappa}\sqrt{\frac{\bar{\tau}_0}{\rho}} \ln \frac{y}{D} \quad [14]$$

from which is readily obtained[2]

$$U = \bar{u}_{max} - \frac{1}{\kappa}\sqrt{\frac{\bar{\tau}_0}{\rho}} \quad [15]$$

where τ_0 is the shear at the bottom and κ is the universal constant.

Subtraction of Equation [15] from Equation [14] gives

$$\bar{u} = U + \frac{1}{\kappa}\sqrt{\frac{\bar{\tau}_0}{\rho}}\left(1 + \ln \frac{y}{D}\right) \quad [16]$$

whence

$$\alpha = \frac{\int_0^D \bar{u}^2 dy}{U^2 D} = 1 + \left(\frac{\sqrt{\frac{\bar{\tau}_0}{\rho}}}{\kappa U}\right)^2 \quad [17]$$

$$= 1 + \left(\frac{\bar{u}_{max}}{U} - 1\right)^2 \quad [18]$$

Data on clear water flowing in an open channel were obtained from experiments on rough channels[2] and these data together with the results of computation of α (computed from Equation [17]) are presented in Table 1. The results are plotted in Fig. 4, and an average line is extended through the points to indicate the general trend. Term ϵ is the size of the roughness grains glued to the channel bottom.

(*b*) *Effect of Skin Friction.* Skin friction tends to shift the basic curve, Equation [11], in Fig. 3 to the right, and an estimate of this effect can be obtained as follows:

The term $\frac{R}{P_1}$ of Equation [10] can be written for wide channels

$$\frac{R}{P_1} = \frac{2\int_L \tau_0 dL}{\gamma D_1^2} \quad [19]$$

Since

$$\tau_0 = c_f \frac{\rho}{2} U^2 = c_f \frac{\rho}{2} \frac{(U_1 D_1)^2}{D^2}$$

it follows that

$$\int_0^L \tau_0 dL = c_f \frac{\rho}{2} (U_1 D_1)^2 \int_L \frac{dL}{D^2} \quad [20]$$

where D is the depth at any point along the jump and c_f is assumed constant. It is further assumed that the shock expands linearly whence

$$dL = \frac{L}{D_2 - D_1} dD$$

[2] "Transportation of Suspended Sediment by Water," by Vito A. Vanoni, Proceedings of the A.S.C.E., vol. 70, 1944, p. 793.

TABLE 1 DATA ON CLEAR WATER FLOWING IN OPEN CHANNEL

$\sqrt{\frac{\tau_0}{\rho}}$ fps	U fps	D ft	$\frac{\epsilon}{D}$	$\frac{b}{D}$	$\frac{UD}{\nu}$	α	β	$\frac{U}{U_{max}}$
0.197	3.62	0.481	0.003	5.76	171000	1.018	1.050	0.880
0.200	3.60	0.496	0.003	5.58	175000	1.019	1.053	0.877
0.197	3.45	0.481	0.003	5.76	162000	1.020	1.055	0.873
0.211	3.38	0.554	0.005	5.00	183000	1.024	1.065	0.863
0.193	3.21	0.462	0.006	6.00	146000	1.023	1.061	0.868
0.138	1.99	0.234	0.012	11.83	45600	1.030	1.079	0.851

NOTE: κ is taken as 0.40. Term ν is kinematic viscosity.

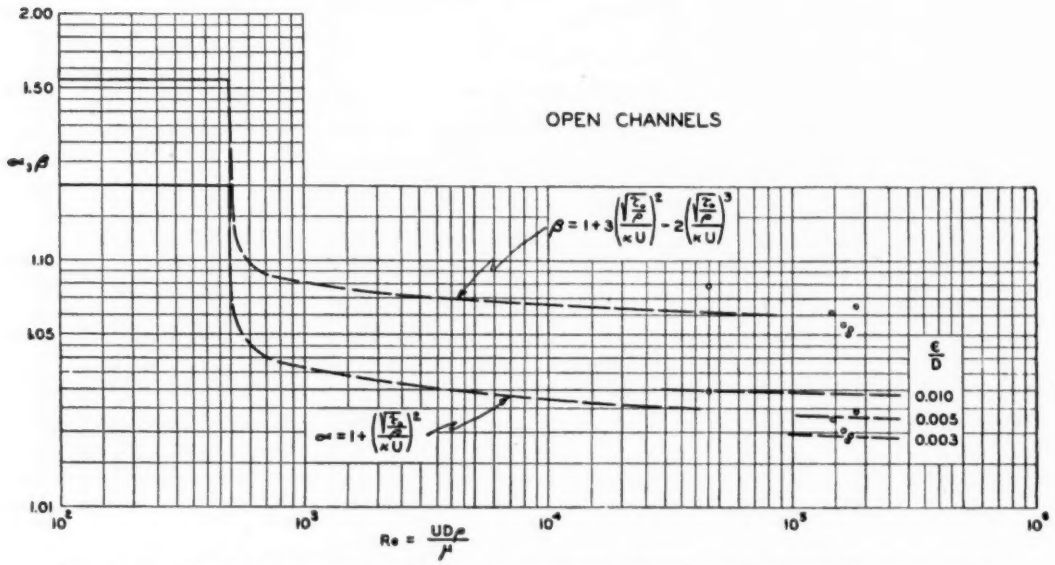

FIG. 4 MOMENTUM- AND ENERGY-CORRECTION FACTORS FOR NONUNIFORM VELOCITY DISTRIBUTION IN INFINITELY WIDE-OPEN CHANNELS

and Equation [20] becomes

$$\int_0^L \tau_0 dL = c_f \frac{\rho}{2} U^2 \frac{D_1}{D_2} L$$

which results in

$$\frac{R}{P_1} = c_f \frac{\mathbf{F}^2}{J} \cdot \frac{L}{D_1} \quad \ldots\ldots [21]$$

Now data obtained by Bakhmeteff and Matzke[4] show that the length of the jump is represented fairly well by

$$\frac{L}{D_1} = 6\mathbf{F}$$

so that

$$\frac{R}{P_1} = 6 \frac{c_f}{J} \mathbf{F}^2 \quad \ldots\ldots [22]$$

When Equation [10] contains only the effect of skin friction, it becomes by Equation [22]

$$\mathbf{F}^2 = \frac{J(J+1)(J-1) + 6c_f \mathbf{F}^2}{2(J-1)}$$

$$= \frac{1}{2} J(J+1) + \frac{3c_f \mathbf{F}^2}{J-1} \quad \ldots\ldots [23]$$

For purposes of computation a reasonably high value of c_f can be obtained by first placing $c_f = \frac{f}{4}$, where f is the friction factor for pipe flow, and then choosing a value $f = 0.03$, giving $c_f = 0.0075$. Equation [23] then is written

$$\mathbf{F}^2 = \frac{1}{2} J(J+1) + \frac{0.0225 \mathbf{F}^2}{J-1} \quad \ldots\ldots [24]$$

This equation is plotted in Fig. 3 and indicates an extreme effect of skin friction.

(c) *Effect of Turbulence.* Equation [10], including only the turbulence terms, is

$$\mathbf{F}^2 = \frac{J(J+1)(J-1)}{2[(J-1) + (I_1 J - I_2)]} \quad \ldots\ldots [25]$$

In such cases where the fluid enters the shock turbulent-free, $I_1 = 0$ and

$$\mathbf{F}^2 = \frac{J(J+1)(J-1)}{2(J-1-I_2)} \quad \ldots\ldots [26]$$

The Bakhmeteff-Matzke data were obtained in just such a case, and hence the effect of turbulence should make itself felt according to Equation [26]. That this is true can be seen from Fig. 5 which shows the basic Equation [11], Equation [26] for various values of I_2, and the data.

Since the shock wave is known to be a generator of intense turbulence, the fall of the data to the right of the basic curve is undoubtedly due principally to the turbulence effect. It should be noted that the average intensity of turbulence as defined by I_2 is upward of 100 per cent for the higher values of relative depth J.

[4] "The Hydraulic Jump in Terms of Dynamic Similarity," by B. A. Bakhmeteff and A. E. Matzke, Trans. A.S.C.E., vol. 101, 1936, p. 631.

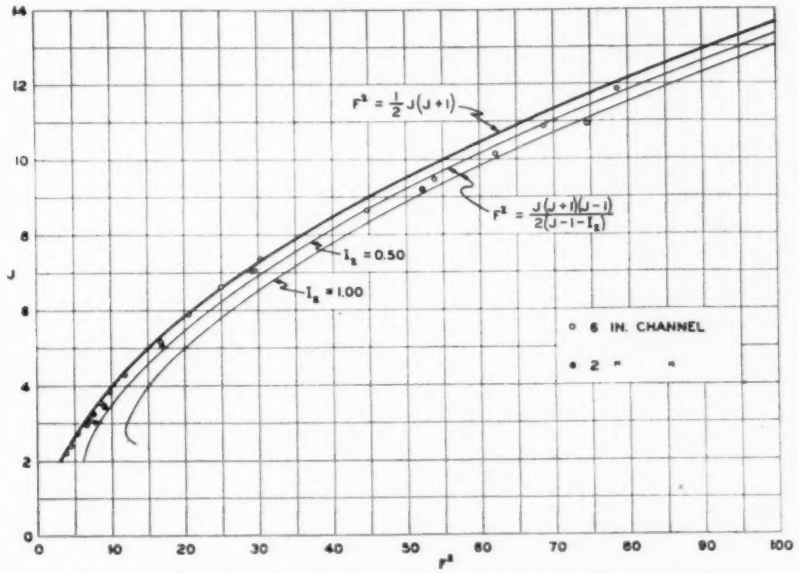

FIG. 5 THE EFFECT OF TURBULENCE ON DEPTH AFTER THE HYDRAULIC JUMP

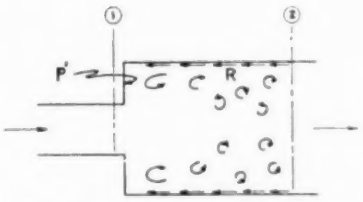

FIG. 6 THE SUDDEN ENLARGEMENT

The Sudden Enlargement. When Equation [6] is applied to the sudden enlargement of Fig. 6 there results

$$p_1A_1 + p'(A_2 - A_1) - p_2A_2 - R = \rho\left(\int^{A_2}\bar{u}_2^2\,dA - \int^{A_1}\bar{u}_1^2\,dA + \int^{A_2}\overline{u_2'^2}\,dA - \int^{A_1}\overline{u_1'^2}\,dA\right) = \rho U_2A_2[(\alpha_2 + I_2)U_2 - (\alpha_1 + I_1)U_1]$$

whence

$$\frac{(p_1 - p')\frac{A_1}{A_2} + p' - p_2 - \frac{R}{A_2}}{\rho U_1^2} = \frac{A_1}{A_2}\left[(\alpha_2 + I_2)\frac{A_1}{A_2} - (\alpha_1 + I_1)\right] \quad [27]$$

where p' is the average pressure over the annular plate, and p_1 and p_2 are the average pressures over sections 1 and 2, respectively.

If it is assumed that $p_1 = p'$, $R = 0$, $\alpha_1 = \alpha_2 = 1$ and $I_1 = I_2 = 0$, Equation [27] reduces to

$$\frac{p_1 - p_2}{\rho U_1^2} = \frac{A_1}{A_2}\left(\frac{A_1}{A_2} - 1\right) \quad [28]$$

or, introducing $E = \frac{p_2 - p_1}{\rho U_1^2/2}$ and $m = \frac{A_2}{A_1}$

$$E = \frac{2}{m}\left(1 - \frac{1}{m}\right) \quad [29]$$

With regard to the velocity-distribution correction for flow in pipes, the value of α can be determined analytically if the equation of velocity distribution is known.

For laminar flow through a long pipe of inner radius r_0

$$u = 2U\left(1 - \frac{r^2}{r_0^2}\right) \quad [30]$$

whereupon

$$\alpha = \frac{\int^A u^2dA}{U^2A} = \frac{\int_0^{r_0} u^2 2\pi r dr}{U^2\pi r_0^2} = \frac{4}{3} = 1.33$$

For fully developed turbulent flow, the von Kármán velocity-defect law, viz.

$$\bar{u} = \bar{u}_{max} + \frac{1}{\kappa}\sqrt{\frac{\tau_0}{\rho}}\ln\frac{y}{r_0} \quad [31]$$

leads to the expression[5]

$$U = \bar{u}_{max} - \frac{3}{2}\frac{1}{\kappa}\sqrt{\frac{\tau_0}{\rho}} \quad [32]$$

subtraction of which from Equation [31] yields

$$\bar{u} = U + \frac{1}{\kappa}\sqrt{\frac{\tau_0}{\rho}}\left(\frac{3}{2} + \ln\frac{y}{r_0}\right) \quad [33]$$

whence

$$\alpha = \frac{\int^A \bar{u}^2\,dA}{U^2A} = 1 + \frac{5}{4}\left(\frac{\sqrt{\frac{\tau_0}{\rho}}}{\kappa U}\right)^2 \quad [34]$$

$$= 1 + \frac{5}{9}\left(\frac{\bar{u}_{max}}{U} - 1\right)^2 \quad [35]$$

Equation [34] can be written in terms of the friction factor f by first noting that

[5] "Strömungsgesetze in rauhen Rohren," by J. Nikuradse, *Forschungsheft*, 361, V.D.I., 4, 1933, pp. 1–22.

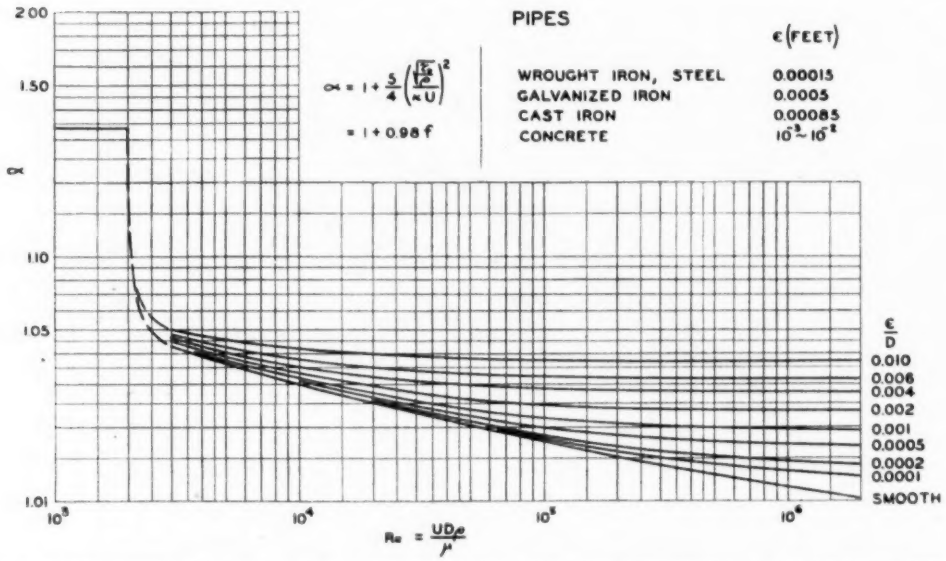

FIG. 7 MOMENTUM-CORRECTION FACTOR FOR NONUNIFORM VELOCITY DISTRIBUTION IN COMMERCIAL PIPES

$$\sqrt{\frac{\tau_0}{\rho}}\Big/U = \sqrt{\frac{f}{8}}$$

so that for a value of $\kappa = 0.40$

$$\alpha = 1 + \frac{5}{4}\frac{1}{\kappa^2}\cdot\frac{f}{8} = 1 + 0.98f \quad \ldots\ldots\ldots\ldots [36]$$

$$= 1 + f \text{ (approx.)}$$

Fig. 7 shows a plot of Equation [36], using factors[6] for commercial pipes.

The sudden enlargement is another seat of turbulence generation[7] and therefore it is to be expected that the intensity of turbulence at section 2 will have considerable effect upon the data. Assuming that $p_1 = p'$ and including only the turbulence terms, Equation [27] becomes

$$E = \frac{2}{m}\left[\left(1 - \frac{1}{m}\right) + \left(I_1 - I_2\frac{1}{m}\right)\right] \quad \ldots\ldots\ldots [37]$$

and if I_1 is negligible compared to $\frac{I_2}{m}$, then there follows

$$E = \frac{2}{m}\left(1 - \frac{1}{m} - \frac{I_2}{m}\right) \quad \ldots\ldots\ldots\ldots [38]$$

Fig. 8 shows the base Equation [29] along with Equation [38] for various values of I_2. Also in this figure are plotted data given by Gibson.[8] Of course, the presence of skin friction and the fact that p' is somewhat less[7] than p_1 will tend to shift the data in Fig. 8 to smaller values of E. Nevertheless, an appreciable part of the total shift must be due to the turbulence, particularly at greater values of m, as is evident from the plot. An observed value of 150 per cent for the average intensity of turbulence defined by I_2 should be noted.

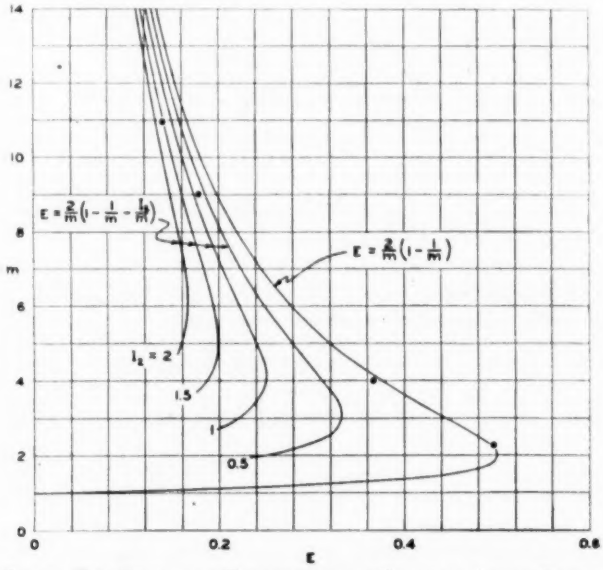

FIG. 8 THE EFFECT OF TURBULENCE ON PRESSURE AFTER SUDDEN ENLARGEMENT

ENERGY

The steady turbulent-flow-energy equation for finite systems is derived from the first law of thermodynamics which reads

$$dE = dQ - dW \quad \ldots\ldots\ldots\ldots [39]$$

in which dE is the change in internal energy of a system, dQ is the heat transferred to the system and dW is the work done by the system during an infinitesimal change of state. Assuming no heat transfer or shaft work, application of Equation [39] to the system in Fig. 1 for the change in state over the time interval dt yields

$$\int^{A_2} i_2\gamma_2 u_2\, dA\, dt - \int^{A_1} i_1\gamma_1 u_1\, dA\, dt + \frac{1}{2g}\int^{A_2} q_2{}^2\gamma_2 u_2\, dA\, dt$$

$$- \frac{1}{2g}\int^{A_1} q_1{}^2\gamma_1 u_1\, dA\, dt + E_{c/t+dt} - E_{c/t} = -\int^{A_2} p_2 u_2\, dA\, dt$$

$$+ \int^{A_1} p_1 u_1 \, dA \, dt - \int^{A_2} \tau_{xy_2} v_2 \, dA \, dt - \int^{A_2} \tau_{xz_2} w_2 \, dA \, dt + \int^{A_1} \tau_{xy_1} v_1 \, dA \, dt + \int^{A_1} \tau_{xz_1} w_1 \, dA \, dt \quad \ldots\ldots [40]$$

where i_1 and i_2 are the molecular internal energies per unit weight, v_1 and v_2 the transverse velocities in the y-direction, w_1 and w_2 the transverse velocities in the z-direction, and τ_1 and τ_2 the transverse shear stresses at sections 1 and 2, respectively, all of which are instantaneous; furthermore, $q^2 = u^2 + v^2 + w^2$, and E_c is the energy in the volume common to the initial and final positions of the boundary of the system. Following the previous procedure, the average of Equation [40] is

$$\int^{A_2} \overline{i_2 \gamma_2 u_2} \, dA - \int^{A_1} \overline{i_1 \gamma_1 u_1} \, dA + \frac{1}{2g} \int^{A_2} \overline{q_2^2 \gamma_2 u_2} \, dA - \frac{1}{2g} \int^{A_1} \overline{q_1^2 \gamma_1 u_1} dA = - \int^{A_2} \overline{p_2 u_2} \, dA + \int^{A_1} \overline{p_1 u_1} \, dA - \int^{A_2} \overline{\tau_{xy_2} v_2} \, dA - \int^{A_2} \overline{\tau_{xz_2} w_2} \, dA + \int^{A_1} \overline{\tau_{xy_1} v_1} \, dA + \int^{A_1} \overline{\tau_{xz_1} w_1} \, dA \quad \ldots\ldots [41]$$

Assuming incompressibility and dividing through by the mean weight rate of flow, viz.

$$\gamma \int^{A_1} \bar{u}_1 \, dA = \gamma \int^{A_2} \bar{u}_2 \, dA$$

there results per unit weight of fluid flowing

$$\frac{\int^{A_1} \overline{i_1 u_1} dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} \overline{q_1^2 u_1} \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{p_1 u_1} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xy_1} v_1} \, dA}{\gamma \int^{A_1} \bar{u}_1 dA} + \frac{\int^{A_1} \overline{\tau_{xz_1} w_1} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} = \frac{\int^{A_2} \overline{i_2 u_2} \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} \overline{q_2^2 u_2} \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{p_2 u_2} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xy_2} v_2} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xz_2} w_2} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} \quad \ldots\ldots [42]$$

The next step is to substitute $i = \bar{i} + i'$, $p = \bar{p} + p'$, $u = \bar{u} + u'$, $v = \bar{v} + v'$, and $w = \bar{w} + w'$. Equation [42] then expands to

$$\frac{\int^{A_1} \bar{i}_1 \bar{u}_1 \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{i_1' u_1'} \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} (\bar{u}_1^2 + \bar{v}_1^2 + \bar{w}_1^2) \bar{u}_1 \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} (\overline{u_1'^2} + \overline{v_1'^2} + \overline{w_1'^2}) \bar{u}_1 \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{2}{2g} \int^{A_1} (\bar{u}_1 \overline{u_1'^2} + \bar{v}_1 \overline{u_1' v_1'} + \bar{w}_1 \overline{u_1' w_1'}) \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} (\overline{u_1'^3} + \overline{u_1' v_1'^2} + \overline{u_1' w_1'^2}) \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \bar{p}_1 \bar{u}_1 \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{p_1' u_1'} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xy_1} v_1} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xy_1}' v_1'} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xz_1} w_1} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xz_1}' w_1'} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} = \frac{\int^{A_2} \bar{i}_2 \bar{u}_2 \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{i_2' u_2'} \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} \bar{u}_2^3 \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} (\overline{u_2'^2} + \overline{v_2'^2} + \overline{w_2'^2}) \bar{u}_2 \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{2}{2g} \int^{A_2} \bar{u}_2 \overline{u_2'^2} \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} (\bar{u}_2 \overline{u_2'^2} + \bar{v}_2 \overline{u_2' v_2'} + \bar{w}_2 \overline{u_2' w_2'}) \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} (\overline{u_2'^3} + \overline{u_2' v_2'^2} + \overline{u_2' w_2'^2}) \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \bar{p}_2 \bar{u}_2 \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{p_2' u_2'} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xy_2} v_2} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xy_2}' v_2'} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xz_2} w_2} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xz_2}' w_2'} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} \quad \ldots\ldots [43]$$

If the sections 1 and 2 are taken such that $\bar{v} = \bar{w} = 0$, Equation [43] reduces to

$$\frac{\int^{A_1} \bar{i}_1 \bar{u}_1 dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{i_1' u_1'} \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} \bar{u}_1^3 \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} (\overline{u_1'^2} + \overline{v_1'^2} + \overline{w_1'^2}) \bar{u}_1 \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{2}{2g} \int^{A_1} \bar{u}_1 \overline{u_1'^2} \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\frac{1}{2g} \int^{A_1} (\overline{u_1'^3} + \overline{u_1' v_1'^2} + \overline{u_1' w_1'^2}) \, dA}{\int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \bar{p}_1 \bar{u}_1 \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{p_1' u_1'} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xy_1}' v_1'} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} + \frac{\int^{A_1} \overline{\tau_{xz_1}' w_1'} \, dA}{\gamma \int^{A_1} \bar{u}_1 \, dA} = \frac{\int^{A_2} \bar{i}_2 \bar{u}_2 \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{i_2' u_2'} \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} \bar{u}_2^3 \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} (\overline{u_2'^2} + \overline{v_2'^2} + \overline{w_2'^2}) \bar{u}_2 \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{2}{2g} \int^{A_2} \bar{u}_2 \overline{u_2'^2} \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\frac{1}{2g} \int^{A_2} (\bar{u}_2 \overline{u_2'^2} + \bar{v}_2 \overline{u_2' v_2'} + \bar{w}_2 \overline{u_2' w_2'}) \, dA}{\int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \bar{p}_2 \bar{u}_2 \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{p_2' u_2'} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xy_2}' v_2'} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} + \frac{\int^{A_2} \overline{\tau_{xz_2}' w_2'} \, dA}{\gamma \int^{A_2} \bar{u}_2 \, dA} \quad \ldots [44]$$

The extreme complexity of the energy Equation [44] compared to the simplicity of the momentum Equation [6] is immediately apparent. Whereas the momentum equation involves only mean-square terms, the energy equation contains mean squares, mean cubes, and double and triple correlations. Some measurements[7,9,10,11] of the mean-square terms have been made so that some information is available as to their variation, but no information is available concerning the double and triple correlations involved in the energy equation.

The energy of mean motion can be computed provided the ve-

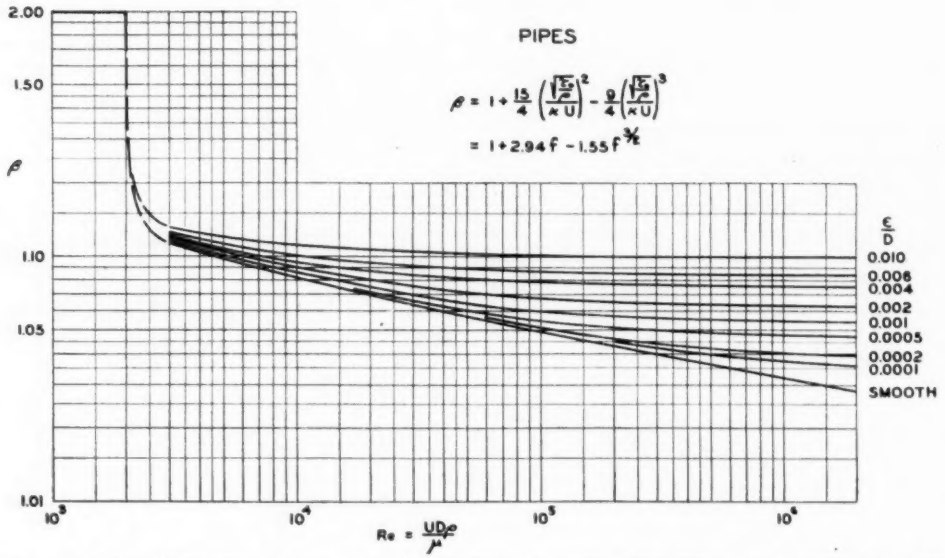

FIG. 9 ENERGY-CORRECTION FACTOR FOR NONUNIFORM VELOCITY DISTRIBUTION IN COMMERCIAL PIPES

locity distribution is known. The correction factor for nonuniform distribution, viz.

$$\beta = \frac{\int \bar{u}^3 dA}{U^3 A} \quad \text{.....[45]}$$

can be obtained for certain distributions as follows:

(*a*) Open channels (laminar): Use of Equation [13] gives

$$\beta = \frac{54}{35} = 1.54$$

(*b*) Open channels (turbulent): Use of Equation [16] leads to

$$\left.\begin{aligned} \beta &= 1 + 3\left(\frac{\sqrt{\tau_0/\rho}}{\kappa U}\right)^2 - 2\left(\frac{\sqrt{\tau_0/\rho}}{\kappa U}\right)^3 \\ &= 1 + 3\left(\frac{\bar{u}_{max}}{U} - 1\right)^2 - 2\left(\frac{\bar{u}_{max}}{U} - 1\right)^3 \end{aligned}\right\} \quad [46]$$

Values of β were computed from the Vanoni data[9] and Equation [46], and these results are also entered in Table 1. Furthermore, the results are plotted in Fig. 4, and an average line is extended through the points to indicate the general trend.

(*c*) Pipes (laminar): By use of Equation [30] it follows that

$$\beta = 2.00$$

(*d*) Pipes (turbulent): The turbulent velocity-distribution Equation [33] yields

$$\left.\begin{aligned} \beta &= 1 + \frac{15}{4}\left(\frac{\sqrt{\tau_0/\rho}}{\kappa U}\right)^2 - \frac{9}{4}\left(\frac{\sqrt{\tau_0/\rho}}{\kappa U}\right)^3 \\ &= 1 + \frac{5}{3}\left(\frac{\bar{u}_{max}}{U} - 1\right)^2 - \frac{2}{3}\left(\frac{\bar{u}_{max}}{U} - 1\right)^3 \end{aligned}\right\} \quad [47]$$

Again noting that $\sqrt{\tau_0/\rho}\,\Big/ U = \sqrt{f/8}$ and using $\kappa = 0.40$, Equation [47] may be written

$$\begin{aligned} \beta &= 1 + \frac{15}{4}\frac{1}{\kappa^2}\frac{f}{8} - \frac{9}{4}\frac{1}{\kappa^3}\left(\frac{f}{8}\right)^{3/2} \\ &= 1 + 2.94f - 1.55f^{3/2} \quad \text{.....[48]} \\ &= 1 + 3f \text{ (roughly)} \end{aligned}$$

Equation [48] is plotted in Fig. 9, again making use of the friction factors[6] for commercial pipes.

It should be noted that for wide-open channels or for pipes, if $\alpha = 1 + \eta$, then $\beta = 1 + 3\eta$ (approx.).

SUMMARY AND CONCLUSION

The steady turbulent-flow equations for continuity, momentum, and energy have been derived for certain finite systems. It was found for a liquid that the continuity relation contained neither nonuniform velocity-distribution correction terms nor turbulence terms, that the momentum equation involved velocity-distribution corrections and mean-square velocity fluctuations, and that the energy relation contained not only velocity-distribution corrections and mean-square terms but in addition mean-cube and double- and triple-correlation terms. The correction factors for nonuniform velocity distribution were evaluated for fully developed open-channel and pipe flow. The effect of turbulence was shown quantitatively in the case of open and closed sudden expansions making use of the momentum law.

In any exact analysis of turbulent-flow problems the turbulence terms must of course be taken into account. Indeed, before such foregoing momentum and energy equations can be used, knowledge of the variation of the turbulence terms including the double and triple correlations must be available.

Design Data

It is important that the data contained in technical papers be made readily available to designing engineers. In order to satisfy these needs of industry, this section of the Journal includes a concise presentation of data and information drawn chiefly from papers previously published by the Applied Mechanics Division of The American Society of Mechanical Engineers.

The data have been prepared by a subcommittee of the Applied Mechanics Division—S. Timoshenko, R. E. Peterson, J. Ormondroyd, J. N. Goodier, and J. M. Lessells.

Calculation of Stress in Crane Hooks

By A. M. WAHL[1]

Two methods for calculating stress in crane hooks which have given good results in practice are described. One method, based on a numerical integration of the curved-bar equations, involves only slide-rule accuracy and may be used for irregular shapes of cross section. The second or analytical method is based on an analysis of an equivalent trapezoidal section, and is applicable to hooks having sections which do not deviate too much from the trapezoidal form. Comparison of the results of the two methods when applied to actual crane hooks indicates that the more rapid analytical method is sufficiently accurate for most practical purposes.

THE usual method of calculation of stress in crane hooks having an irregular cross section is based on curved-bar theory, the equations being integrated using numerical or graphical means (1).[2] However, these methods in general involve small differences between two quantities nearly equal, and for this reason the numerical work must be carried out with considerable precision in order to obtain reasonably accurate final values. To avoid this and to utilize slide-rule methods of calculation, the equations developed by Perkins (2) have been applied. In conjunction with Simpson's rule for numerical integration, this procedure has been found to yield good results in practical work; the method will be described in Part 1 of this paper.

In addition, a more rapid analytical method for calculating crane hooks where the critical section approximates a trapezoid is also described (Part 2). Results obtained by this method have been checked for several practical hooks against the numerical integration method of Part I and found to yield good agreement; also the method has been utilized in practical computation with good results.

The methods described here are limited to the usual case where the resultant load P on the hook passes through the center of curvature O, Fig. 1. It is also assumed that the critical section AA' is at right angles to the resultant load, as is true of the majority of practical hooks.[3]

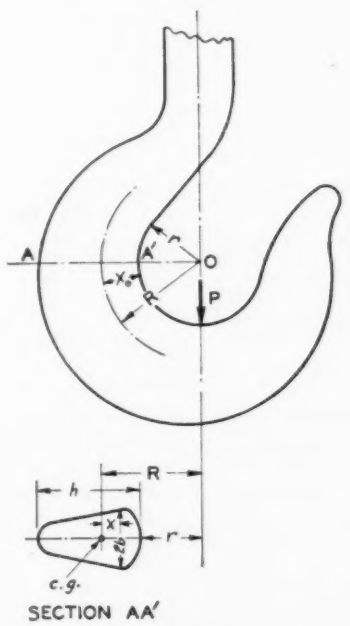

FIG. 1 CRANE HOOK WITH IRREGULAR SECTION

PART 1 NUMERICAL INTEGRATION METHOD FOR HOOK WITH IRREGULAR CROSS SECTION

(*a*) *Theory.* The equation for maximum tensile stress S_{max} (including the direct stress due to the load P) at point A', Fig. 1, may be expressed as

$$S_{max} = \frac{P(R-r)}{Fr} \quad \ldots\ldots\ldots\ldots\ldots [1]$$

where the function F is

$$F = \frac{2}{R}\int \frac{x^2 b\,dx}{R-x} \quad \ldots\ldots\ldots\ldots\ldots [2]$$

This integral is taken over the whole cross section.

P = load on hook, Fig. 1
x = distance from center of gravity to any point of section
r = inside radius of curvature
R = distance from center of curvature O to center of gravity of critical section AA'
$2b$ = width of section at distance x from c.g.

[2] Numbers in parentheses refer to the References at the end of paper.

[3] If these conditions are not fulfilled, methods described in references (1) and (2 may be used.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 W. 39th St., New York, N. Y., and will be accepted until October 10, 1946, for publication at a later date. Discussion received after the closing date will be returned.

To calculate the stress using Equation [1], it is necessary to evaluate the integral of Equation [2] which may be done numerically using Simpson's rule (3). In the following method or procedure, the depth h of the hook cross section has been divided into 30 equal parts (which has given good results in practice).[5] On this basis the detailed procedure for calculating stress in the hook is as follows.

(*b*) *Procedure for Evaluating Stress.* Lay out half of critical section of hook to scale as shown in Fig. 2.

Divide cross section of hook into 30 equal parts as shown. Spacing Δ between each line is equal to $h/30$ where h = depth of critical section. Measure the half widths $b_1, b_2, b_3 \ldots\ldots\ldots b_{29}$ at each point, Fig. 2.

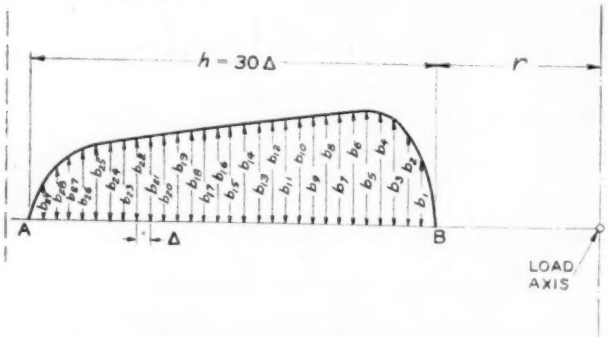

FIG. 2 DIVISION OF HALF SECTION OF CRANE HOOK INTO 30 EQUAL SPACES

Make up a table similar to Table 1 as follows:

In column 1 tabulate $b_1, b_2, b_3 \ldots\ldots\ldots b_{29}$

In column 2 tabulate $2b_1, b_2, 2b_3, b_4 \ldots\ldots\ldots 2b_{29}$ as shown.

The sum of the figures in column 2 is equal to A_2.

In column 3 tabulate $\Delta, 2\Delta, 3\Delta, \ldots\ldots 29\Delta$.

The elements of column 4 are taken equal to the corresponding ones of column 2 multiplied by column 3. Thus the first element of column 4 is equal to $2b_1\Delta$, the second element is b_2 times $2\Delta = 2b_2\Delta$, the third $2b_3$ times $3\Delta = 6b_3\Delta$, etc.

The sum of the elements of column 4 is taken equal to A_4.

Divide A_4 by A_2. The result will be equal to x_0, the distance from point A' of Fig. 1 to the center of gravity of the cross section. The radius R then becomes (from Fig. 1)

$$R = r + x_0$$

Next, in column 5 tabulate the quantities $c_1 = r + \Delta$, $c_2 = r + 2\Delta$, $c_3 = r + 3\Delta$, etc.

In column 6 tabulate $a_1 = (x_0 - \Delta)$, $a_2 = (x_0 - 2\Delta)$, $a_3 = (x_0 - 3\Delta)$, etc., and in column 7, a_1^3, a_2^3, a_3^3, etc.

In column 8 tabulate the quantities $2b_1a_1^3/c_1$, $b_2a_2^3/c_2$, $2b_3a_3^3/c_3$, etc. Each element of column 8 is equal to the corresponding element of column 2 multiplied by that of column 7 and divided by that of column 5.

The sum of the elements of column 8 is taken equal to A_8.

Applying Simpson's rule and using Equations [1] and [2] the maximum tensile stress at the critical section A', Fig. 1, then becomes

$$S_{max} = \frac{3Px_0R}{4r\,\Delta\,A_8} \ldots\ldots\ldots\ldots\ldots [3]$$

(*c*) *Numerical Example.*[4] As an example of the application of this numerical integration method, a hook having the following dimensions was calculated. The load P is taken as 100,000 lb.

$r = 4.5$ in.
$h = 9.59$ in.
$\Delta = h/30 = 0.32$ in.

Values of b_1, b_2, etc., representing the half width of the cross section, Fig. 2, are listed in column 1 of Table 2.

$A_2 = 129.3$ = sum of figures of column 2
$A_4 = 603.0$ = sum of figures of column 4

$$x_0 = \frac{A_4}{A_2} = \frac{603.0}{129.3} = 4.66 \text{ in.} = \text{distance of c.g. from } A' \text{ (Fig. 1)}$$

$R = r + x_0 = 4.5 + 4.66 = 9.16$ in.

With the value of x_0 known, the values of columns 6, 7, and 8 are computed. $A_8 = 100.3$ = sum of figures of column 8.

[4] The author is indebted to G. G. Setterlund of the Westinghouse Electric Corporation for carrying out in these calculations as well as those of Part 2.

29	1.50	3.00	9.28	28.00	13.78	—4.62	21.25	4.63
30	0	0	9.60	0	14.10	—4.94	24.40	0
$\Delta = 0.32$		$\Sigma = 129.3$ $= A_2$		$\Sigma = 603.0$ $= A_4$				$\Sigma = 100.3$ $= A_8$

From Equation [3] the maximum tensile stress at A' (Fig. 1) then becomes

$$S_{max} = \frac{3Px_0R}{4r\ \Delta\ A_3} = \frac{3\ (100{,}000)\ (4.66)(9.16)}{4\ (4.5)\ (0.32)\ (100.3)} = 22{,}200 \text{ psi}$$

Results obtained by using this method have been checked against those using the graphical method described by Timoshenko[5] for several practical hooks. Agreement was obtained in all cases within a few per cent which may be considered satisfactory in view of the possible error inherent in the use of the graphical method. In addition, as mentioned later, the numerical integration method has also been checked against the analytical method of Part 2.

PART 2 ANALYTICAL METHOD FOR HOOK OF APPROXIMATE TRAPEZOIDAL SHAPE

(*a*) *Method of Analysis.* The analytical method given in this part is intended to apply to hooks with cross sections having a shape such as shown by the full lines of Fig. 3, and which do not deviate too much from a trapezoidal form. This includes a large number of practical crane-hook sections. This method, while approximate, is much faster than the numerical integration method of Part 1, and in the cases to which it has been applied, it has given close agreement with the latter method.

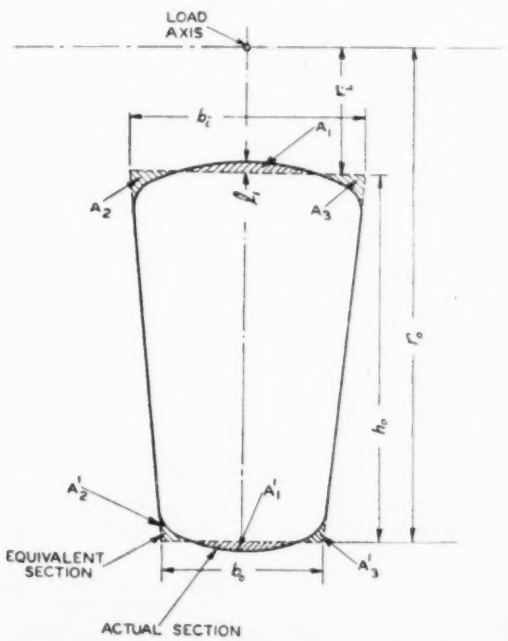

FIG. 3 CRANE-HOOK SECTION OF APPROXIMATE TRAPEZOIDAL FORM

Essentially the analytical method is based on the assumption of an equivalent trapezoidal section having an area equal to that of the actual section. The stress computed in this way is then corrected for the stress increase in the actual section resulting from the fact that the fibers nearest the center of curvature are farther from the neutral axis than in the case of the equivalent trapezoidal section. It is again assumed that the resultant load on the hook passes through the center of curvature of the curved part and that the critical section is at 90 deg to the resultant load.

Referring to Fig. 3, the full lines represent the actual hook section and the dashed lines the equivalent trapezoidal section. The equivalent section is so chosen that the shaded area A_1 is equal to the areas $A_2 + A_3$. Likewise $A_1' = A_2' + A_3'$. Referring to Fig. 3 let

b_i, b_0 = inside and outside widths of equivalent trapezoid, respectively

r_i, r_0 = inside and outside radii of equivalent trapezoid, respectively

$\alpha = b_0/b_i$; $\beta = r_0/r_i$

With these notations, the formulas for bending stress S_b at point A, Fig. 4, at the inside of the trapezoidal section as derived from curved-bar theory become[6]

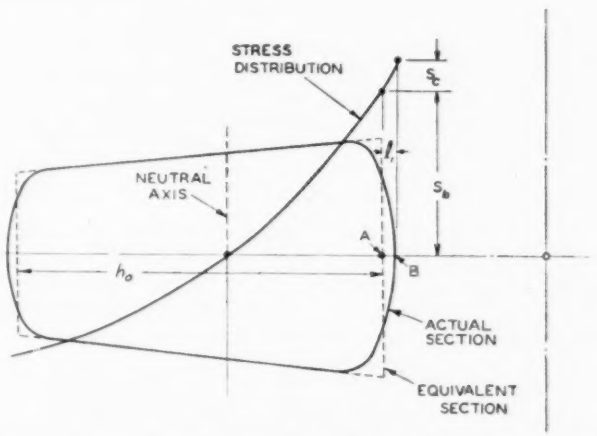

FIG. 4 STRESS DISTRIBUTION OVER CROSS SECTION OF CRANE HOOK

$$S_b = \frac{2PK_1\left(K_2 - \dfrac{1}{\beta - 1}\right)}{b_i r_i (1 + \alpha)(K_1 - K_2)} \quad [4]$$

where

$$K_1 = \frac{1}{\beta - 1} + \frac{2\alpha + 1}{3(\alpha + 1)} \quad [5]$$

$$K_2 = \frac{\dfrac{1}{2}(1 + \alpha)}{\dfrac{(\beta - \alpha)}{(\beta - 1)}\log_e \beta - (1 - \alpha)} \quad [6]$$

In general the factors K_1 and K_2 should be calculated to four significant figures. To do this the use of log tables or a computing machine is advisable.

In Fig. 4 the distribution of stress over the section due to bending alone is indicated. It should be noted that the stress S_b calculated from Equation [4] yields the bending stress at point A at the inside of the equivalent trapezoid. Because of greater distance from the neutral axis the bending stress at B in the actual hook will be appreciably larger than that at point A by an amount S_e as shown. If l_1 is the distance between points B and A then the stress augment S_e will be given approximately by

$$S_e = l_1\left(\frac{dS}{dy}\right)_0 \quad [7]$$

where $(dS/dy)_0$ is the value (at point A, Fig. 4) of the derivative of the stress S with respect to distance y from the neutral axis. From the equations of curved-bar theory, the derivative $(dS/dy)_0$ may be obtained, and by substitution in Equation [7], using the previous notations, the stress augment S_e becomes

[5] Reference (1) page 75.

[6] See reference (1), page 68, for method of derivation.

$$S_e = \frac{S_b K_2 l_1}{r_i[K_2 - 1/(\beta - 1)]} \quad [8]$$

where K_2 is given by Equation [6].

The stress due to direct tension is

$$S_t = \frac{P}{A} \quad [9]$$

where A is the area of the cross section.

$$A = \frac{h_0(b_0 + b_i)}{2} \quad [10]$$

where h_0 = depth of equivalent trapezoid, Fig. 3.

The maximum stress S_{max} in the hook at the critical section will be the sum of the bending stress S_b Equation [4], the stress augment S_e, Equation [8], and the direct tension stress S_t Equation [9]. This gives

$$S_{max} = S_b + S_e + S_t \quad [11]$$

(*b*) *Numerical Example.* These equations have been applied to the hook section having a depth of 8 inches and a maximum width of 5 inches, and the approximate shape shown in Fig. 3. By choosing the area $A_1 = A_2 + A_3$ and $A_1' = A_2' + A_3'$ the following values for the equivalent trapezoid were obtained

$$b_i = 5.1,\ b_0 = 3.9,\ r_i = 4.5,\ r_0 = 12.07,\ l_1 = 0.25 \text{ in.}$$

$$\alpha = b_0/b_i = 0.765,\ \beta = r_0/r_i = 2.68,\ A = 34 \text{ sq in.}$$

Using these values in Equations [5] and [6]

$$K_1 = 1.073$$
$$K_2 = 0.9930$$
$$K_1 - K_2 = 0.080$$

Taking the load P equal to 50,000 lb and using these values in Equations [4], [8], and [9], we find

$$S_b = 13{,}200 \text{ psi};\ S_e = 1830 \text{ psi};\ S_t = 1470 \text{ psi}$$

Adding these the maximum stress becomes

$$S_{max} = 16{,}500 \text{ psi}$$

Computation on this section using the numerical integration method of Part 1 showed a stress value of 16,200 psi which is quite close to the figure obtained by the analytical method.

Similar calculations on a hook section of 9½ in. depth and 6 in. maximum width with the same inside radius showed a figure of 11,000 psi for the analytical method and 10,900 psi for the numerical integration method. This would seem to indicate that the former is sufficiently accurate for most purposes for sections approximating the shape shown in Fig. 3.

Conclusions

The results of calculations on actual crane-hook sections, indicate that for sections such as shown in Fig. 4, which do not deviate too much from a trapezoidal form, the relatively rapid analytical method of Part 2 is sufficiently accurate for practical use.

For irregular sections or for an independent check on the results obtained by the analytical method of Part 2, the numerical integration method of Part 1 has also been found useful.

Discussion

Tension Tests at Constant True Strain Rates[1]

LAWFORD H. FRY.[2] The authors discuss the effect of temperature and strain velocity on the stress-strain properties of various materials. In describing testing methods, the authors say, "The value of the true strain rate was controlled by adjusting the head motion of the testing machine." This reads as though the assumption were made that the travel of the crosshead of the testing machine is the same as the strain of the specimen. This is certainly not the case.

The writer has shown:[3] "Only a small fraction of the crosshead travel appears as strain in the specimen. The proportion of strain to crosshead travel varies during a test as the load is increased, but is unaffected by the rate of crosshead travel." Methods are given in the paper[3] just quoted for comparing the travel of the crosshead with the rate of strain. It would be interesting to have information as to this relationship in the case of the machine used by the authors and the various specimens tested.

Incidentally as a minor point, attention is called to the authors' statement, "The standard 0.505-in-diam tension specimen was employed throughout the testing program." Presumably the authors refer to the standard 2-in-gage-length specimen of the American Society for Testing Materials. Reference to A.S.T.M. Specification E 8-42, Fig. 3, will show that the diameter of the 2-in. specimen is $^1/_2$ in. plus or minus 0.01 in.

S. TIMOSHENKO.[4] The writer would like to bring to the attention of American engineers some recent investigations made in Russia by N. N. Davidenkov. This investigation deals with calculation of true stresses and true strains at the minimum diameter of tension test bars of Armco iron stretched to various degrees of reduction of the cross-sectional area. Eight 1-in-diam bars were stretched up to reduction of area from 41 per cent to 69.2 per cent, after which they were cut at the minimum diameter. The minimum cross sections were polished and microscopically investigated. Numerous measurements of average changes of dimensions of grains showed that radial and tangential strains ϵ_r and ϵ_t are equal and are constant over the entire cross section. Their values obtained from these measurements were in very good agreement with the average values obtained from measurements of the minimum diameter of the test pieces. This indicates that the strains calculated from the measurements of the reduction of area represent true strains.

To obtain the true stress distribution, Davidenkov makes the usually accepted assumption

$$\frac{\sigma_l - \sigma_t}{\epsilon_l - \epsilon_t} = \frac{\sigma_l - \sigma_r}{\epsilon_l - \epsilon_r} \qquad [1]$$

from which he concludes that for $\epsilon_l = \epsilon_r$ we must also have $\sigma_r = \sigma_t$. To calculate these stresses and also the stresses σ_l in the axial direction, the curvature $1/R$ of the longitudinal fibers of the stretched bars at the surface was measured and it was assumed that for any inside fiber at the distance x from the axis of the bar the curvature is

$$\frac{1}{\rho} = \frac{1}{R}\frac{x}{a} \qquad [2]$$

where a is the minimum radius of the stretched bar. This expression for curvature was substituted into the equation of equilibrium of an infinitesimal element and in this way was obtained

$$d\sigma_r = \frac{1}{\rho}(\sigma_l - \sigma_r)\,dx = \frac{x}{Ra}(\sigma_l - \sigma_r)\,dx$$

By integration, we find

$$\sigma_r = (\sigma_l - \sigma_r)\frac{a^2 - x^2}{2Ra} \qquad [3]$$

It is seen that the radial stress σ_r increases as we proceed from the surface of the specimen to its axis. It vanishes at the surface and becomes a maximum at the axis.

From Equation [1] of this discussion we conclude that for $\epsilon_r = \epsilon_t$ the difference $\sigma_l - \sigma_r$ must be constant for the entire cross section. Denoting that constant value by σ_0, we obtain

$$\sigma_l = \sigma_0 + \sigma_r \qquad [4]$$

The summation of stresses σ_l must give us the tensile force S stretching the bar. Hence, using Equations [3], and [4], we find

$$\int_A \sigma_l\,dA = \sigma_0 \int_0^a \left(1 + \frac{a^2 - x^2}{2Ra}\right) 2\pi x\,dx$$

$$= \sigma_0 \pi a^2 \left(1 + \frac{a}{4R}\right) = S$$

$$\sigma_\theta = (\sigma_l)_{\min} = \frac{S}{\pi a^2\left(1 + \frac{a}{4R}\right)} \qquad [5]$$

$$(\sigma_l)_{\max} = \sigma_0\left(1 + \frac{a}{2R}\right) \qquad [6]$$

It is seen that the longitudinal stress is not uniformly distributed over the minimum cross section of the stretched bar and that its maximum value at the axis of the bar depends upon the magnitude of the ratio $a/2R$.

This represents the principal result of Davidenkov's work. We see that the simple tensile test brings us to a complicated stress distribution at the reduced cross section. Thus it seems desirable, in studying the effect of speed on the stress-strain relation, to use the experiments in which stress distribution is not affected by plastic deformation. Such conditions can be approached in torsion of tubular specimens. Several experiments of this kind with tubes of lead were made some time ago by James Jamieson at the University of Michigan.

Authors' Closure

The question of the control of the strain rates was brought up by Mr. Fry.

No assumption was either made or used in our experiments to the effect that the travel of the crosshead of the testing machine is the same as the strain of the specimen as mentioned by Mr. Fry. In fact the paper emphasizes that one of the reasons for developing the true-strain-rate approach was just to avoid such an inequality between rate of head motion and the rate of straining of the specimen. Mr. Fry is referred to the first paragraph under the heading "Testing Procedure" which brings this out clearly. The last sentence of this paragraph states "If the rate of head motion is constant it is not true that the strain rate is also constant."

In the authors' tests, the *true strain rate of the specimen* was maintained *constant* by *varying* the rate of head motion of the testing machine throughout each test so that the proper minimum diameter was attained at the appropriate time. Since the true strain $\epsilon = 2 \log_e \frac{d_0}{d}$, the absolute value of the true strain rate is

$$\dot{\epsilon} = 2 \frac{\dot{d}}{d} \qquad [1]$$

where $\dot{\epsilon}$, d, and $\dot{d}$ are the true strain rate, the instantaneous diameter, and the time rate of change of the instantaneous diameter, respectively. To maintain a constant true strain rate it is only necessary then to force the diameter of the specimen to follow a certain predetermined schedule of values with respect to time by varying the rate of head motion of the testing machine through adjustments of the control valve. Hence it is the true strain rate of the specimen which is maintained constant and *not* the rate of head motion.

In addition to the difference between the rate of head motion and the strain rate of the specimen to which Mr. Fry refers, it is also true that due to the increase in gage length of a specimen under tension, the true strain rate is not obtained by dividing the change in gage length per unit of time by the original gage length. While this procedure does not make any appreciable error at the yield point, the error increases with the amount of strain. In Fig. 2 of Mr. Fry's paper,[5] for example, the effect of strain rate on the tensile strength is shown. Unless a correction was made for increase of gage length these values do not represent true strain rates.

Likewise, during necking, even if a correction is made for increased gage length which originally was, say, 2.0 in., the definition of strain rate customarily used has little physical significance due to the great variation in strain rate along the test bar. These various disadvantages are overcome through the use of the true-strain-rate definition employed in the paper and given by Equation [1] of this closure.

Professor Timoshenko has very kindly called the authors' attention to a recent interesting paper by N. N. Davidenkov and N. I. Spiridonova in which a discussion is given of the true stress and true strain conditions in a necked tension specimen. Previous contributions on this same subject have been made by E. Siebel[6] and P. W. Bridgman.[7] The Davidenkov formula is the same as the one given earlier by Siebel.

The formula developed in the paper referred to by Professor Timoshenko is based in part on the assumed validity of Equation [1] of his discussion, namely, the equality of the stress difference and strain difference ratios. Davidenkov points out that this has not yet been proved experimentally as fully accurate, but that it is used as a first approximation.

Davidenkov attempts to prove experimentally that the axial strain is constant across the necked specimen by measuring grain sizes after the specimen has necked down. The scatter of his observations and the absence of control measurements on undeformed specimens reduces the significance of his results.

Tests conducted by the authors two years ago on large 2-in-diam. round steel specimens showed that at the minimum section the average true axial strain $\epsilon = \log_e \frac{A_0}{A}$ determined from diameter measurements was substantially greater than the true axial strain at the surface of the specimen $\epsilon_s = \log_e \frac{l}{l_0}$ as determined by the separation of closely spaced scribed circumferential lines at the minimum section. The possible effect of the curvature of the surfaces at the neck was investigated, and found to be negligible for scribed lines spaced as closely as in these tests. For two such tests carried to strains of about 0.6 to 0.65 the value of $\epsilon = \log_e \frac{A_0}{A}$ was in fact greater than the value of $\epsilon_s = \log_e \left(\frac{l}{l_0}\right)_{\text{at surface}}$ by 8 per cent in the first test and 10 per cent in the second at the minimum section. The second test was carried to a slightly greater true strain than the first. This variation is difficult to reconcile with a constant axial strain value across the minimum section.

Since there is some question as to the validity of the assumptions used by Davidenkov and Spiridonova in their analysis, as well as some question as to the validity of their experimental results as indicated in particular by the existence of experimental contradiction to their observations, the authors have felt that any "correction" of the average true stress would not be justified at this time, as the determination of the correction factor depends on uncertain and controversial premises. Further, if a "correction" of the average true stress is made, then the results of the authors' tests on round bars indicate that a similar correction of the average true strain should be made. Until the question of the strain and stress distribution in the neck of a tension specimen is more satisfactorily determined and conflicting observations have been reconciled, the authors prefer to deal directly with the average true stress (P/A at the minimum section) and the average true strain ($\epsilon = \log_e \frac{A_0}{A}$ at the minimum section).

Professor Timoshenko mentions the use of hollow torsion bars as a more suitable form of test. Our experience has been that if sufficiently thin-walled torsion-test specimens are used to provide a uniform state of stress, considerable difficulty is encountered due to plastic buckling. If the uniform gage length is made small to overcome this, the effect of an unknown restraint is introduced. On the other hand, if the wall is thick enough to prevent buckling, an appreciable error is introduced in the calculation of the stress. The use of solid torsion bars is thus preferable for these reasons and also because of the greater amount of machining necessary for hollow specimens.

The authors would like to take this opportunity to thank Mr. Fry and Professor Timoshenko, and also those who contributed oral discussion to this paper, for bringing to their attention several problems of interest in connection with the constant-true-strain-rate tension test.

The Axial Vibration of Turbine Disks[1]

E. L. Robinson.[2] This paper emphasizes the importance of knowing the natural frequencies of axial vibration of turbine disk wheels and presents a method for calculating these frequencies. The author has followed the formulation of energies given by Stodola[3] but has worked out and tabulated coefficients applicable to a somewhat different type of deflection curve. It would be interesting to check through the mathematics from the beginning, but this would divert discussion from matters of more consequence. Suffice it to say that it is advantageous to perform the circular integration around a complete circumference rather than over one half the angular distance between nodal radii as done by Stodola. This detail, however, does not affect the validity of the result.

It is unfortunate that the wheels whose frequencies are of least importance are the ones whose frequencies are most easily computed. On the other hand, the exhaust-stage wheels, having long buckets and the lowest frequencies, are the ones whose frequencies it is most important to know and, at the same time, the ones for which it is most difficult to make a reliable calculation.

For more than 20 years the writer's company has made it a point to determine the critical frequencies of such wheels by actual test, using the methods described by Campbell.[4] Throughout this period it has been the opinion of the writer that it was possible by calculation to predict the frequencies of a wheel with sufficient accuracy to assure that it could be tuned satisfactorily for use, and thus preclude any possibility of having to scrap a wheel after its manufacture had been completed. On the other hand, when it is necessary to work to reasonably close margins from resonance, it has never appeared proper to dispense with the test determination of the actual frequencies. There are certain rather fundamental reasons why this is so.

With wheels having short buckets some one of the "high-node" types of vibration will occur in proximity to running speed, and such wheels must be sufficiently rugged to withstand the vicissitudes of service even if operating on a high-node resonance. The margins between one resonance and another are too small to assure avoidance.

With such wheels the potential energy of bending is very largely in the wheel and but little in the buckets. Even though a considerable fraction of the kinetic energy of vibration is in the buckets, this may be estimated with reasonable accuracy.

On the other hand, with long exhaust-stage buckets it is often the case that almost all of the energy of bending as well as practically all of the kinetic energy of vibration is in the buckets. In this case what goes on in the web of the wheel is of minor consequence, but what goes on in the attachment of the buckets to the rotor, whether a wheel or a drum, is of controlling importance. It is necessary to consider whether the attachment is such as to bend the rim of the wheel or the outermost continous ring of material in the rotor both in the radial and tangential directions or only in a tangential direction. There may be a very sharp curvature in the radial direction, but much of this may be provided by hinging so that it may or may not result in bending the outer ring of the disk or rotor in a radial direction. How to represent this portion of the structure in any scheme of calculation is almost certain to be vital with long buckets. When the true frequency has been determined by test it is always possible to sketch in an equivalent rim or to say what proportion of a heavy wheel or drum participates in bending. However, the real problem is not to explain in a satisfactory manner what has been found by test but to determine it without a test.

The shape of deflection curve is most important, but the writer has never found it possible to use a standard curve for more than a limited type of wheel design. Admitting that the assumed deflection curve may differ from the true curve and still yield a reasonably good answer, it must also be admitted that if the curve is not of a reasonably correct shape, the resulting calculated frequency can be so much off as to be of no value.

When confronted with the double set of uncertainties as to how to describe a rim or ring of attachment while at the same time having to choose a reasonable deflection curve, either choice having a wide and important effect on the answer, it becomes almost impossible to proceed without reference to the analyses of the behavior of many similar designs whose frequencies have been determined by test.

The writer realizes that this is not a very comforting situation. Without wishing to appear unappreciative of an excellent attack upon the problem of the frequencies of a wheel with short buckets, it does seem necessary to point out some of the very real limitations when the problem involves long buckets.

W. E. Trumpler, Jr.[5] In assuming a simplified analytical form for the vibratory deflection curve of a radial element, it is evident that the effect of complications such as a heavy rim and blades attached to it, cannot be adequately accounted for. The author has provided certain empirical correction factors to take care of a range of these effects. However, it is possible in the range of practical design, that the rim and the blades become the controlling influence on the disk frequency.

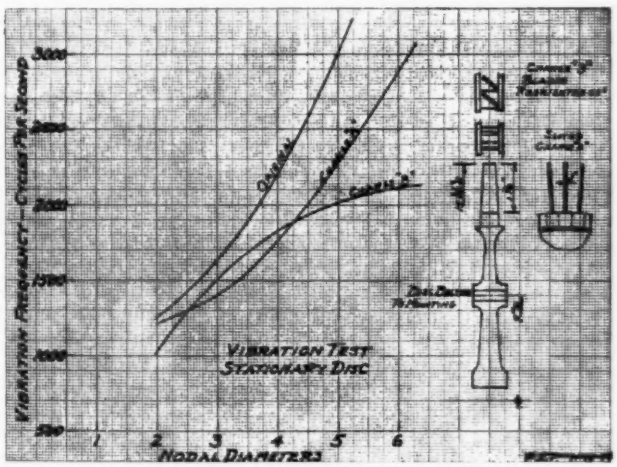

Fig. 1 Vibration Test Results Showing Effect of Several Changes in Rim and Blades

To demonstrate that this possibility exists, reference is made to some recent tests run in the laboratory of the Westinghouse Steam Division at South Philadelphia. Fig. 1 of this discussion shows the data for the small disk as drawn approximately to scale. Although this disk is mounted by bolting rather than a shrink or

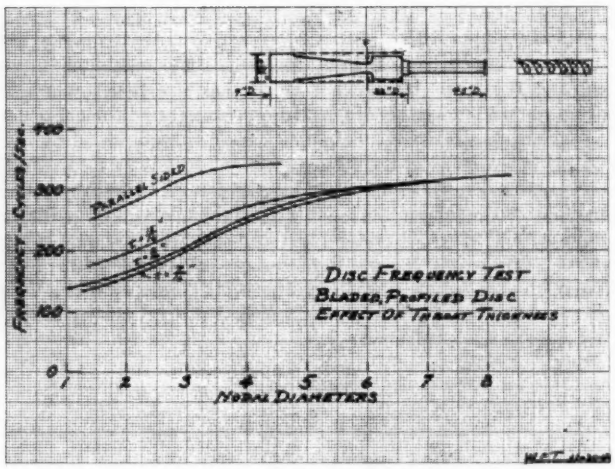

FIG. 2 RESULTS OF STATIONARY TEST ON DISK WITH VARIOUS PROFILES

drive fit at the bore, it acts in the common modes of vibration just like any other disk, assuming the hub at the bolt circle. In the original test the simulated blades were machined from the solid rotor. In the second test, indicated as change "A," slots were cut between blades through part of the rim. In the last one, marked change "B," the blades were sawed off and soldered back at an orientation of 45 deg. Here is a demonstration of the important effect which several apparently minor changes have on the frequency. The mass was not substantially affected. In the case of the reoriented blades, the curve seems to become asymptotic to a line which is approximately equal to the lowest mode blade frequency, that about its minimum axis. A high-frequency low-mass magnetic vibrator was used to excite these vibrations.

The results of another series of tests on a disk are shown in Fig. 2. These blades are shrouded in small groups. Having run the first test with the unprofiled wheel, it was possible then to recut the disk with profiles of successively smaller neck thickness. Here it is seen that all the frequency curves approach the same line, which again is found to be the lowest mode blade-group frequency.

These tests indicate that in the system of wheel, rim, and blades, all three elements have importance of the same order over a wide range of practical interest. Of course there are some situations where only the blade frequency is of interest, and some where the blades are so small that only disk vibration is involved (with corrections), but there is an important range where a satisfactory analysis cannot ignore a combined consideration. This has been pointed out previously by I. Malkin.[6]

The restrictions imposed by the Rayleigh-Ritz method are such that in order to take into account adequately the effect of blades and rim, we have resorted to a different approach which has given highly satisfactory results at least for those systems for which we have experimental data.

It would be of considerable interest and help to those applying his method if the author would report the correlation of calculated and test frequencies so that limits for rim and blade proportions may be indicated for satisfactory results.

AUTHOR'S CLOSURE

Mr. E. L. Robinson's contributions to the field of mechanical problems in turbine design and particularly to the subject of disk vibration have been so considerable that it is a source of great satisfaction to the author to have his comments on the subject paper. All his points are well taken, and while some of them were touched upon in the paper, they should perhaps have been given more emphasis. The method described is simply of no value for wheels having extremely long blades. In the paper it was suggested that a blade length equal to 40 per cent of the radius of the disk proper be adopted as an upper limit. Excellent results have been obtained with blades close to this length.

To be sure, Mr. Robinson's point that the longer blades are precisely those which it is important to know accurately is perfectly valid. Nevertheless, the author feels that it is of real value to the designer to have a relatively simple and quick method for making sure of wheels with short blades which, as pointed out in the paper, do constitute the large majority of all turbine wheels.

More emphasis might well have been given to testing, though this has been well treated in the literature, as will be seen by reference to the papers listed in the bibliography given by the author. No program of vibration calculation should be contemplated which is not closely tied in with experimental checks. The method presented would not have been developed if previously described methods had not failed to check closely with experimental observations.

Mr. Trumpler's discussion presents some interesting information and, like Mr. Robinson's, emphasizes the importance of the blades. The difference in frequency caused by reorienting the blades is large, and indicates that in practice if a blade design radically different from the conventional were to be tried, too much faith should not be placed in calculations. This would, however, be an unusual situation. Furthermore, it applies only to relatively long blades. One thought which it gives rise to is that blade length alone is not the determining criterion, since a disk whose hub diameter is a large percentage of its rim diameter, such as that indicated in Fig. 1 of the discussion, would naturally be more susceptible to changes in blade shape than one supported nearer the center.

Unfortunately, the author has no clear information on the range in which blades and disk both have a major effect on the frequency, and can only repeat that the method is not to be used there. With blades having a length of nearly 40 per cent of the radius, calculations have come consistently within 5 per cent of the test values and this is considered satisfactory.

The author wishes to express his appreciation to Messrs. Robinson and Trumpler for valuable and interesting discussions.

Distribution of Tooth Load Along a Pinion[1]

D. W. DUDLEY.[2] The authors of this paper have obtained a precise mathematical solution to one of the gear-designer's most complicated problems. Considering the complexity of the results, it is not surprising that approximate and rule-of-thumb methods have been used in the past to govern the relation of pinion face width to pinion diameter.

In spite of the complexity of the direct mathematical solution of the load-distribution problem, the solution obtained may be checked by simple deflection formulas. It is only necessary to take the distribution of load curve, w_f versus l, and replace this loading by a series of concentrated loads spaced at regular intervals; these concentrated loads having individual amounts proportional to the w_f value for each of their locations, and a total

[6] "On a Generalization of Kirchhoff's Theory of Transversal Plate Vibrations in the Vibration Problem of Steam Turbine Disks," by I. Malkin, *Journal of The Franklin Institute*, vol. 234, Oct., 1942, pp. 355–370; and vol. 234, Nov., 1942, pp. 431–452.

[2] Gear Engineering Division, General Electric Company, River Works, Lynn, Mass.

value equal to the total applied load. By superpositioning the deflections of these concentrated loads, total deflections can be obtained. If a sufficiently large number of concentrated loads are used, the total deflections obtained by this method should closely check with those obtained by the equations in the paper. The writer has used this method to check numerical answers to the illustrative problems given.

The solution of the distribution-of-load problem can probably be best put into a proper perspective by considering it as step 2 of a problem of 3 steps. Step 1 is the determination of the various stiffness constants. This in itself is no small problem, since the geometry of the gear teeth and the pinion cross section tend to place them in a boundary region where the usual textbook formulas for bending, torsion, and shear do not apply exactly. The bending of a helical gear tooth is particularly difficult, since such a tooth in different transverse sections is loaded simultaneously from the base to the tip. Formulas for the stiffness constants can best be obtained by making a careful study of the pinion-and-gear geometry and then "calibrating" tentative formulas by actual laboratory check.

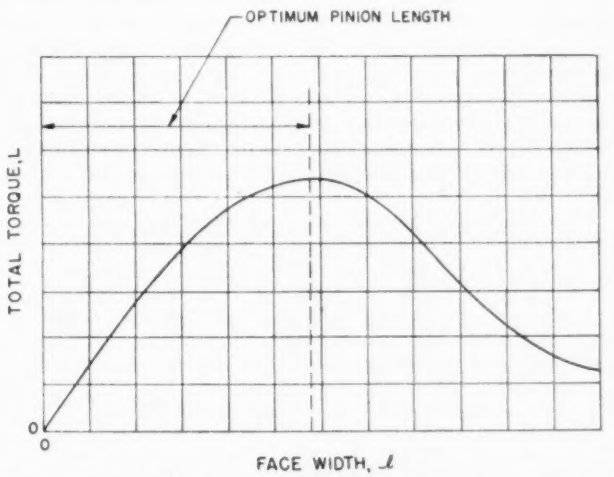

FIG. 1 TORQUE CAPACITY OF A PINION WHEN CONTACT PRESSURE IS HELD CONSTANT

The second part of the general problem is, of course, the solution for the load distribution using the given stiffness constants. The third part of the problem is the actual application of the results to solve a design problem. Here it is necessary to consider the expected range of cutting inaccuracies, the effect of lubrication, the effect of dynamic load, possible corrective wear, and changes in alignment which can be made in the casing. From a consideration of all these, the designer should be able to decide what constitutes the optimum design.

A few words should be said to define the optimum design from the standpoint of load distribution since neither in this paper nor in the parallel paper by Lewis[3] was there a clear statement of the ultimate objective in load-distribution studies. A designer limited by a certain maximum intensity of contact pressure and given a pinion of certain diameter, a certain size and shape of pinion teeth, and a certain specified pinion cross section must decide what face width will carry the maximum torque. Fig. 1 of this discussion shows schematically how the torque carrying capacity of a pinion might be plotted as a function of its face width. Locating the high point of this torque curve is of course the final solution to the load-distribution problem.

[3] "Load Distribution of Reduction Gears," by F. M. Lewis, published in the June, 1945, issue of the JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 67, 1945, p. A-87.

In summary, the writer feels that the paper presented by Messrs. Poritsky, Sutton, and Pernick, while not a complete work in itself on the subject of gear deflection, is still a big step forward in the direction of more scientific handling of the deflection problem.

ALEXANDER HAMMER.[4] The mathematical solution of such a complex problem on load distribution along the pinion, as presented itself after the authors took so many deciding factors into consideration, is clear and comprehensive to the gear designer. The authors emphasize that the examples chosen do not correspond to actual design practice but were selected for the purpose of bringing out, in an exaggerated manner, the effect of some of the factors involved. But if the method is applied to problems which do correspond to actual and good design practice, the difference in the results when the actual load distribution is taken into consideration, or when uniformly distributed load is assumed, is not so pronounced.

Messrs. C. R. Waller and A. Peterson,[5] of the writer's company, assuming uniformly distributed load along the pinion, established load-carrying capacities based on certain designing factors, which in turn did not allow an increase in the sum of torsional and lateral deflection above 0.001 in. These factors have guided our design for many years. More recently, we have conducted an elaborate investigation in which helix angle, pressure angle in plane of rotation, contact ratios in the axial and radial planes, i.e., the number of teeth in contact in the same planes, the total length of contact and especially tip relief, were taken into consideration. Although we increased our load-carrying capacities, we did not exceed the allowable 0.001 in. for the total, i.e., the sum of torsional and lateral deflection.

It is noted that the load-concentration curve established for a double-helical pinion, which the authors selected as a practical example, shows a maximum load-concentration factor at the torque end of the pinion as high as 1.9, but elimination of the negative portion of the load will lead to a decrease of this value. Making the tooth more flexible, using tip relief, we reduce the stiffness, causing considerable reduction in the maximum load-concentration factor.

Taking the effect of the oil film between mating teeth into consideration, we have been able, by using E. K. Gatcombe's method,[6] to determine the minimum thickness and the width of the oil wedge which separates the tooth surfaces. It was found that the width of the supporting wedge was considerably larger than the Hertz contact area and after determining the supporting effect of this wedge along the line of contact for the different mating phases, it was safe to assume that the oil film will induce a more evenly distributed load concentration.

The increased load carrying capacities applied to unchanged transmitted horsepower do indicate an allowable decrease in the width of face of pinion, which in turn leads to a considerable reduction in the maximum value of the load-concentration factor. In one of the examples given by the authors, a 25 per cent reduction in the face width produces a 31.5 per cent reduction in the maximum value of w_f.

There are many other factors, mostly taken into consideration by the authors, which have a tendency to equalize the load distribution along the face width of the pinion. Of course, one knows that a very small misalignment gap may affect the load

[4] Research Engineer, De Laval Steam Turbine Company, Trenton, N. J.

[5] "Reduction Gears," by C. R. Waller and A. Peterson, chapt. 8 in *Marine Engineering*, vol. 1, edited by H. L. Seward, published by The Society of Naval Architects and Marine Engineers, New York, N. Y., 1942.

[6] "Lubrication Characteristics of Involute Spur Gears," by E. K. Gatcombe, Trans. A.S.M.E., vol 67, 1945, pp. 177–188.

distribution profoundly, but on the other hand, with tooth relief we could achieve absolutely uniform load distribution for a particular applied torque. The authors state that this relief did not exceed 0.00019 in. for the example considered, but for practical consideration such small differences could be expected to be relieved by the wear on the teeth under high load.

Practical experience gained from actual performance and measurements taken in our gear department verify the deflection results which were calculated, assuming uniform load distribution along the face of the pinion, and taking the previously mentioned corrective factors into consideration. But for special gear-reduction problems where the designing factors are predetermined to such an extent that one cannot keep the ratio of face width to pitch diameter under 2.5, the method given by the authors will find a most welcome application.

Authors' Closure

The authors are grateful to Messrs. D. W. Dudley and Alexander Hammer for their interesting discussions of the paper and have read with interest F. M. Lewis's paper.[3] It is quite true as Mr. Dudley points out, that the calculation of the stiffness constants is the first step the gear designer is faced with in solving the problem of distribution of load. Except in section 3, very little was said about this step, since—due to space limitation—the attempt was made to concentrate on the effect of these constants, after they had been determined, upon the load distribution. While approximate methods of calculating these constants are known,[7] it is clear that their precise evaluation is not a simple matter and involves complex analysis, good engineering judgment, as well as measurements, to substantiate the approximate theoretical formulas which can be worked out.

It is of interest to point out that the Hertz compressibility effect near the contact region yields a compression which is not linear with the load thus resulting in a variable and a nonlinear substitute for Equation [11] or [13]. Furthermore, owing to the variable curvatures and the variable bending stiffness, there is a slight variation in tooth deflection as contact proceeds from the pitch line in either direction; this effect and the variation of the number of teeth in the arc of action lead to a variation in stiffness constant as contact moves along a tooth, and may produce a pulsation of half tooth frequency.

[7] "The Strength of Gear Teeth," by S. Timoshenko and R. V. Baud, *Mechanical Engineering*, vol. 48, 1926, p. 1108.

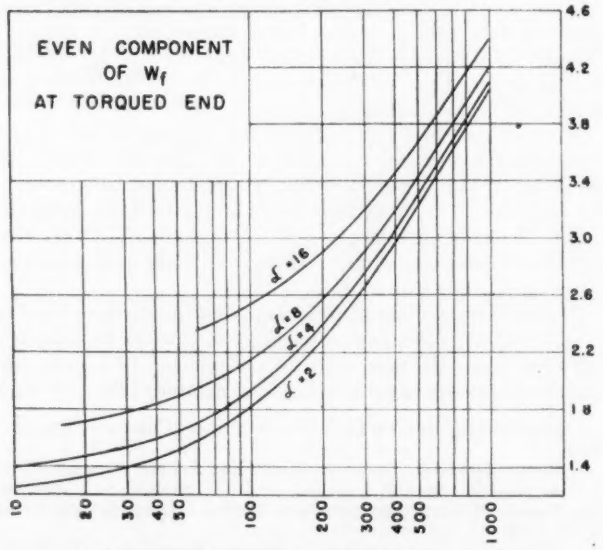

Fig. 2 Even Component of w_f at Torqued End

The effect of the oil film in increasing the equivalent tooth flexibility reported by Mr. Hammer is interesting and is worth reporting in the literature.

The successive-approximation method described by Mr. Lewis in his paper is a welcome alternative to the analytical method of the authors' paper. For almost any problem, it is well to have several alternative ways of solution and be able to choose the proper one for the particular occasion. As a matter of fact, the authors, too, had tried a graphical successive approximation method on the rather flexible pinion of Example 1, but after carrying out several steps and finding no signs of convergence, gave up the attempt, being pressed for time.

In defense of the analytical method the authors wish to state that it is not really as complex as might appear at first sight. The "complex" appearance of the solution ("complex" in the sense of complex numbers) can, of course, be completely eliminated by adding conjugate imaginary terms. By breaking the solution into an even component and odd one, it was possible to minimize the algebraic work involved in the determination of the constants; in examining the effect of misalignment, it then turned out that only the odd solution was changed while the even one remained unchanged. Thus a physical meaning was obtained for the simplification which first was suggested by analytical expediency.

By further algebraic reduction, the effect of the two pertinent design constants α and β on the stress factor in the middle of the pinion and at its end was computed for the even component of the load. For these calculations the authors are indebted to

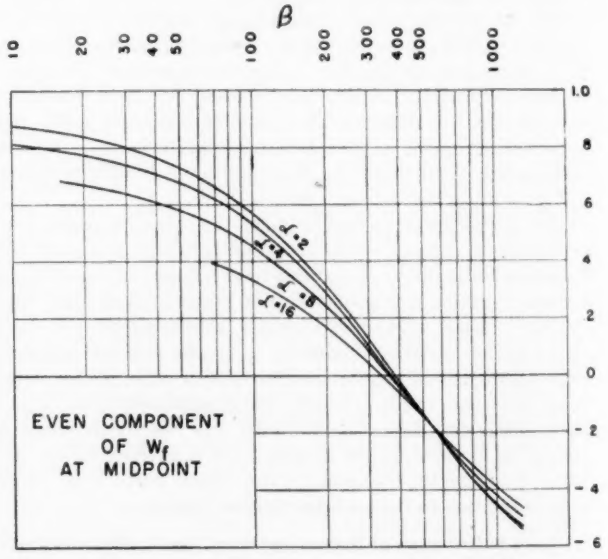

Fig. 3 Even Component of w_f at Mid-Point

W. B. Jordan. Tables 1 and 2 and Figs. 2 and 3 show the resulting values of w_f as a function of β for various α's. A glance at these curves will show whether any proposed design, that is, any value of α and β, will lead to a very flexible pinion or not. Clearly high flexibility relative to the tooth stiffness is obtained when the maximum stress-concentration factor in Fig. 2, departs appreciably from unity, while in Fig. 3 there is a tendency for low or even negative value of w_f at the middle.

Quite a few years ago there was evidence of difficulty at the ends of a pinion of rather extreme proportions. This difficulty was remedied by a change of design which served to increase the diameter slightly and alter the tooth form. Recent review of the case in accordance with the methods set forth in the paper reveals that the design change resulted in a decrease in β from 438 to 257 and α from 9.8 to 7.0. The concentration factor at the torqued end was thus reduced from 3.3 to 2.7 and at the middle the change was from —0.08 to +0.15.

The ratio of length to diameter is often used as a measure of pinion flexibility and for the case just cited, the change in this ratio was from 3.74 to 3.38. That this ratio is not the complete criterion for determining allowable pinion flexibility can be inferred from a consideration of a third pinion having a ratio of 3.9. This pinion has operated satisfactorily for the past decade; however, in this case, the tooth stiffness is greatly reduced so that the values of α and β are 7.36 and 359. Comparison of the first and third pinions on the basis of amount of wear relief to uniformize the load indicates that a maximum of 0.0008 in. would be required in the latter as against 0.003 in. in the former.

The Effect of Transverse Shear Deformation on the Bending of Elastic Plates[1]

L. H. Donnell.[2] It may be of interest in connection with this excellent paper to present another method of considering transverse shear strains in plates, which the writer developed at Chance Vought Aircraft to solve certain problems involving sandwich-type plates. The method seems to approach the problem from a somewhat different and perhaps simpler viewpoint than the author's, but the solution is doubtless much more approximate than his.

It will be helpful to review first the case of shear deformation

Fig. 1

in rectangular beams.[3] The lateral deflection due to shear, designated by w_s, can be considered to be superposed on the usual deflection due to bending, which will be designated by w_b. The bending moment per unit width of section is, Fig. 1

$$m \approx -\frac{Eh^3}{12}\frac{d^2w_b}{dx^2} \quad \ldots\ldots [1]$$

and the transverse shear force per unit width of section is

$$f_s = \frac{dm}{dx} \approx -\frac{Eh^3}{12}\frac{d^3w_b}{dx^3} \quad \ldots\ldots [2]$$

The additional slope of the deflection curve due to transverse shear is, for the symmetrical case

$$\frac{dw_s}{dx} = \frac{n f_s}{h G} \approx -\frac{n(1+\mu)h^2}{6}\frac{d^3w_b}{dx^3} \quad \ldots\ldots [3]$$

where n is a numerical factor having a value between 1.5 (which it would have if there were no restraint against warping of cross sections) and 1.0 (if there were complete restraint against warping of all cross sections.) Actually there is always some restraint against warping due to symmetry or end fixity, and a value of $n = 1.2$ can be used for most practical cases.

$$w_s = -\frac{1}{2}\beta a^2\frac{d^2w_b}{dx^2} + C \quad \ldots\ldots [4]$$

where a is the length of the beam, C is an integration constant which can be determined from the condition that $w_s = 0$ at reactions, and

$$\beta = \frac{n(1+\mu)}{3}\left(\frac{h}{a}\right)^2 \quad \ldots\ldots [5]$$

For the general case another constant C' should be added to the right-hand side of Equation [3]. $C'x$ to the right-hand side of Equation [4], and C and C' determined from the two end conditions for w_s.

As an example of the application of the fundamental Equation [4] consider the case of a beam supported at the ends and with a uniformly distributed load q per unit length. From elementary beam theory the deflection due to bending is

$$w_b = \frac{q}{24\,EI}(a^3x - 2ax^3 + x^4) \quad \ldots\ldots [6]$$

Using Equation [4] and the end condition $x = 0 : w_s = 0$ to determine C, we find

$$w_s = \frac{\beta q a^2}{4\,EI}(ax - x^2)$$

The maximum deflection is therefore increased by the factor

$$\left[1 + \left(\frac{w_s}{w_b}\right)_{x=\frac{a}{2}}\right] = (1 + 4.8\,\beta) \quad \ldots\ldots [7]$$

Similarly, the factor for increase of the maximum deflection due to shear is found to be $(1 + 24\,\beta)$ for the case of a uniform load and fixed ends. For the case of a concentrated load in the middle, this factor is found to be $(1 + 6\,\beta)$ for supported ends and $(1 + 24\,\beta)$ for fixed ends.

In the case of buckling of struts the buckling load is reduced due to shear by a factor similar to Equation [7], since the bending moments are proportional to $w_b + w_s$, while the internal resisting moments are the same as if w_b alone were the deflection. For a hinged-end strut, if we assume that

$$w_b = W_b \sin\frac{\pi x}{a} \quad \ldots\ldots [8]$$

we find from Equation [4] and the condition $x = 0 : w_s = 0$

$$w_s = \frac{\pi^2}{2}\beta W_b \sin\frac{\pi x}{a} = \frac{\pi^2}{2}\beta w_b \quad \ldots\ldots [9]$$

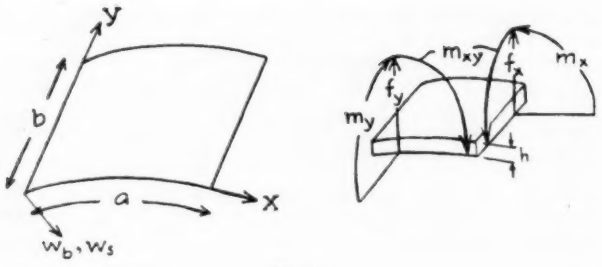

FIG. 2

Since w_s has the same shape as w_b, the usual equilibrium conditions will be satisfied if the critical load is reduced by the factor

$$\left(1 + \frac{w_s}{w_b}\right) = \left(1 + \frac{\pi^2}{2}\beta\right) \approx (1 + 5\beta) \quad \ldots\ldots [10]$$

which checks with a solution obtained in a somewhat different manner.[3] Similarly, the buckling load of a fixed-end strut is decreased by a factor

$$(1 + 2\pi^2\beta) \approx (1 + 20\beta)$$

This method will now be extended to the case of a plate or shell, such as is shown in Fig. 2 of this discussion. The bending and twisting moments per unit length of section are

$$\left.\begin{aligned} m_x &= -D\left(\frac{\partial^2 w_b}{\partial x^2} + \mu\frac{\partial^2 w_b}{\partial y^2}\right) \\ m_y &= -D\left(\frac{\partial^2 w_b}{\partial y^2} + \mu\frac{\partial^2 w_b}{\partial x^2}\right) \\ m_{xy} &= -D(1-\mu)\frac{\partial^2 w_b}{\partial x \partial y} \end{aligned}\right\} \quad \ldots\ldots [11]$$

From the moment equilibrium of an element, and using Equation [11], we obtain

$$\left.\begin{aligned} f_x &= \frac{\partial m_y}{\partial x} + \frac{\partial m_{xy}}{\partial y} = -D\frac{\partial}{\partial x}(\nabla^2 w_b) \\ f_y &= \frac{\partial m_y}{\partial y} + \frac{\partial m_{xy}}{\partial x} = -D\frac{\partial}{\partial y}(\nabla^2 w_b) \end{aligned}\right\} \quad \ldots\ldots [12]$$

Using Equation [5] as in the derivation of Equation [8] and taking $\mu = 0.3$, for the symmetrical case

$$\left.\begin{aligned} \frac{\partial w_s}{\partial x} &= \frac{nf_x}{Gh} = -0.55\,\beta a^2\frac{\partial}{\partial x}(\nabla^2 w_b) \\ \frac{\partial w_s}{\partial y} &= \frac{nf_y}{Gh} = -0.55\,\beta a^2\frac{\partial}{\partial y}(\nabla^2 w_b) \end{aligned}\right\} \quad \ldots\ldots [13]$$

where β is the same as defined by Equation [5]. Integrating, we obtain

$$w_s = -0.55\,\beta a^2\nabla^2 w_b + C \quad \ldots\ldots [14]$$

where C is a constant of integration, as before, which can be determined from edge conditions. There are no variables of integration, as usual in the integration of partial derivatives, because both Equations [13] would not be satisfied if they were present.

As an example of the application of the basic Equation [14], consider the case of a flat or curved panel with hinged edges, whose deflection, neglecting shear, can always be expressed in the form

$$w_b = \sum_{\substack{m=\\1,3,\ldots.}}\sum_{\substack{n=\\1,3,\ldots.}} W_{mn}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \quad \ldots\ldots [15]$$

Substituting this expression in Equation [14] and using the condition $x = y = 0 : w_s = 0$, we find

$$w_s = 5.4\,\beta\sum_m\sum_n\left(m^2 + n^2\frac{a^2}{b^2}\right)W_{mn}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \quad [16]$$

Values of the coefficients W_{mn} can be obtained by strain-energy methods, which have been worked out in general form for the case of a flat panel. For example, for a flat panel under uniformly distributed pressure p, it is found that

$$W_{mn} = \left(\frac{192\,(1-\mu^2)pa^4}{\pi^6 Eh^3}\right)\frac{1}{mn\left(m^2 + n^2\frac{a^2}{b^2}\right)^2} \quad \ldots\ldots [17]$$

The deflection in the middle is therefore increased due to shear by the factor

$$\left[1 + \left(\frac{w_s}{w_b}\right)_{x=\frac{a}{2},\,y=\frac{b}{2}}\right] = 1 + 5.4\beta\left[\frac{\sum\sum\dfrac{\sin\frac{m\pi}{2}\sin\frac{n\pi}{2}}{mn\left(m^2 + n^2\frac{a^2}{b^2}\right)}}{\sum\sum\dfrac{\sin\frac{m\pi}{2}\sin\frac{n\pi}{2}}{mn\left(m^2 + n^2\frac{a^2}{b^2}\right)^2}}\right] \quad \ldots\ldots [18]$$

The final fraction converges rapidly and it is sufficient to calculate it for the first few terms, say, for m, n (1, 1) (1, 3) (3, 1) (3, 3) in this manner the factor is found to be

$$(1 + 9.7\,\beta) \text{ for } \frac{a}{b} = 1; \quad (1 + 6.0\,\beta) \text{ for } \frac{a}{b} = \frac{1}{2} \quad \ldots\ldots [19]$$

For the buckling of a flat panel under a uniform compressive stress in the b direction, the theory, neglecting shear, indicates that the deflection consists of one term only of Equation [15], and for this term $m = n = 1$ when $a > b$, and $m = 1$, $n \approx b/a$ when $a < b$. Using these values in Equations [15] and [16], we find that the factor by which the deflection is increased and hence the buckling stress is decreased by shear is

$$\left.\begin{aligned} &\left[1 + 5.4\left(1 + \frac{a^2}{b^2}\right)\beta\right] \quad \text{when } a > b \\ &(1 + 10.8\,\beta) \quad \text{when } a < b \end{aligned}\right\} \quad \ldots\ldots [20]$$

These methods apply equally well to "large-deflection" or "second-order" plate and shell theories, but in this case the additional deflections due to shear should be calculated from the deflections given by ordinary small-deflection theory, and then added to the deflections given by the large-deflection theory.

D. C. DRUCKER.[4] The remarkable extension of the theory of plates presented in this paper is of great interest both to the elastician and to the practical engineer. Therefore it would seem to be worth noting that experimental results published by

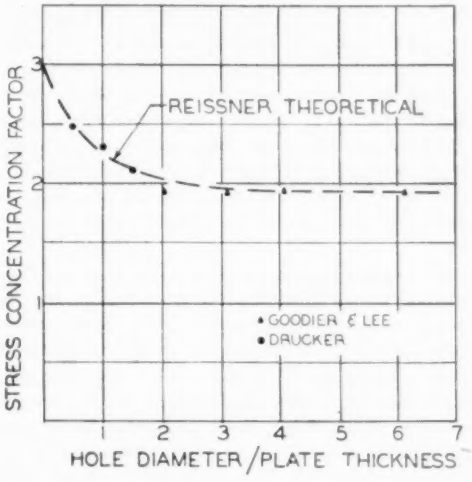

FIG. 3

The dots and triangles plotted in Fig. 3 of this discussion, represent the data arbitrarily corrected for the finite width of plate by the factors which hold for the case of pure tension (see footnote to Table 1 of this discussion). Many of the points are thus subject to question, but the most important value of 2.5 for a $^1/_8$-in. hole in a $^1/_4$-in. plate is not affected.

Although the agreement between theory and experiment is very good, some caution must still be exercised in the application of the results. Of necessity the experimenters also assumed that the distribution of the stress through the thickness was linear, or more precisely, they interpreted their experimental results on this basis. Nonlinear distributions, especially local disturbances at or near the surfaces of the plate, would thus be averaged out and could not easily be detected.

Another point of interest is that the large value found by the author for the magnitude of the transverse shearing stress when the plate is thin is very close to the residual shearing stress at the boundary of the hole appearing in the theory of moderately thick plates.

[5] "An Extension of the Photoelastic Method of Stress Measurement to Plates in Transverse Bending," by J. N. Goodier and G. H. Lee, JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 63, 1941, p. A-27.

[6] "The Photoelastic Analysis of Transverse Bending of Plates in the Standard Transmission Polariscope," by D. C. Drucker, JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 64, 1942, p. A-161.

J. N. GOODIER.[7] The paper is an interesting attempt to free the small-deflection theory of plates from one of its most serious defects, i.e., its inability to meet the conditions of prescribed bending moment, twisting moment, and transverse shear force at an edge, except by replacing the horizontal (in the plane) shear stress of the twisting moment by statically equivalent vertical stress. The error so introduced is local to the edge, but, as in stress concentration at a hole, this is often objectionable.

The author's theory makes two principal assumptions, (1) that the stress components σ_x, σ_y, τ_{xy} are linear through the thickness; (2) that at an edge the displacements u_n, u_s vary linearly, and w does not vary, through the thickness. The second raises some questions because the essence of the theory is to take into account deformation due to shear (τ_{xz}, τ_{yz}) and transverse stress (σ_z) as well as bending stress (σ_x, σ_y, τ_{xy}). The shear deformation will cause departure from linearity of u_n, u_s, and the effects of σ_z will cause w to vary through the thickness.

Terms such as, but slightly different from, those introduced by the author can be derived by somewhat more elementary considerations without making the assumption (2). But also the well-known equations of the old theory can equally well be derived without neglecting any part of the deformation, that is, by making assumption (1) alone. The analysis follows:

Making assumption (1), that is, starting from Equations [1*a*], [1*b*], [1*c*] of the paper, Equations [2*a*], [2*b*], [4] for τ_{xz}, τ_{yz} and σ_z follow from the differential equations of equilibrium. The strain components can then be evaluated, and from these the curvatures and twist of the plate, of the middle surface, or the faces, or of intermediate surfaces, can be found by means of the identities

$$\frac{\partial^2 w}{\partial x^2} = \frac{\partial e_{xz}}{\partial x} - \frac{\partial e_{-z}}{\partial z}, \quad \frac{\partial^2 w}{\partial y^2} = \frac{\partial e_{yz}}{\partial y} - \frac{\partial e_{yy}}{\partial z}, \quad 2\,\frac{\partial^2 w}{\partial x \partial y} = \frac{\partial e_{yz}}{\partial x} + \frac{\partial e_{xz}}{\partial y} - \frac{\partial e_{xy}}{\partial z}$$

For instance, the first of these gives for the curvature of the middle surface

$$\left(\frac{\partial^2 w}{\partial x^2}\right)_{z=0} = -\frac{12}{Eh^3}(M_x - \nu M_y) + \frac{3(1+\nu)}{Eh}\frac{\partial V_x}{\partial x} + \frac{3\nu}{2Eh}p$$

Comparing this with the expression multiplying δM_x in Equation [13] of the paper, it will be observed that the terms involving V_x and p are of the same nature as the author's, but the numerical coefficient in the $\partial V_x/\partial n$ term is here 3, instead of the author's 12/5, and in the p-term it is here 3/2 instead of the author's 12/10.

The twist of the middle surface is found from the third identity as

$$2\left(\frac{\partial^2 w}{\partial x \partial y}\right)_{z=0} = -\frac{24(1+\nu)}{Eh^3}H_{xy} + \frac{3(1+\nu)}{Eh}\left(\frac{\partial V_y}{\partial x} + \frac{\partial V_x}{\partial y}\right)$$

Again 3 appears instead of the author's 12/5.

If instead of considering the curvatures and twist of the middle surface we evaluate them for the upper or lower face of the plate, the terms in V_x, V_y, p disappear, and the results are of exactly the same form as in the unmodified plate theory. This shows that the "correction terms" express (granted assumption 1) the difference in curvature and twist between the middle surface and the upper or lower surface. It is therefore not en-

[7] Professor of Mechanics, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

tirely consistent to disregard the variation of w through the thickness, as in the author's assumption (2).

The expressions for the curvatures and twist of the upper (or lower) face can be used just as well as those of the middle surface. In conjunction with the equations of equilibrium, they will yield the usual equation $D\nabla^4 w = p$ for the deflection. The boundary conditions must now of course be put in terms of the upper (or lower) face deflection. This theory would thus consist of all the usual equations, but nevertheless takes into account all kinds of deformation.

In a problem where the boundary conditions are in terms of the edge deflection, it would differ from the theory incorporating "correction terms" only in employing the face deflection at the edge instead of the middle-surface deflection. In a problem specifying bending moment, twisting moment, and transverse shearing force at an edge, as at a free edge, it would proceed exactly as does the old theory—and be equally unable to satisfy three conditions exactly, instead of two. We are thus confronted with this question: Why should a theory involving precisely the same assumptions, but using the deflection of the middle surface instead of that of the face, lead to the possibility of satisfying all three edge conditions?

Author's Closure

The author appreciates Professor Donnell's comments and the communication of his earlier unpublished results on the effect of transverse-shear deformation on the bending deflection and buckling loads of elastic plates. He would like to say that for the problems considered by Professor Donnell and restricting attention to isotropic homogeneous plates, these earlier results are substantially confirmed by results which can be obtained from the author's formulas. It may be permitted to say, however, that as far as the author can see, Professor Donnell's approach to the subject does not include the possibility of satisfying three edge conditions instead of the two conditions which are used in the theory without transverse-shear deformation, and also in the theory of moderately thick plates. The author thinks that as a consequence of this it is not possible to apply Professor Donnell's formulas to the two problems to which the author's results were applied, namely, (1) the problem of Saint Venant torsion of a rod with rectangular cross section; (2) the problem of the stress concentration at the edge of a circular hole in transversely bent plates.

In these and other problems, but not in the problems considered by Professor Donnell, it is essential that provision be made to take account of the fact that the stresses may change substantially within edge zones, the width of which is of the order of magnitude of the plate thickness itself. The possibility of providing for this necessity is given not by including extra terms in the relations between couples and curvatures[8] (as in Equations [II] to [IV] of the paper under discussion), but rather by replacing the relations

$$(V_x, V_y) = -D\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)\nabla^2 w \qquad [21]$$

which are used in the theory of thin as well as of moderately thick plates, by the relations

$$\left(1 - \frac{h^2}{10}\nabla^2\right)(V_x, V_y) = -D\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)\nabla^2 w \qquad [22]$$

which were obtained in the author's paper.

The author is grateful to Dr. Drucker for the two additional references to experimental results and in particular for his kindness in supplying a comparison between the results of the photoelastic tests and the calculated data of the present paper.

Dr. Drucker brings up an important point by mentioning that in interpreting the results of the photoelastic experiments as well as of the calculations, one is led to what might be called "stress couple concentration factors" rather than to stress-concentration factors. To calculate the difference between these two kinds of factors it would be necessary to extend the theory in such a way that in addition to components of the bending stresses which vary linearly across the thickness, there are taken into account additional terms which vary across the thickness like, say, cubic parabolas. The author believes that such an extension, while analytically quite heavy, could be made and numerical results be obtained.

It is the author's feeling that the differences between stress-couple-concentration factors and stress-concentration factors should, in order of magnitude, not go beyond 10 per cent of the values of the couple-concentration factors obtained in the paper and possibly be appreciably smaller than this.

Professor Goodier raises some interesting questions concerning the meaning of the author's results by contrasting them with formulas which he obtains without the use of a minimum-energy principle. He finds that in so doing two different kinds of results are obtained, depending upon whether attention is focused on the middle surface of the plate or on the face surfaces of the plate. Perhaps one should say that the variational method used in the paper strikes in a natural way a balance between the two possibilities indicated by Professor Goodier and leads then also automatically to the appropriate three boundary conditions of the problem.

Professor Goodier further questions the compatibility of the author's assumptions regarding the distribution of stress across the thickness and of the distribution of the displacements at the edge across the thickness. The author is indebted to Professor Goodier for bringing up this point. It has led the author to reconsider the question of the displacements in the interior as well as at the edge, and he finds that his analysis, while not needing reinterpretation in so far as the two applications which were made in the paper are concerned, does stand in need of such reinterpretation in so far as the meaning of the Lagrangian multiplier w is concerned. It is found that the quantity w which occurs in Equations [I] to [VI] of the paper, does not represent an approximation to the transverse deflection of the middle surface (or of the face surfaces) but rather represents an approximation to a weighted average across the thickness of the deflections W of all surfaces contained in between the two faces of the plates. This average w is, for the assumed stress distribution

$$w = \frac{\int_{-h/2}^{h/2}\left[1 - \left(\frac{z}{h/2}\right)^2\right] W dz}{\int_{-h/2}^{h/2}\left[1 - \left(\frac{z}{h/2}\right)^2\right] dz} \qquad [23]$$

Likewise one should not define the quantities $\bar{u}_n'$ and $\bar{u}_s'$ which occur in Equations [15a] and [15b] by means of Equations [9a] and [9b], but rather in the following way

$$\bar{u}_n' = \frac{\int_{-h/2}^{h/2} \bar{u}_n \frac{z}{h/2} dz}{\int_{-h/2}^{h/2} z \frac{z}{h/2} dz}, \qquad \bar{u}_s' = \frac{\int_{-h/2}^{h/2} \bar{u}_s \frac{z}{h/2} dz}{\int_{-h/2}^{h/2} z \frac{z}{h/2} dz} \qquad [24]$$

Only these averaged components of direction change of the normal to the undeformed middle surface are of importance in the present theory. Distributions of $\bar{u}_n$ and $\bar{u}_s$ across the thickness which lead to the same values of $\bar{u}_n'$ and $\bar{u}_s'$ are equivalent within the framework of the present developments.

[8] For the inclusion of such extra terms see also "Theory of Plates and Shells," by S. Timoshenko, McGraw-Hill Book Company, Inc., New York, N. Y., 1940, p. 111.

Cylindrical Buckling of Sandwich Plates

By J. N. GOODIER,[1] ITHACA, N. Y.

In the buckling of "sandwich plates" with a relatively easily deformed interior, or core, material, the core is not stiff enough to keep plane sections plane when the bending occurs. The core must then be analyzed according to the equations of plane strain, but the fact that the bending takes place in the presence of thrust means that terms representing the destabilizing tendency of the thrust must be included. The resulting problem is solved in the present paper for a sandwich plate in "cylindrical buckling"—that is in a mode analogous to that of the hinged column.

Nomenclature

The following nomenclature is used in the paper: Subscript 1 designates faces; subscript 2 the core

E_1, E_2 = Young's moduli

ν_1, ν_2 = Poisson's ratios

P = thrust per unit width on sandwich plate

t = thickness of each face

h = thickness of core

$r = t/h$

$\rho = E_1/E_2$

$D_1 = E_1t^3/12(1-\nu_1^2)$

$\lambda = \dfrac{\nu_2 E_2}{(1-2\nu_2)(1+\nu_2)}$, $G = \dfrac{E_2}{2(1+\nu_2)}$ ..... Lamé constants of core

α = 2π/wave length of sinusoidal deformation

$\epsilon = \alpha h/2$

$\gamma = 2 + \dfrac{\lambda}{G} = \dfrac{2(1-\nu_2)}{1-2\nu_2}$

σ_{z2} = critical stress in core

$\sigma = -\sigma_{z2}$

$s = \sigma/2G$

$$c_1 = \frac{2E_1}{3(1-\nu_1^2)G} = \frac{4}{3}\,\frac{1+\nu_2}{1-\nu_1^2}\,\rho$$

$$c_2 = 2\alpha t \cdot \frac{1-\nu_1\nu_2+2r\rho(1-\nu_2^2)}{2r(1-\nu_1\nu_2)+(1/\rho)(1-\nu_1^2)} = c_2' r\epsilon$$

$$c_2' = 4\rho \cdot \frac{1-\nu_1\nu_2+2r\rho(1-\nu_2^2)}{1-\nu_1^2+2r\rho(1-\nu_1\nu_2)}$$

Introduction

By "sandwich plate," Fig. 1, is meant a nonhomogeneous flat thin plate made by bonding two like cover sheets (the faces) to a plate of another material (the core). The combination is required to withstand as much compression (e.g., vertically in Fig. 1) as possible without buckling. Several types of buckling are conceivable. The whole plate being simply, or otherwise, supported, it may buckle as a whole as a homogeneous plate would, Fig. 2(*a*); or the faces, stiffened by the action of the core as an elastic support, may buckle to a rather small wave length. A symmetrical mode of this kind is indicated in Fig. 2(*b*). Such modes have been investigated by Gough, Elam, and de Bruyne

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1947, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

(1),[2] and by Hoff and Mautner (2), who have observed in tests and made calculations for, a "skew" mode different from Fig. 2(*a*) or (*b*). The stresses occurring at the bond when the buckling deformation occurs constitute distributed loads on the faces, which at the same time are under compression. They also constitute distributed loads on the core. In these investigations, the displacements of faces and core at the interface are equated. In calculating the displacements of the core the fact that the core is also under compression has been disregarded. When the Young's modulus of the core is relatively small, a case of practical interest, the compressive stress in the core is also relatively small. But the question of whether or not the pre-existing compressive stress in the core can be ignored in computing the displacements due to the stresses appearing at the interface will depend upon whether the core is far from instability or not under its own compression; and its critical compressive stress will be small if its Young's modulus is small. Evidently the smallness of the compressive stress in the core relative to that in the faces is not conclusive.

The usual object of the sandwich construction is to stabilize the plates, which are essentially the (compressive) load-bearing elements, by holding them at a suitable distance apart by means of a light core. The greatest stabilization would be achieved by a core stiff enough to cause the sandwich to deform as a homogeneous plate does, i.e., with plane sections remaining plane in bending. Then, taking a unit width of plate normal to the paper in Fig. 2, the section by a plane such as *aa* would have a moment of inertia $^1/_2\ th^2$. Ignoring the bending stresses in the core, the critical thrust for buckling to cylindrical form is given by the Euler formula as

$$N_1 = \pi^2 E_1' \cdot \frac{1}{2}\, th^2/l^2 \qquad [1]$$

where $E'\ (1 - \nu_1^2)$ is the Young's modulus of the face material. The corresponding critical compressive strain in the faces is $N_1/2tE_1$ or

$$\pi^2 h^2/(1 - \nu_1^2)4l^2 \qquad [2]$$

The same strain will, of course, exist in the core.

If now the core without the faces is considered in the same way, its critical load per unit width is

$$N_2 = \pi^2 E_2' \left(\frac{1}{12}\, h^3\right) \Big/ l^2$$

and the critical strain is

$$N_2/hE_2$$

or

$$\pi^2 h^2/(1 - \nu_2^2)12l^2 \qquad [3]$$

This is only about one third of the critical strain just calculated for the two plates constrained to simple bending as a single section. Such behavior of the plates clearly requires the core to be at a stress some 3 times its own critical stress and therefore it cannot be realized.

Instead of considering the behavior of the faces as a section themselves, we may examine how they behave when part of a homogeneous plate of thickness h. The critical strain of such a plate is

$$\pi^2 h^2/12(1 - \nu_1^2)l^2 \qquad [4]$$

This is less than the value given by Equation [2] by a factor $^1/_3$, for when the faces are part of a homogeneous section they are subject to forces at their attachment to the rest of the section. The critical strain of the core by itself is the same as Equation [4] except for the Poisson's ratio. Thus if the core is to cause the faces to act as they would when part of a solid section, it must work at its own critical strain.

The actual state at buckling of a sandwich plate with a core of light material will of course be different. In the present investigation of it the compressive stress in the core is taken into account, the results being applicable to sandwich plates of any face-core thickness ratio and any homogeneous isotropic materials.

Initial State Under Compression

By "initial state" is meant the compressed state of the sandwich just before buckling. The sandwich is under thrust P per unit width (in the x-direction, axes as in Fig. 1) and is taken to be in a state of plane strain in the x, y plane, as it will be except locally at the vertical edges, in accordance with Saint Venant's principle. With subscripts 1 and 2 designating faces and core, respectively, continuity of the strain components ϵ_x, ϵ_z, at an interface requires

$$\left.\begin{aligned} \frac{1}{E_1}(\sigma_{x1} - \nu_1\sigma_{z1}) &= \frac{1}{E_2}(\sigma_{x2} - \nu_2\sigma_{z2}) \\ \frac{1}{E_1}(\sigma_{z1} - \nu_1\sigma_{x1}) &= \frac{1}{E_2}(\sigma_{z2} - \nu_2\sigma_{x2}) \end{aligned}\right\} \qquad [5]$$

Since the stress components σ_{x1} and σ_{x2} constitute the thrust P

$$2t\sigma_{x1} + h\sigma_{x2} = -P \qquad [6]$$

and, since the components σ_{z1} and σ_{z2} form a zero resultant on sections parallel to the x, y plane

$$2t\sigma_{z1} + h\sigma_{z2} = 0 \qquad [7]$$

These four equations yield

$$\sigma_{x1} = -\frac{P}{h} \cdot \frac{1 - \nu_1\nu_2 + 2r\rho(1 - \nu_2^2)}{4r(1 - \nu_1\nu_2) + \frac{1}{\rho}(1 - \nu_1^2) + 4r^2\rho(1 - \nu_2^2)} \qquad [8]$$

$$\sigma_{x2} = -\frac{P}{h} \cdot \frac{2r(1 - \nu_1\nu_2) + \frac{1}{\rho}(1 - \nu_1^2)}{4r(1 - \nu_1\nu_2) + \frac{1}{\rho}(1 - \nu_1^2) + 4r^2\rho(1 - \nu_2^2)} \qquad [9]$$

Equations of Faces

Fig. 3 represents an element (of unit width) of the left-hand face of Fig. 1 after buckling has occurred. It is cut out by planes parallel to the y, z plane at x and $x + dx$ in the initial state. These sections are regarded as remaining plane and normal to the middle surface. The forces exerted by the core are, to the first order, $p'dx$, $q'dx$, p' and q' being interface stress components. The thrust in the face is no longer the initial thrust P_1 (corresponding to σ_{x1}) and is now designated as $P_1 - p_1't$.

The equations of equilibrium are

$$\frac{dM}{dx} + Q - q'\frac{t}{2} = 0 \qquad [10]$$

$$\frac{dQ}{dx} - P_1\frac{d^2v_1}{dx^2} - p' = 0 \qquad [11]$$

$$q' - t\frac{dp_1'}{dx} = 0 \qquad [12]$$

where v_1 is the deflection of the face in the y direction.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

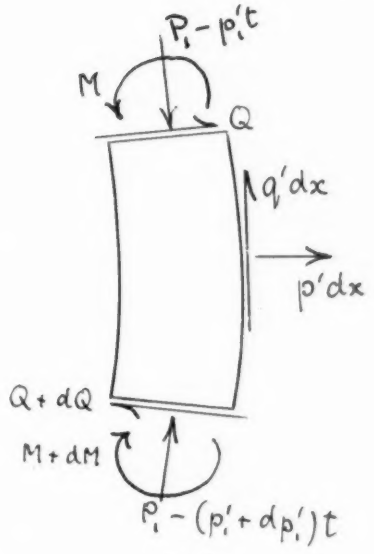

FIG. 3

In Equation [11] the product $p_1't\,\frac{d^2v_1}{dx^2}$ has been dropped. The buckling under investigation is infinitesimal, that is, the stresses and displacements appearing on buckling may be as small as we please. We have also

$$M = D_1\frac{d^2v_1}{dx^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

These equations yield

$$D_1\frac{d^4v_1}{dx^4} + P_1\frac{d^2v_1}{dx^2} + p' - \frac{t}{2}\frac{dq'}{dx} = 0 \quad \ldots\ldots\ldots [14]$$

Since the modes of deformation to be considered are either symmetrical or antisymmetrical with respect to the middle plane (x, z) of the sandwich, it is not necessary to consider the other face separately. Since they are also to be sinusoidal in x, we write $v_1 = V \sin \alpha x$, $p' = p \sin \alpha x$, $q' = q \cos \alpha x$, $p_1' = p_1 \sin \alpha x$, giving Equations [12] and [14] the forms

$$q - \alpha t p_1 = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots [12a]$$

$$(D_1\alpha^4 - P_1\alpha^2)V + p + \frac{\alpha t}{2}\cdot q = 0 \quad \ldots\ldots\ldots [14a]$$

EQUATIONS OF CORE, ANTISYMMETRICAL DEFORMATION

The mode of buckling deformation is now taken to be antisymmetrical with respect to the x, z plane, that is, the displacement component v is even in y, the component u odd in y. The normal stress components are then odd in y, and the shearing component of the type τ_{xy} is even in y. This is the case in the simple flexural buckling of a homogeneous section. Here, however, it is not appropriate to assume that the deformation of the core is like that of simple bending. For instance, if the core is very light and flexible it exerts very little restraint on the faces, and they buckle virtually as two independent sheets, Fig. 5. Then the core is stretched on the left and contracted on the right to conform to the faces. These are exactly the opposites of the strains produced by simple bending of the core in a similar state of over-all deformation.

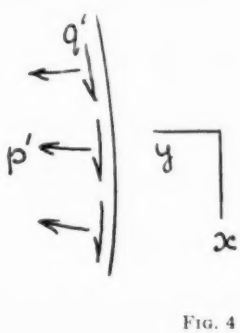

FIG. 4

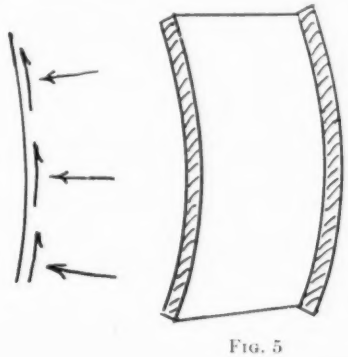

FIG. 5

In the "cylindrical" bending of a sandwich, as in a homogeneous plate, the displacement w is zero except in the local zone at the free vertical edges, and u, v are independent of z. The deformation is thus one of plane strain. General equations of equilibrium for a solid slightly deformed from a state of initial stress have been derived in a form suitable for the present purpose by Biezeno and Hencky (3) and by Biot (4). The initial stress in the core has uniform components σ_{x2}, σ_{y2}, the other components being zero. In the buckled state the stress and strain are referred to axes which have rotated with the material, as defined by the authors quoted. The stress components are written $S_{xx} + s_{11}$, etc., $S_{xy} + s_{12}$, etc., where $S_{xx}\ldots$, $S_{xy}\ldots$, are the components of initial stress. For uniform initial stress and no body force the equations (Biot)[3] are three of the type

$$\frac{\partial s_{11}}{\partial x} + \frac{\partial s_{12}}{\partial y} + \frac{\partial s_{13}}{\partial z} + (S_{xx} - S_{yy})\frac{\partial \omega_z}{\partial y} - 2S_{xy}\frac{\partial \omega_z}{\partial x} + S_{xy}\frac{\partial \omega_x}{\partial z}$$

$$- (S_{xx} - S_{zz})\frac{\partial \omega_y}{\partial z} - 2S_{xz}\frac{\partial \omega_y}{\partial x} - S_{xz}\frac{\partial \omega_z}{\partial y} + S_{yz}\left(\frac{\partial \omega_y}{\partial y} - \frac{\partial \omega_z}{\partial z}\right)$$

$$\ldots\ldots = 0 \quad [15]$$

where ω_x, ω_y, ω_z are the components of the rotation, $\frac{1}{2}$ curl (u, v, w).

In the present problem

$$S_{xx} = \sigma_{x2},\ S_{yy} = 0,\ S_{zz} = \sigma_{z2},\ S_{xy} = S_{yz} = S_{zx} = 0$$

Also, since the displacement u, v, w is plane strain $\omega_x = \omega_y = 0$, and ω_z is independent of z. The three equations of the type of Equation [15] reduce to

$$\frac{\partial s_{11}}{\partial x} + \frac{\partial s_{12}}{\partial y} + \frac{\partial s_{13}}{\partial z} + \sigma_{x2}\frac{\partial \omega_z}{\partial y} = 0 \quad \ldots\ldots\ldots [16]$$

$$\frac{\partial s_{22}}{\partial y} + \frac{\partial s_{23}}{\partial z} + \frac{\partial s_{12}}{\partial x} + \sigma_{x2}\frac{\partial \omega_z}{\partial x} = 0 \quad \ldots\ldots\ldots [17]$$

$$\frac{\partial s_{33}}{\partial z} + \frac{\partial s_{13}}{\partial x} + \frac{\partial s_{23}}{\partial y} = 0 \quad \ldots\ldots\ldots\ldots [18]$$

The stress components s_{ij} are related to the displacement by Hooke's law, that is, by three equations of the type

$$s_{11} = \lambda(e_{11} + e_{22}) + 2Ge_{11} \quad \ldots\ldots\ldots\ldots [19]$$

and three of the type

$$s_{12} = 2Ge_{12} \quad \ldots\ldots\ldots\ldots\ldots\ldots [20]$$

where e_{11}, etc., are $\partial u/\partial x$, etc., e_{12} is $\frac{1}{2}(\partial v/\partial x + \partial u/\partial y)$, to the first order, and λ, G are the Lamé constants of the core. Substitution of Equations [19] and [20] in [16] and [17] yields

$$G\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) + (G + \lambda)\frac{\partial e}{\partial x} - \sigma\frac{\partial \omega}{\partial y} = 0 \quad \ldots\ldots [21]$$

[3] Reference (4a), Equation 4.7, p. 484.

$$G\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right)+(G+\lambda)\frac{\partial e}{\partial y}-\sigma\frac{\partial \omega_z}{\partial x}=0 \quad [22]$$

where

$$e=\partial u/\partial x+\partial v/\partial y, \quad \omega_z=\tfrac{1}{2}(\partial v/\partial x-\partial u/\partial y)$$

and σ is written for $-\sigma_{x2}$. Equation [18] is satisfied identically on account of the plane strain.

The boundary conditions associated with the equations of the type of Equation [15] are three of the type

$$\begin{aligned}\Delta f_x &= s_{11}\alpha+s_{12}\beta+s_{13}\gamma+(S_{xx}\omega_y-S_{xy}\omega_x)\alpha\\&+(S_{yx}\omega_y-S_{yy}\omega_x)\beta+(S_{zx}\omega_y-S_{yx}\omega_z)\gamma\\&+S_{xx}(e_{yy}+e_{zz})\alpha+S_{xy}(e_{xx}+e_{zz})\beta\\&+S_{xz}(e_{xz}+e_{yy})\gamma-(S_{xy}e_{xy}+S_{xz}e_{xz})\alpha\\&-(S_{xx}e_{xy}+S_{xx}e_{yz})\beta-(S_{xx}e_{xz}+S_{xy}e_{yz})\gamma\end{aligned}$$

where Δf_x is the x-component of boundary force, accompanying the displacement u, v, w, per unit area (before deformation), and α, β, γ are the direction cosines of the normal to the boundary element; e_{xx}, etc., are $\partial u/\partial x$, etc., and e_{xy}, etc., are $\tfrac{1}{2}(\partial v/\partial x+\partial u/\partial y)$, etc., being identical with $e_{11}\ldots$, $e_{12}\ldots$, to the first order. For the core face $y=h/2$, $\alpha=\gamma=0$, $\beta=1$, and the first boundary condition reduces to

$$\Delta f_x = s_{12}+\sigma e_{xy}$$

or

$$\Delta f_x=\left(1+\frac{\sigma}{2G}\right)s_{12} \quad [23]$$

The second boundary condition reduces to

$$\Delta f_y = s_{22} \quad [24]$$

and the third to

$$\Delta f_z = s_{23}$$

The values of Δf_x, Δf_y and Δf_z required at the interface are q', p', and 0. The third boundary condition is identically satisfied, and the first two become

$$q'=s_{12}, \quad p'=s_{22} \quad [25]$$

neglecting $\sigma/2G$ in comparison with unity.

The problem of the core is thus to obtain a solution of Equations [21] and [22], satisfying conditions [25]. It must also satisfy the conditions of continuity of displacement at the interface. The displacement v must be the deflection v_1 of the face. The displacement w is already taken as zero in both core and face. The remaining condition is continuity of strain in the x-direction between core and face. In the investigations of Gough, Elam, and de Bruyne (1) and of Hoff and Mautner (2), the displacement u is taken as zero at the interface, on the ground that the deformation of the face is preponderantly the deflection v_1. This assumption is of doubtful value here for several reasons. It does not simplify the calculations much and it is not correct in the limiting case, useful as a check, when the thickness of face, or the Young's modulus of the face, goes to zero, and only the core is left. For then the core buckles in the Euler manner. The displacement u at the face is then small, it is true, but the implied imposition of a constraint to make it zero is not unimportant. In fact, in the work of Gough, Elam, and de Bruyne it leads to the conclusion that the critical stress for infinite wave length is not zero and invalidates their results for long wave lengths. It may easily be seen that if plane sections remain plane, as of course they do to an adequate approximation in the buckling of the core alone when the wave length is several times the thickness, such a constraint introduces complete stabilization.

Sinusoidal Deformation

The Equations [21] and [22] are satisfied by

$$u=\cos\alpha x[A\sinh\alpha y+Ck(1-\beta)\sinh k\alpha y] \quad [26]$$

$$v=\sin\alpha x[A\cosh\alpha y+C(1-k^2\beta)\cosh k\alpha y] \quad [27]$$

where α, A, C are as yet arbitrary, and $k^2=\dfrac{1-s}{1+s}$, $\beta=\dfrac{1}{\gamma}(1+s)$, $s=\dfrac{\sigma}{2G}$, $\gamma=2+\dfrac{\lambda}{G}=\dfrac{2(1-\nu_2)}{1-2\nu_2}$. The wave length of the deformation, $2\pi/\alpha$, will be kept arbitrary, and a critical value of s determined to correspond to it. Simple sinusoidal modes of buckling are to be expected, as counterparts of the modes of the homogeneous plate, but the existence of other modes for the sandwich plate remains an open question.

The solution in Equations [26] and [27] can be used directly in conjunction with Equations [19], [20], [25], [14], and the conditions of continuity of displacement at the interface to establish the condition for the critical load as a transcendental equation. This equation is very intractable and a different procedure is followed which results in an explicit formula for the critical load.

Limit of Sinusoidal Core Displacements for $s \to 0$

When $s=0$ (i.e., $\sigma=0$) Equations [21] and [22] reduce to those of ordinary plane strain in the elastic solid free from initial stress. The sinusoidal solution is

$$u=\cos\alpha x(A'\sinh\alpha y+C'\alpha y\cosh\alpha y) \quad [28]$$

$$v=\sin\alpha x\left[\left(A'-C'\frac{\gamma+1}{\gamma-1}\right)\cosh\alpha y+C'\alpha y\sinh\alpha y\right] \quad [29]$$

with A' and C' arbitrary.

But taking the solution Equations [26] and [27] in the limit $s\to 0$, we have $k\to 1$, $\beta\to 1/\gamma$ and, in the limit

$$u=\cos\alpha x\left[A\sinh\alpha y+C\left(1-\frac{1}{\gamma}\right)\sinh\alpha y\right] \quad [30]$$

$$v=\sin\alpha x\left[A\cosh\alpha y+C\left(1-\frac{1}{\gamma}\right)\cosh\alpha y\right] \quad [31]$$

These agree with Equations [28] and [29] only for the special case $C'=0$. The discrepancy arises from the fact that in a completely defined problem A and C in Equations [26] and [27] would be determined from boundary conditions and would emerge as functions of k and β. It is to be expected therefore that A and C must be involved in the limiting process. Write

$$k=1+\eta=1-s+\frac{1}{2}s^2-\frac{1}{2}s^3\ldots$$

Then Equation [26] may be expanded as

$$u=\cos\alpha x\left\{[A+Ck(1-\beta)]\sinh\alpha y+Ck(1-\beta)\left(\frac{\eta^2\alpha^2y^2}{2!}+\frac{\eta^4\alpha^4y^4}{4!}+\ldots\right)\sinh\alpha y+Ck(1-\beta)\left(\eta\alpha y+\frac{\eta^3\alpha^3y^3}{3!}+\ldots\right)\cosh\alpha y\right\}$$

Let

$$Ck(1-\beta)\eta = C' \quad \text{and} \quad A + Ck(1-\beta) = A' \ldots\ldots [32]$$

Then

$$u = \cos \alpha x \left\{ A' \sinh \alpha y + C' \alpha y \cosh \alpha y + C' \left[\eta \cdot \frac{\alpha^2 y^2}{2!} + \eta^3 \cdot \frac{\alpha^4 y^4}{4!} + \ldots \right] \sinh \alpha y + C' \left[\eta^2 \cdot \frac{\alpha^3 y^3}{3!} + \ldots \right] \cosh \alpha y \right\} \ldots\ldots [33]$$

If the limiting process is carried out with $C \to \infty$, $A \to \infty$ in such a way that C', A' remain finite, the limiting form of Equation [33] is [28], and the limiting form of Equation [27] will be shown later to be [29].

Now the conditions under which Equations [26] and [27] are to be used involve small values of s and therefore the appropriate values of A and C are likely to be very large. It becomes advantageous to employ the constants A' and C' which do not tend to infinity in the limiting case.

Sinusoidal Deformation for Small s

In the application of the present theory the quantity s will be of the order of the allowable strains, say, 5×10^{-3}. We retain terms up to and including s^2, and it will be seen in the result that this is adequate.

Replacing η by its expansion in terms of s, we have from Equation [33]

$$u = \cos \alpha x \left\{ A' \sinh \alpha y + C' \left[\alpha y \cosh \alpha y + \frac{1}{2} \left(-s + \frac{1}{2} s^2 \right) \alpha^2 y^2 \sinh \alpha y + \frac{1}{6} s^2 \alpha^3 y^3 \cosh \alpha y \right] \right\} \ldots. [34]$$

The expansion of Equation [27] in powers of η is

$$v = \sin \alpha x \left\{ \left[A + C(1-k^2\beta) \left(1 + \eta^2 \cdot \frac{\alpha^2 y^2}{2!} + \ldots \right) \right] \cosh \alpha y + C(1-k^2\beta) \left(\eta \alpha y + \eta^3 \frac{\alpha^3 y^3}{3!} \ldots \right) \sinh \alpha y \right\} \ldots [35]$$

Now, in accordance with Equation [32]

$$C(1-k^2\beta)\eta = C' \frac{1-k^2\beta}{k(1-\beta)}$$

This can be expanded in powers of s, with the result

$$C' \left\{ 1 + \frac{\gamma+1}{\gamma-1} s + \frac{(\gamma+1)^2}{2(\gamma-1)^2} s^2 + \frac{3\gamma^3 - 7\gamma^2 + 7\gamma + 1}{2(\gamma-1)^3} s^3 \right\} \ldots\ldots [36]$$

The combination $A + C(1-k^2\beta)$ has the value

$$A + \frac{C'}{\eta} \left\{ 1 + \frac{\gamma+1}{\gamma-1} s + \frac{(\gamma+1)^2}{2(\gamma-1)^2} s^2 + \frac{3\gamma^3 - 7\gamma^2 + 7\gamma + 1}{2(\gamma-1)^3} s^3 \ldots \right\}$$

and on expansion of $1/\eta$ in powers of s this becomes

$$A' - C' \left\{ \frac{\gamma+1}{\gamma-1} + \frac{\gamma(\gamma+1)}{(\gamma-1)^2} s + \frac{\gamma(3\gamma^2-6\gamma+7)}{2(\gamma-1)^3} s^2 \ldots \right\}$$

On substitution of these developments in Equation [35], and expansion of η, Equation [35] becomes

$$v = \sin \alpha x \left\{ \left[A' - C' \left(\frac{\gamma+1}{\gamma-1} + \frac{\gamma \cdot (\gamma+1)}{(\gamma-1)^2} s + \frac{\gamma(3\gamma^2-6\gamma+7)}{2(\gamma-1)^3} s^2 + \ldots \right) \right] \cosh \alpha y + C' \left[\left(1 + \frac{\gamma+1}{\gamma-1} s + \frac{(\gamma+1)^2}{2(\gamma-1)^2} s^2 \right) \alpha y \sinh \alpha y - \frac{1}{2} \left(s + \frac{\gamma+3}{2(\gamma-1)} s^2 \right) \alpha^2 y^2 \cosh \alpha y + \frac{1}{6} s^2 \alpha^3 y^3 \sinh \alpha y \right] \right\} \ldots. [37]$$

The limiting forms of Equations [34] and [37] as $S \to 0$ agree with Equations [28] and [29]. The results, Equations [34] and [37], can also be obtained directly from the differential Equations [21] and [22], dividing them through by $2G$, replacing $\sigma/2G$ by s, taking $u = \Sigma u_n s^n$, $v = \Sigma v_n s^n$ and equating the coefficients of each s^n to zero.

Critical Condition From Small s Solution

Writing

$$\left. \begin{aligned} s_1 &= -\frac{1}{2} s + \frac{1}{4} s^2, \; s_2 = \frac{1}{6} s^2, \; s_3 = \frac{\gamma+1}{\gamma-1} + \frac{\gamma(\gamma+1)}{(\gamma-1)^2} s + \frac{\gamma(3\gamma^2-6\gamma+7)}{2(\gamma-1)^3} s^2 \\ s_4 &= -\frac{1}{2} s - \frac{\gamma+3}{4(\gamma-1)} s^2, \; s_5 = 1 + \frac{\gamma+1}{\gamma-1} s + \frac{(\gamma+1)^2}{2(\gamma-1)^2} s^2 \end{aligned} \right\} \ldots [38]$$

the values of $s_{22} = p \sin \alpha x$ and $s_{12} = q \cos \alpha x$ are computed, by formulas of the types of Equations [19] and [20], from Equations [34] and [37] and yield

$$p = A' \cdot 2G\alpha \sinh \epsilon + C'\alpha \{ \lambda [(s_5 - s_3) \sinh \epsilon + (s_5 + 2s_4 - 1)\epsilon \cosh \epsilon + (s_4 + 3s_2 - s_1)\epsilon^2 \sinh \epsilon] + 2G[(s_5 - s_3) \sinh \epsilon + (2s_4 + s_5)\epsilon \cosh \epsilon + (s_4 + 3s_2)\epsilon^2 \sinh \epsilon + s_2\epsilon^3 \cosh \epsilon] \} \ldots [39]$$

$$q = G\alpha \{ 2A' \cosh \epsilon + C'[(1 - s_3) \cosh \epsilon + (1 + 2s_1 + s_5)\epsilon \sinh \epsilon + (s_1 + 3s_2 + s_4)\epsilon^2 \cosh \epsilon + 2s_2\epsilon^3 \sinh \epsilon] \} \ldots\ldots [40]$$

The value of V (defined by $v_{y=\frac{h}{2}} = V \sin \alpha x$) is from Equation [37]

$$V = A' \cosh \epsilon + C'(-s_3 \cosh \epsilon + s_3\epsilon \sinh \epsilon + s_4\epsilon^2 \cosh \epsilon + s_2\epsilon^3 \sinh \epsilon) \ldots\ldots [41]$$

On substitution from these in Equation [14a] (with $v_1 = v_{y=\frac{h}{2}}$)

$$(D_1\alpha^4 - P_1\alpha^2) \{ A' \cosh \epsilon + C'(-s_3 \cosh \epsilon + s_3\epsilon \sinh \epsilon + s_4\epsilon^2 \cosh \epsilon + s_2\epsilon^3 \sinh \epsilon) \} + A'(2G\alpha \sinh \epsilon + G\alpha^2 t \cosh \epsilon) + C'\alpha \{ \lambda [(s_5 - s_3) \sinh \epsilon + (s_5 + 2s_4 - 1)\epsilon \cosh \epsilon + (s_4 + 3s_2 - s_1)\epsilon^2 \sinh \epsilon] + 2G[(s_5 - s_3) \sinh \epsilon + (2s_4 + s_5)\epsilon \cosh \epsilon + (s_4 + 3s_2)\epsilon^2 \sinh \epsilon + s_2\epsilon^3 \cosh \epsilon] + G \cdot \frac{\alpha t}{2} [(1 - s_4) \cosh \epsilon + (1 + 2s_1 + s_5)\epsilon \sinh \epsilon + (s_1 + 3s_2 + s_4)\epsilon^2 \cosh \epsilon + 2s_2\epsilon^3 \sinh \epsilon] \} = 0$$

Dividing by αG, writing

$$\frac{D_1\alpha^3}{G} = \frac{E_1 t^3 \alpha^3}{12(1-\nu_1^2)G} = c_1 r^3 \epsilon^2$$

and

$$\frac{P_1\alpha}{G} = -\frac{\sigma_{x1} t \alpha}{G} = c_2 s$$

where

$$c_2 = 2\alpha t \frac{\sigma_{x1}}{\sigma_{x2}} = 2\alpha t \cdot \frac{1 - \nu_1\nu_2 + 2r\rho(1 - \nu_2^2)}{2r(1 - \nu_1\nu_2) + \frac{1}{\rho}(1 - \nu_1^2)}$$

we have

$$A'\{(c_1r^3\epsilon^3 - c_2s)\cosh\epsilon + 2\sinh\epsilon + 2r\epsilon\cosh\epsilon\} + C'\{(c_1r^3\epsilon^3 - c_2s)(-s_3\cosh\epsilon + s_5\epsilon\sinh\epsilon + s_4\epsilon^2\cosh\epsilon + s_2\epsilon^3\sinh\epsilon) + \gamma(s_5 - s_3)\sinh\epsilon + [\gamma(s_5 + 2s_4) - \gamma + 2 + r(1 - s_3)]\epsilon\cosh\epsilon + [\gamma(s_4 + 3s_2) - (\gamma - 2)s_1 + r(1 + 2s_1 + s_5)]\epsilon^2\sinh\epsilon + [2s_2 + r(s_1 + 3s_2 + s_4)]\epsilon^3\cosh\epsilon + 2rs_2\epsilon^4\sinh\epsilon\} = 0 \ldots [42]$$

Continuity of stress and of the displacement v is assured by Equation [42]. In addition, the displacement u is to be continuous at the interface. This condition may equally well be taken as continuity of the strain e_x. In the face there is strain $\frac{1}{2}t\,d^2v_1/dx^2$ at the interface due to bending. This is, however, not an adequate representation of the strain if the analysis is to be valid for all values of face and core moduli. For when the face and core are of the same material the plate will buckle in the Euler fashion, plane sections remaining plane. The state of the face (a thin surface skin) is then predominantly one of tension or compression, rather than bending with a neutral surface at mid-thickness (of the face). The strain in the face is therefore taken as due to both bending and direct stress (p_1'), and the continuity of e_x at the interface is expressed by

$$\frac{t}{2}\frac{d^2v_1}{dx^2} + \frac{1 - \nu_1^2}{E_1}\frac{q'}{\alpha t} = \left(\frac{\partial u}{\partial x}\right)_{y = h/2} \ldots\ldots\ldots [43]$$

where Equation [12a] has been employed, and the term on the right refers to the core. By means of Equations [41], [40], and [34], Equation [43] becomes after some rearrangement

$$A'(2\cosh\epsilon + 3c_1r\epsilon\sinh\epsilon - 3c_1r^2\epsilon^2\cosh\epsilon) + C'\{(1 - s_2)\cosh\epsilon + (1 + 2s_1 + s_5)\epsilon\sinh\epsilon + (s_1 + 3s_2 + s_4 + 3c_1r + 3c_1r^2s_3)\epsilon^2\cosh\epsilon + (2s_2 + 3c_1rs_1 - 3c_1r^2s_5)\epsilon^3\sinh\epsilon + (3c_1rs_2 - 3c_1r^2s_4)\epsilon^4\cosh\epsilon - 3c_1r^2s_2\epsilon^5\sinh\epsilon\} = 0 \ldots\ldots [44]$$

Equations [44] and [42] are rewritten in the form

$$A'\chi_1 + C'(\chi_2 + \chi_3 s + \chi_4 s^2) = 0 \ldots\ldots\ldots\ldots [44a]$$

$$A'(\chi_5 - c_2\chi_6 s) + C'[(\chi_7 - c_2 s)(\chi_8 + \chi_9 s + \chi_{10}s^2) + \chi_{11} + \chi_{12}s + \chi_{13}s^2] = 0 \ldots\ldots\ldots\ldots [42a]$$

and the χ's, which can be computed from Equation [38], are

$$\chi_n = \psi_n + c_1r\epsilon^2\psi_n', \quad n = 1, 2, 3, 4$$

$$\chi_5 = \psi_5\epsilon + c_1r^3\epsilon^3\psi_5'$$

$$\chi_6 = \psi_6$$

$$\chi_7 = c_1r^3\epsilon^3$$

$$\chi_8, \chi_9, \chi_{10} = \psi_8, \psi_9, \psi_{10}$$

$$\chi_{11}, \chi_{12}, \chi_{13} = \psi_{11}\epsilon, \psi_{12}\epsilon, \psi_{13}\epsilon$$

where

$$\psi_1 = 2\cosh\epsilon, \qquad \psi_1' = \frac{3}{\epsilon}(\sinh\epsilon - r\epsilon\cosh\epsilon)$$

$$\psi_2 = -\frac{2}{\gamma - 1}\cosh\epsilon + 2\epsilon\sinh\epsilon$$

$$\psi_2' = 3\left[\left(1 + r\frac{\gamma + 1}{\gamma - 1}\right)\cosh\epsilon - r\epsilon\sinh\epsilon\right]$$

$$\psi_3 = -\frac{\gamma(\gamma + 1)}{(\gamma - 1)^2}\cosh\epsilon + \frac{2}{\gamma - 1}\epsilon\sinh\epsilon - \epsilon^2\cosh\epsilon$$

$$\psi_3' = 3\left\{r\frac{\gamma(\gamma + 1)}{(\gamma - 1)^2}\cosh\epsilon - \left(\frac{1}{2} + r\frac{\gamma + 1}{\gamma - 1}\right)\epsilon\sinh\epsilon + \frac{1}{2}r\epsilon^2\cosh\epsilon\right\}$$

$$\psi_4 = -\frac{\gamma(3\gamma^2 - 6\gamma + 7)}{2(\gamma - 1)^3}\cosh\epsilon + \left(\frac{1}{2} + \frac{(\gamma + 1)^2}{2(\gamma - 1)^2}\right)\epsilon\sinh\epsilon + \left(\frac{3}{4} - \frac{\gamma + 3}{4(\gamma - 1)}\right)\epsilon^2\cosh\epsilon + \frac{1}{3}\epsilon^3\sinh\epsilon$$

$$\psi_4' = 3r\frac{\gamma(3\gamma^2 - 6\gamma + 7)}{2(\gamma - 1)^3}\cosh\epsilon + \left(\frac{3}{4} - 3r\frac{(\gamma + 1)^2}{2(\gamma - 1)^2}\right)\epsilon\sinh\epsilon + \left(\frac{1}{2} + 3r\frac{\gamma + 1}{4(\gamma - 1)}\right)\epsilon^2\cosh\epsilon - \frac{1}{2}r\epsilon^3\sinh\epsilon$$

$$\psi_5 = \frac{2}{\epsilon}(\sinh\epsilon + r\epsilon\cosh\epsilon) \qquad \psi_5' = \psi_6 = \cosh\epsilon$$

$$\psi_8 = -\frac{\gamma + 1}{\gamma - 1}\cosh\epsilon + \epsilon\sinh\epsilon$$

$$\psi_9 = -\frac{\gamma(\gamma + 1)}{(\gamma - 1)^2}\cosh\epsilon + \frac{\gamma + 1}{\gamma - 1}\epsilon\sinh\epsilon - \frac{1}{2}\epsilon^2\cosh\epsilon$$

$$\psi_{10} = -\frac{\gamma(3\gamma^2 - 6\gamma + 7)}{2(\gamma - 1)^3}\cosh\epsilon + \frac{(\gamma + 1)^2}{2(\gamma - 1)^2}\epsilon\sinh\epsilon - \frac{\gamma + 3}{4(\gamma - 1)}\epsilon^2\cosh\epsilon + \frac{1}{6}\epsilon^3\sinh\epsilon$$

$$\psi_{11} = -\frac{2\gamma}{\gamma - 1}\frac{\sinh\epsilon}{\epsilon} + \left(2 - \frac{2r}{\gamma - 1}\right)\cosh\epsilon + 2r\epsilon\sinh\epsilon$$

$$\psi_{12} = -\gamma\frac{\gamma + 1}{(\gamma - 1)^2}\frac{\sinh\epsilon}{\epsilon} + \frac{\gamma}{\gamma - 1}\left(2 - r\frac{\gamma + 1}{\gamma - 1}\right)\cosh\epsilon - \left(1 - \frac{2r}{\gamma - 1}\right)\epsilon\sinh\epsilon - r\epsilon^2\cosh\epsilon$$

$$\psi_{13} = \gamma\left(\frac{(\gamma + 1)^2}{2(\gamma - 1)^2} - \frac{\gamma(3\gamma^2 - 6\gamma + 7)}{2(\gamma - 1)^3}\right)\frac{\sinh\epsilon}{\epsilon} + \left[\gamma\left(\frac{(\gamma + 1)^2}{2(\gamma - 1)^2} - \frac{\gamma + 3}{2(\gamma - 1)}\right) - r\frac{\gamma(3\gamma^2 - 6\gamma + 7)}{2(\gamma - 1)^3}\right]\cdot\cosh\epsilon + \left[\gamma\left(\frac{1}{2} - \frac{\gamma + 3}{4(\gamma - 1)}\right) - \frac{1}{4}(\gamma - 2) + r\left(\frac{1}{2} + \frac{(\gamma + 1)^2}{2(\gamma - 1)^2}\right)\right]\epsilon\sinh\epsilon + \left[\frac{1}{3} + r\left(\frac{3}{4} - \frac{\gamma + 3}{4(\gamma - 1)}\right)\right]\cdot\epsilon^2\cosh\epsilon + \frac{r}{3}\epsilon^3\sinh\epsilon$$

Functions θ and ϕ being defined by

$$\theta = -\frac{2}{\epsilon^3}(\sinh 2\epsilon - 2\epsilon)$$

$$\phi = \frac{4}{\gamma - 1}(\sinh^2 \epsilon - \gamma \cosh^2 \epsilon)$$

the following useful relations may be established

$$\psi_1\psi_{11} - \psi_5\psi_2 = \theta\epsilon^2, \ \psi_5\psi_3 - \psi_1\psi_{12} = \phi$$

The ψ's, θ, and ϕ are all chosen so that their expansions as power series in ϵ begin with terms of order 1.

The condition that Equations [44a] and [42a] should permit nonzero values of A' and C'' yields an equation for the critical value of s

$$\left[\chi_7\chi_{10} + \chi_{13} - \frac{\chi_5\chi_4}{\chi_1} - c_2\left(\chi_9 - \frac{\chi_6\chi_3}{\chi_1}\right)\right]s^2 + \left[\chi_7\chi_9 + \chi_{13} - \frac{\chi_5\chi_3}{\chi_1} - c_2\left(\chi_8 - \frac{\chi_6\chi_2}{\chi_1}\right)\right]s + \chi_7\chi_8 + \chi_{11} - \frac{\chi_5\chi_2}{\chi_1} = 0 \quad \ldots [45]$$

The term in s^3 is disregarded, being incomplete because powers of s beyond s^2 were not retained in Equations [34] and [37]. The values of ϵ to be expected in practical problems are such that the coefficients of s^2 and s in Equation [45] are of the same order of magnitude. On the other hand s, being the critical stress in the core divided by twice the shear modulus of the core, is necessarily small, of the order of the compressive strain in core and faces at the critical load. A reasonable upper limit for this is 5×10^{-3}. Consequently, an adequate approximation to the critical value of s may be obtained from Equation [45] by discarding the term in s^2. On introducing the functions ψ, θ, ϕ, the solution is found as

$$s = \frac{\theta\epsilon^2 + c_1 r\epsilon^2[\psi_1'\psi_{11} - \psi_5\psi_2' + r^2(\psi_1\psi_3 - \psi_5'\psi_2) + c_1 r^3\epsilon^2(\psi_1'\psi_3 - \psi_5'\psi_2')]}{\phi + c_2' r(\psi_{11}\psi_8 - \psi_6\psi_2) + c_1 r\epsilon^2[c_2' r(\psi_1'\psi_3 - \psi_6\psi_2') + \psi_5\psi_3' - \psi_1'\psi_{12} + r^2(\psi_5'\psi_3 - \psi_1\psi_9) - c_1 r^3\epsilon^2(\psi_1'\psi_9 - \psi_5'\psi_2')]} \quad \ldots [46]$$

Limiting Cases

If $E_1 \to 0$ we have in the limit a core with faces of vanishing stiffness which have ceased to exert any constraint on the core. The corresponding limiting value of Equation [46] ($c_1 \to 0$, $c_2' \to 0$) should lead to the Euler value for cylindrical buckling of the core alone. The limiting value obtained is

$$s = \frac{\gamma - 1}{2} \cdot \frac{\sinh 2\epsilon - 2\epsilon}{\epsilon(\gamma \cosh^2 \epsilon - \sinh^2 \epsilon)}$$

This can be small only if ϵ is small, that is, if the wave length of the buckling deformation is many times the thickness. On expansion in powers of ϵ^2 the leading term is $\epsilon^2/[3(1 - \nu)]$ which is the Euler value.

If $r \to 0$, but E_1 is left unrestricted, we should again expect the same result and it is in fact obtained from Equation [46].

The limit of Equation [46] for long wave lengths ($\epsilon \to 0$) may be obtained by expanding the θ, ϕ, ψ functions in powers of ϵ^2 and so reducing Equation [46] is a power series in ϵ^2. The leading term of this expansion is

$$s = \frac{\dfrac{1}{3(1 - \nu_2)} + \dfrac{rE_1}{3(1 - \nu_1^2)G}(3 + 6r + 4r^2)}{1 + 2r\rho\dfrac{1 - \nu_1\nu_2 + 2r\rho(1 - \nu_2^2)}{1 - \nu_1^2 + 2r\rho(1 - \nu_1\nu_2)}} \cdot \epsilon^2$$

This, however, is exactly the result obtained by a simple direct calculation based upon the assumption that plane sections remain plane, using the straightforward flexural rigidity of the composite section in the Euler formula. We have therefore established that the sandwich plate, no matter how deformable the core is, will always buckle in the "plane sections remain plane" manner for a sufficiently long wave length. In fact, however, the wave length for a very deformable core will be that of short corrugation and will not be determined by the distance between supports. The present result contrasts with the conclusion by Gough, Elam, and de Bruyne that the critical stress for long wave lengths ($\epsilon \to 0$) approaches a nonzero limit.[4]

The Equations [34] and [37] for the displacements in the core take into account the destabilizing effect of the compressive stress in the core. If this effect is disregarded,[5] we put $s = 0$ in s_1, s_2, s_3, s_4, and s_5, and the resulting expressions are simply those of plane strain in the core. The effect of this in Equations [44a] and [42a] is the disappearance of the terms in χ_3, χ_4, χ_9, χ_{10}, χ_{12}, χ_{13}. The effect on Equation [46] is to leave the numerator unchanged, and to change the denominator to

$$c_2' r(\psi_1\psi_8 - \psi_6\psi_2) + c_1 r\epsilon^2 c_2' r(\psi_1'\psi_8 - \psi_6\psi_2') \quad \ldots [47]$$

The question arises as to whether the change is important or not. This depends upon the magnitude of [47], relative to that of the other terms in the denominator of Equation [46], which are

$$\phi + c_1 r\epsilon^2[\psi_5\psi_3' - \psi_1'\psi_{12} + r^2(\psi_5'\psi_3 - \psi_{11}\psi_8) - c_1 r^3\epsilon^2(\psi_1'\psi_9 - \psi_5'\psi_2')] \quad \ldots [48]$$

Now c_1 and c_2' are of the same order of magnitude as ρ, the ratio of the Young's moduli of face and core. Taking the ψ, θ, ϕ functions as of the same order of magnitude, it is clear that [48] will be small compared with [47] only if $r^2\epsilon^2$ is small compared with 1. If the faces are thin, r is small, but the buckling is then likely to take the form of corrugations of short wave length and so rather large ϵ. When the wave length is equal to the core thickness, the value of ϵ is π. Numerical evaluation of Equation [46] will show the range of validity of the method adopted by Gough, Elam, and de Bruyne and Hoff and Mautner for very deformable cores. At the other extreme it will show what range of core stiffnesses will cause the sandwich to buckle in a "plane sections remain plane" fashion to a given approximation.

Addendum

In deriving the boundary conditions [25] for the core the quantity $\sigma/2G$ ($= s$) was neglected in comparison with unity. From the physical point of view it appears unlikely that the stability criterion can be significantly affected by so small a change in the boundary forces of the core—or the faces. From the mathematical point of view the change is open to objection, since it does affect the coefficients of s and s^2 derived subsequently, and the final formula [46] obtained for the critical value of s. The required changes in the calculations follow.

The boundary conditions [25] become

$$q' = (1 + s)s_{12}, \quad p' = s_{22} \ldots\ldots\ldots\ldots [25c]$$

Thus Equation [39] remains unchanged but the right hand side of Equation [40] must be multiplied by $1 + s$.

Equation [42] now becomes

$$A'\{(c_1r^3\epsilon^3 - c_2s)\cosh\epsilon + 2\sinh\epsilon + (1 + s)\,2r\epsilon\cosh\epsilon\}$$
$$+ C'\{(c_1r^3\epsilon^3 - c_2s)(-s_3\cosh\epsilon + s_5\epsilon\sinh\epsilon + s_4\epsilon^2\cosh\epsilon$$
$$+ s_2\epsilon^3\sinh\epsilon) + \gamma(s_5 - s_3)\sinh\epsilon + [\gamma(s_5 + 2s_4) - \gamma + 2$$
$$+ r(1 + s)(1 - s_3)]\,\epsilon\cosh\epsilon + [\gamma(s_4 + 3s_2) - (\gamma - 2)s_1$$
$$+ r(1 + s)(1 + 2s_1 + s_5)]\epsilon^2\sinh\epsilon + [2s_2 + r(1 + s)$$
$$(s_1 + 3s_2 + s_4)]\epsilon^3\cosh\epsilon + 2r(1 + s)s_2\epsilon^4\sinh\epsilon\} = 0 \ldots [42c]$$

and Equation [44] becomes

$$A'\{2(1 + s)\cosh\epsilon + 3c_1r\,\epsilon\sinh\epsilon - 3c_1r^2\epsilon^2\cosh\epsilon\}$$
$$+ C'\{(1 + s)(1 - s_3)\cosh\epsilon + (1 + s)(1 + 2s_1 + s_5)\,\epsilon\sinh\epsilon$$
$$+ [(1 + s)(s_1 + 3s_2 + s_4) + 3c_1r + 3c_1r^2s_3]\epsilon^2\cosh\epsilon$$
$$+ [2(1 + s)s_2 + 3c_1rs_1 - 3c_1r^2s_5]\epsilon^3\sinh\epsilon + [3c_1rs_2 - 3c_1r^2s_4]\epsilon^4\cosh$$
$$\epsilon - 3c_1r^2s_2\epsilon^5\sinh\epsilon\} = 0 \ldots\ldots\ldots\ldots\ldots\ldots [44c]$$

These equations can be written in the form (replacing Equations [44a] and [42a])

$$A'(\chi_1 + 2\chi_6 s) + C'(\chi_2 + \chi_3 s + \chi_4 s^2) = 0 \ldots\ldots [44ac]$$
$$A'[\chi_5 + \chi_6(2r\epsilon - c_2)s] + C'[(\chi_7 - c_2 s)(\chi_8 + \chi_9 s + \chi_{10}s^2) + \chi_{11}$$
$$+ \chi_{12}s + \chi_{13}s^2] = 0 \ldots\ldots [42ac]$$

The definitions of the functions χ in terms of the functions ψ, ψ' are unchanged. The definitions of the functions ψ' are unchanged. The definitions of the functions ψ are unchanged except as follows:

$$\psi_3 : \text{Add } -\frac{2}{\gamma - 1}\cosh\epsilon + 2\epsilon\sinh\epsilon$$

$$\psi_4 : \text{Add } -\frac{\gamma(\gamma + 1)}{(\gamma - 1)^2}\cosh\epsilon + \frac{2}{\gamma - 1}\epsilon\sinh\epsilon - \epsilon^2\cosh\epsilon$$

$$\psi_{12} : \text{Add } r\left\{-\frac{2}{\gamma - 1}\cosh\epsilon + 2\epsilon\sinh\epsilon\right\}$$

$$\psi_{13} : \text{Add } r\left\{-\frac{\gamma(\gamma + 1)}{(\gamma - 1)^2}\cosh\epsilon + \frac{2}{\gamma - 1}\epsilon\sinh\epsilon - \epsilon^2\cosh\epsilon\right\}$$

Equation [45] for the critical value of s is now replaced by one derived from Equations [44ac] and [42ac]. The coefficient of s^2 is changed by the addition of

$$2\frac{\chi_6}{\chi_1}(\chi_7\chi_9 + \chi_{12} - c_2\chi_8) - 2r\epsilon\frac{\chi_3\chi_6}{\chi_1}$$

The term independent of s remains the same, both in form and in the definitions of the χ-functions. The changes in the coefficient of s may be seen from the final equation for s obtained by discarding the term in s^2. This is

$$\{\chi_1(\chi_7\chi_9 + \chi_{12} - c_2\chi_8) + 2\chi_6(\chi_7\chi_8 + \chi_{11}) - \chi_2\chi_6(2r\epsilon - c_2) -$$
$$\chi_3\chi_5\}s = \chi_2\chi_5 - \chi_1(\chi_7\chi_8 + \chi_{11}) \ldots\ldots\ldots\ldots [46c]$$

This result has been checked for the limiting cases considered in the paper. It satisfies them all. In the first result given under "Limiting Cases", to the term $\epsilon(\gamma\cosh^2\epsilon - \sinh^2\epsilon)$ appearing in the denominator, the term $-(1/2)(\gamma - 1)(\sinh 2\epsilon - 2\epsilon)$ must be added. Since this term is of order ϵ^3 it does not alter the conclusion.

Two further checks are possible, and are met by Equation [46c]. One is the limiting case $h \to 0$, so that the sandwich reduces to a plate of the face material of thickness $2t$. The limiting form of Equation [46c] yields the required Euler result for long wave lengths. The other is the limiting case $E_2 \to 0$, so that the sandwich reduces to two independent plates (the faces) of thickness t. The limiting form of Equation [46c] again yields the required Euler result for long wave lengths. Here the expansion in powers of ϵ^2 is made (to obtain the leading term) *after* passing to the limit as $E_2 \to 0$.

General Stress-Strain Laws of Elasticity and Plasticity

By A. GLEYZAL,[1] WASHINGTON, D. C.

The stress-strain laws discussed in this paper apply to problems where the material is elastic in some regions and plastic in others, for example, in a plastic-torsion problem or in a plastic-bending problem. These laws have experimental verification for metals in cases where strains are small and stresses and strains are either monotonically increasing or monotonically decreasing at any one point.

Introduction

THE laws to be considered are of the same form as the laws of elasticity. It is sometimes possible in a given plasticity problem to write down immediately the equations for the problem by merely referring to already known equations for the problem in the elastic case. Of course, account must be taken of the fact that the elastic constants are replaced by quantities which are functions of the strains.

The laws may be written in tensor form and apply to finite strains if the strain components of finite strain are defined in such a way that they form a tensor. For infinitesimal or finite strains the axes of principal stress coincide with the axes of principal strain. The stresses according to these laws depend upon the final strains alone and not upon the "strain path."

These laws for finite strains are therefore of simple nature. The extent of their validity would, however, require experimental determination for any given material.

The General Stress-Strain Law

The general laws we shall consider for elasticity and plasticity are

$$\left.\begin{aligned} &\frac{\sigma_1-\sigma_2}{\epsilon_1-\epsilon_2}=\frac{\sigma_2-\sigma_3}{\epsilon_2-\epsilon_3}=\frac{\sigma_3-\sigma_1}{\epsilon_3-\epsilon_1} \quad [1a]\\ &\tau=\tau(\gamma) \quad [1b]\\ &\sigma=\sigma(\delta) \quad [1c]\end{aligned}\right\} \quad [1]$$

where, by definition

$$\left.\begin{aligned} &\tau=\frac{1}{3}\sqrt{(\sigma_1-\sigma_2)^2+(\sigma_2-\sigma_3)^2+(\sigma_3-\sigma_1)^2} \quad [2a]\\ &\gamma=\frac{1}{3}\sqrt{(\epsilon_1-\epsilon_2)^2+(\epsilon_2-\epsilon_3)^2+(\epsilon_3-\epsilon_1)^2} \quad [2b][2]\\ &\sigma=\frac{1}{3}(\sigma_1+\sigma_2+\sigma_3) \quad [2c]\\ &\delta=\frac{1}{3}(\epsilon_1+\epsilon_2+\epsilon_3) \quad [2d]\end{aligned}\right\} \quad [2]$$

$\sigma_1, \sigma_2, \sigma_3$, and $\epsilon_1, \epsilon_2, \epsilon_3$ are principal stresses and strains, respectively, whose axes are assumed to coincide at each point of the material. Later these equations will be expressed in general tensor form and this requirement on the principal axes will be a consequence of the tensor equations. The terms $\tau(\gamma)$ and $\sigma(\delta)$ are functions associated with the material, the same for all types of deformation, provided that all strains are either monotonically increasing or monotonically decreasing.

Nadai (1)[3] has shown that for small strains, τ and γ as just given are, respectively, the shear stress and shear strain in an octahedral plane, i.e., a plane making equal angles with each of the three principal directions of stress.

The first and second of Equations [1] have been considered by Nadai (2) and subjected to experimental verification by Schmidt (3) and Davis (4). The third law is a new plasticity law which we consider in conjunction with the other two plasticity laws in this paper. It may be stated as follows: The average stress σ at a point is an invariant function of the average strain δ at the point for a given material.

Implications and Development

Equations [1] are three equations in the three principal stresses and three principal strains. They may be solved for the principal stresses in terms of the principal strains as follows: Let λ be the ratio

$$\lambda=\frac{\sigma_1-\sigma_2}{\epsilon_1-\epsilon_2}=\frac{\sigma_2-\sigma_3}{\epsilon_2-\epsilon_3}=\frac{\sigma_3-\sigma_1}{\epsilon_3-\epsilon_1}$$

Multiplying both members of Equation [2b] by λ there is found, using Equation [2a]

$$\lambda=\tau/\gamma$$

Equation [1a] may then be rewritten

$$\left.\begin{aligned} &\sigma_1-\sigma_2=\frac{\tau}{\gamma}(\epsilon_1-\epsilon_2)\\ &\sigma_2-\sigma_3=\frac{\tau}{\gamma}(\epsilon_2-\epsilon_3)\\ &\sigma_3-\sigma_1=\frac{\tau}{\gamma}(\epsilon_3-\epsilon_1)\end{aligned}\right\} \quad [3]$$

Using the first two of Equations [3], we get by subtraction

$$\sigma_1+\sigma_3-2\sigma_2=\frac{\tau}{\gamma}(\epsilon_1+\epsilon_3-2\epsilon_2)$$

or

$$\sigma_1+\sigma_2+\sigma_3-3\sigma_2=\frac{\tau}{\gamma}(\epsilon_1+\epsilon_2+\epsilon_3-3\epsilon_2)$$

Therefore

[2] Employment of $1/3$ or $2/3$ as coefficient in the expression for γ depends on the choice of definition of shear strain. For this report we have used $1/3$.

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of The American Society of Mechanical Engineers.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1947, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

$$\sigma_2 = \frac{\tau}{\gamma}(\epsilon_2 - \delta) + \sigma$$

This equation may also be written

$$\sigma_2 = \frac{\tau}{\gamma}\epsilon_2 + \left(\frac{\sigma}{\delta} - \frac{\tau}{\gamma}\right)\delta$$

Two similar equations exist for σ_1 and σ_3. Thus when the two invariant functions $\sigma = \sigma(\delta)$ and $\tau = \tau(\gamma)$ are known, the following equations give the principal stresses in terms of principal strains only

$$\left.\begin{aligned}\sigma_1 &= \frac{\tau}{\gamma}\epsilon_1 + \left(\frac{\sigma}{\delta} - \frac{\tau}{\gamma}\right)\delta \\ \sigma_2 &= \frac{\tau}{\gamma}\epsilon_2 + \left(\frac{\sigma}{\delta} - \frac{\tau}{\gamma}\right)\delta \\ \sigma_3 &= \frac{\tau}{\gamma}\epsilon_3 + \left(\frac{\sigma}{\delta} - \frac{\tau}{\gamma}\right)\delta\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [4]$$

We now write these laws in tensor form in order to facilitate their use in non-Cartesian co-ordinate systems and to remove the possibility of ambiguity of their meaning. After the laws have been so written we shall return again to the Cartesian notation.

It follows from Equations [2] and [4] and the requirement that the principal axes of stress coincide with those of principal strain that the general tensor equation is referred to an arbitrarily chosen curvilinear system of co-ordinates x^i, $i = 1, 2, 3$, is

$$\sigma_{ij} = \frac{\tau}{\gamma}\epsilon_{ij} + \delta\left(\frac{\sigma}{\delta} - \frac{\tau}{\gamma}\right)g_{ij}, \quad (i, j = 1, 2, 3) \ldots\ldots [5]$$

where σ_{ij} is the stress tensor, and the quantities ϵ_{ij}, g_{ij}, σ, δ, τ and γ are defined as follows:

A definition of a strain tensor ϵ_{ij} which has a clear meaning for finite strains as well as infinitesimal strains is obtained by setting $\epsilon_{ij} = (1/2)(g_{ij} - h_{ij})$, where the co-ordinate system x^i, $i = 1, 2, 3$, is considered to remain embedded in the material as it deforms and the two tensors h_{ij} and g_{ij} are the coefficients of the fundamental tensor in the x^i co-ordinate system before and after deformation, respectively. That is, the square of the differential of arc length before deformation is

$$ds^2 = \sum_j \sum_i h_{ij}dx^i dx^j, \quad (i, j = 1, 2, 3)$$

and after deformation is

$$ds^2 = \sum_j \sum_i g_{ij}\, dx^i\, dx^j, \quad (i, j = 1, 2, 3)$$

The invariant quantities σ, δ, τ, and γ for the general co-ordinate system x^i are

$$\sigma = \frac{1}{3}\sum_j \sum_i g^{ij}\sigma_{ij}, \quad (i, j = 1, 2, 3)$$

$$\delta = \frac{1}{3}\sum_j \sum_i g^{ij}\epsilon_{ij}, \quad (i, j = 1, 2, 3)$$

$$\tau = \frac{1}{3}\left[3\left(\sum_l \sum_k \sum_j \sum_i g^{ij}g^{kl}\sigma_{ik}\sigma_{jl}\right) - \left(\sum_j \sum_i g^{ij}\sigma_{ij}\right)^2\right]^{1/2}, \quad (i, j, k, l = 1, 2, 3)$$

$$\gamma = \frac{1}{3}\left[3\left(\sum_l \sum_k \sum_j \sum_i g^{ij}g^{kl}\epsilon_{ik}\epsilon_{jl}\right) - \left(\sum_j \sum_i g^{ij}\epsilon_{ij}\right)^2\right]^{1/2}, \quad (i, j, k, l = 1, 2, 3)$$

where the contravariant tensor g^{ij} is computed from the values of g_{ij} by solving the following system of nine linear equations.

$$\sum_j g^{ij}g_{jk} = \delta^i{}_k, \quad (i, j, k = 1, 2, 3)$$

$\delta^i{}_k$ in this equation is the "*Kronecker delta*," that is, $\delta^i{}_k = 0$ if $i \neq k$ and $\delta^i{}_k = 1$ if $i = k$.

Equation [5] implies that at all times the principal axes of stress coincide with those of finite strain.

These equations are similar to the elasticity equations and suggest the following equations to be satisfied by generalized quantities E and ν, where E is Young's modulus and ν is Poisson's ratio

$$\left.\begin{aligned}\frac{E}{1+\nu} &= \frac{\tau}{\gamma} \\ \frac{E}{1+\nu}\frac{\nu}{1-2\nu} &= \frac{1}{3}\left(\frac{\sigma}{\delta} - \frac{\tau}{\gamma}\right)\end{aligned}\right\} \quad \ldots\ldots\ldots [6]$$

In the elastic range, when E and ν are constant, the expression $\frac{1}{3}\cdot\frac{E}{(1-2\nu)}$ is the bulk modulus of elasticity as would be expected; the quantity $E/(1+\nu)$ may be termed the octahedral-shear modulus.

We may solve Equations [6] for E and ν in terms of τ, γ, σ, and δ; there results

$$\left.\begin{aligned}E &= \frac{3\frac{\tau}{\gamma}}{2 + \frac{\delta}{\sigma}\frac{\tau}{\gamma}}; \qquad \nu = \frac{1 - \frac{\delta}{\sigma}\frac{\tau}{\gamma}}{2 + \frac{\delta}{\sigma}\frac{\tau}{\gamma}}\end{aligned}\right\} \quad \ldots\ldots\ldots [7]$$

Consequently the general stress-strain relations are given either by Equations [4] or by the following equation of familiar form

$$\left.\begin{aligned}\sigma_1 &= \frac{E}{1+\nu}\left(\epsilon_1 + \frac{\nu}{1-2\nu}\Delta\right) \\ \sigma_2 &= \frac{E}{1+\nu}\left(\epsilon_2 + \frac{\nu}{1-2\nu}\Delta\right) \\ \sigma_3 &= \frac{E}{1+\nu}\left(\epsilon_3 + \frac{\nu}{1-2\nu}\Delta\right)\end{aligned}\right\} \quad \ldots\ldots\ldots [8]$$

where $\Delta = 3\delta$, E and ν are defined by Equations [7], and $\tau(\gamma)$ and $\sigma(\delta)$ are considered to be known functions which for our purposes define the material.

Since τ and σ are functions of γ and δ, respectively, E and ν may each be regarded as functions of the three principal strains ϵ_1, ϵ_2, and ϵ_3 only. E and ν then may also be considered to be the fundamental functions which describe the material, in place of $\tau(\gamma)$ and $\sigma(\delta)$.

A step in the direction of generalization would be to assume at the start of a theory that the two functions

$$\tau = \tau(\gamma, \delta)$$

and

$$\sigma = \sigma(\gamma, \delta)$$

are functions of γ and δ, instead of γ alone or of δ alone. In view of experimental evidence one may go, rather, in the direction of particularization and consider that $\sigma(\delta)$ is the linear function $3k\delta$, where the constant k is the bulk modulus of elasticity for the material. That the same value of k is also reasonably valid in the plastic range has been verified experimentally for a number of materials in the case of compression (5, 6). Equations [7] show that if $\sigma = 3k\delta$, then E and ν do not depend on δ but only on γ.

Equionsat [8] may be solved for the strains giving

$$\left.\begin{aligned} \epsilon_1 &= \frac{1}{E}\left[\sigma_1 - \nu\,(\sigma_2 + \sigma_3)\right] \\ \epsilon_2 &= \frac{1}{E}\left[\sigma_2 - \nu\,(\sigma_3 + \sigma_1)\right] \\ \epsilon_3 &= \frac{1}{E}\left[\sigma_3 - \nu(\sigma_1 + \sigma_2)\right] \end{aligned}\right\} \quad \ldots\ldots\ldots [9]$$

If ν is taken to be $^1/_2$ in these equations it is seen that the mean strain $\delta = {}^1/_3\,(\epsilon_1 + \epsilon_2 + \epsilon_3)$ is identically zero.

If it is assumed that $\delta = 0$, Equations [1] reduce to certain well-known laws of plasticity (1, 2). Thus Equations [4] or [9] include simultaneously both these plasticity laws and the ordinary elasticity equations.[4]

It is interesting to note that Equations [1] imply, when $\sigma = 3k\delta$, that different hydrostatic pressures p applied to a solid do not change the relationship of the increments of stress, $\sigma_1 - p$, $\sigma_2 - p$, $\sigma_3 - p$ and strain, $\epsilon_1 - p/3k$, $\epsilon_2 - p/3k$, $\epsilon_3 - p/3k$. In other words, suppose stress-strain measurements in the elastic or plastic range are made upon a solid under ordinary atmospheric pressure. Then imagine the entire test laboratory to be put under high atmospheric pressure and the test repeated. The observed stresses and strains will have, according to Equations [1], the same relation in the second test as in the first test. To prove this statement we need merely note that if $\sigma_1, \sigma_2, \sigma_3; \epsilon_1, \epsilon_2, \epsilon_3$, satisfy Equations [1] with $\sigma = 3k\delta$, then the quantities

$$\bar{\sigma_1} = \sigma_1 + p, \quad \bar{\sigma_2} = \sigma_2 + p, \quad \bar{\sigma_3} = \sigma_3 + p$$
$$\bar{\epsilon_1} = \epsilon_1 + p/3k, \quad \bar{\epsilon_2} = \epsilon_2 + p/3k, \quad \bar{\epsilon_3} = \epsilon_3 + p/3k$$

also satisfy Equations [1], with $\bar{\sigma} = 3k\bar{\delta}$, for all values of p. After compression of the entire test laboratory the stresses and strains are $\sigma_1 = p$, $\sigma_2 = p$, $\sigma_3 = p$, $\epsilon_1 = p/3k$, $\epsilon_2 = p/3k$, $\epsilon_3 = p/3k$. Hence the observed quantities in the repeated test after compression are $\sigma_1 = \bar{\sigma_1} - p$, $\sigma_2 = \bar{\sigma_2} - p$, $\sigma_3 = \bar{\sigma_3} - p$, $\epsilon_1 = \bar{\epsilon_1} - p/3k$, $\epsilon_2 = \bar{\epsilon_2} - p/3k$, $\epsilon_3 = \bar{\epsilon_3} - p/3k$. These stresses and strains are identical with those of the original test.

When the shear strains are small Equations [1], [8], or [9] are the laws of elasticity even though the principal strains may be large, as when a high hydrostatic pressure is applied. When the

[4] It is not possible to solve for stresses in terms of strain if δ is taken to be zero, since the stresses are then determined only up to an additive quantity which may be taken to be the hydrostatic stress.

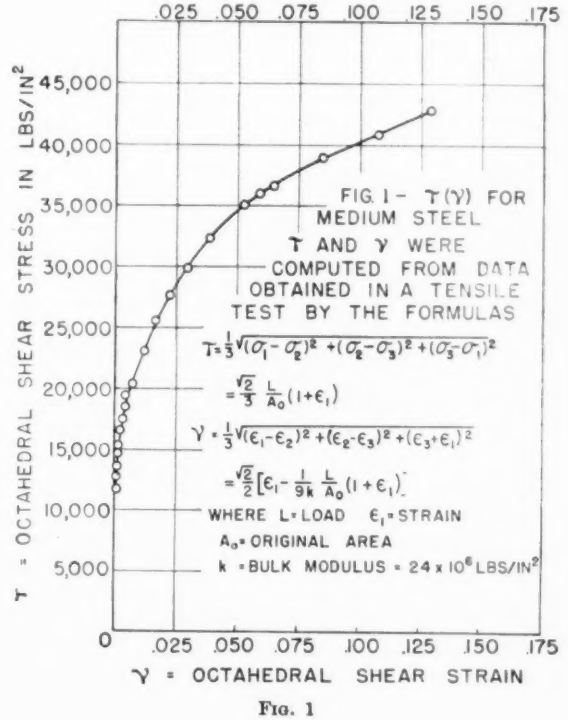

Fig. 1

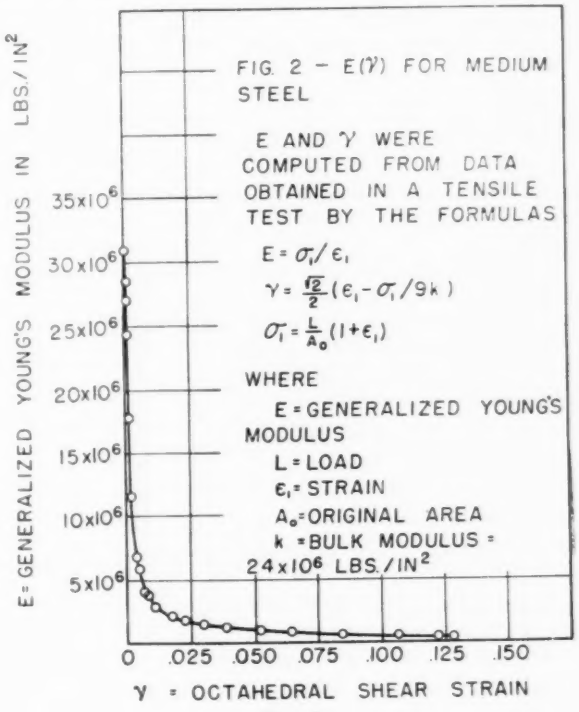

Fig. 2

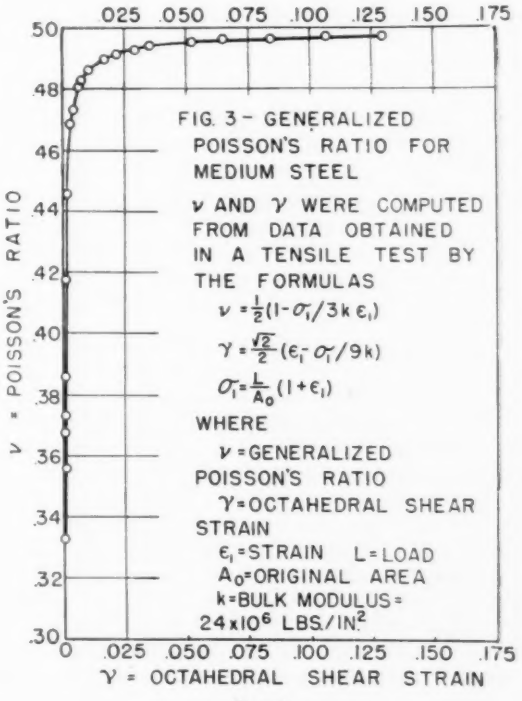

Fig. 3

shear strains are large these equations are very nearly the plasticity equations written in the foregoing. These facts correspond to the known properties of a material such as steel in its elastic and plastic behavior under ordinary or under high pressures.

$\tau(\gamma)$ and $\sigma(\delta)$ in Terms of Quantities Measured in a Tensile Test

To complete the theory of this paper we write equations for the two invariant functions $\tau(\gamma)$ and $\sigma(\delta)$ in terms of quantities measured in a tensile test. Let σ_1, $\sigma_2 = 0$, $\sigma_3 = 0$, be the stresses and ϵ_1, $\epsilon_2 = \epsilon_3$, be the strains in a tensile test. In elasticity theory it is known that

$$E = \sigma_1/\epsilon_1$$

and

$$\nu = -\epsilon_2/\epsilon_1$$

But these equations apply equally well in the present theory since they may be derived from the general stress-strain relations, Equations [8].

Thus E is the slope of the line joining a point on the uniaxial stress-strain curve to the origin. The quantity ν is Poisson's ratio (5) and should be expected to vary between its value of approximately 0.3 in the elastic range and its approximate value 0.5 in the plastic range.

If the function $\sigma(\delta)$ is taken to be $3k\delta$ the parametric equations for E and ν in terms of σ_1 and ϵ_1 may be found as follows: The equation $\sigma = 3k\delta$ implies for the tensile specimen

$$\sigma_1 = 3k\,(\epsilon_1 + 2\epsilon_2)$$

therefore

$$\epsilon_2 = -\frac{1}{2}\,\epsilon_1 + \frac{1}{6}\,\sigma_1/k \qquad [10]$$

Consequently the parametric equations for E and ν are

$$E = \sigma_1/\epsilon_1$$

$$\nu = \frac{1}{2}\left(1 - \frac{1}{3}\,\frac{\sigma_1}{\epsilon_1}\,\frac{1}{k}\right)$$

As ϵ_1 increases, σ_1/ϵ_1 becomes small in comparison with k and as a consequence ν approaches 1/2 as expected. Equations [2] for τ and γ imply for the tensile test

$$\tau = \frac{\sqrt{2}}{3}\,\sigma_1 \qquad \gamma = \frac{\sqrt{2}}{3}\,(\epsilon_1 - \epsilon_2)$$

Making use of Equations [8], the parametric equations for τ and γ are found to be

$$\tau = \frac{\sqrt{2}}{3}\,\sigma_1 \qquad \gamma = \frac{\sqrt{2}}{2}\,(\epsilon_1 - 1/9\,\sigma_1/k)$$

The term $\frac{1}{9}\,\sigma_1/k$ becomes negligible in comparison with ϵ_1 as ϵ_1 increases, but is appreciable for ϵ_1 in the elastic range. Inclusion of this term in the equation for γ is therefore of some importance in a tensile-test determination of $\tau(\gamma)$ for ranges which include the elastic range.

Fig. 1 shows a graph of $\tau(\gamma)$ for medium steel computed from results of a tensile test where we have assumed $k = 24 \times 10^4$ psi. Figs. 2 and 3 show E and ν corresponding to this $\tau(\gamma)$ for the case where $\sigma = 3k\delta$.

Supersonic Nozzle Design

By A. E. PUCKETT,[1] PASADENA, CALIF.

A two-dimensional flow field in which the velocity is everywhere supersonic can always be represented approximately by a number of small adjacent quadrilateral flow fields in each of which the velocity and pressure are constant. These quadrilaterals must be separated by lines representing waves in the flow; changes in velocity and pressure through any wave can be computed. By increasing the number of small areas into which the complete flow field is divided, the accuracy of this approximate solutions may be increased without limit. This constitutes the "method of characteristics" solution, which has been known for many years. This method may be applied to the graphical computation of flow in a supersonic nozzle, with the particular aim of producing uniform supersonic flow at the end of the nozzle. It is pointed out that such a computation is essentially simple and rapid, and its essential features are presented in a form which, it is hoped, may be easily applied to engineering problems.

Nomenclature

The following nomenclature will be used in the paper:

- w = velocity of flow
- a = velocity of sound
- $\mathbf{M}$ = Mach number = w/a
- a^* = critical speed of sound
- θ = Prandtl-Meyer angle
- θ_a = flow inclination
- N = speed index = 2θ
- γ = ratio of specific heats, C_p/C_v
- A_e = nozzle exit area
- A^* = nozzle throat area

Introduction

The computation of exact or nearly exact flows of a frictionless incompressible fluid around general two-dimensional boundaries offers problems of some mathematical difficulty. The additional condition that the density of the fluid may vary will complicate the problem under certain conditions; however, in those cases where the velocities in the flow field are everywhere greater than the local speed of sound, a fundamental simplication occurs. The equations of motion assume such a form that they may be solved graphically, in a step-by-step process. This process is known to mathematicians as the "method of characteristics." It was first applied to supersonic flows by Prandtl and Busemann (1)[2] in 1929 and has been much used since. Although the discussion in the present paper is limited to two-dimensional flows, a similar but more complicated method has been developed for three-dimensional flows, with axial symmetry (2).

The "method of characteristics" provides a means of computing the flow through a given two-dimensional supersonic nozzle. It also provides a means of determining the shape of the walls of a supersonic nozzle in such a way that the velocity at the end of the nozzle is uniform and parallel across the entire section. The use of the method of characteristics for this purpose was also described by Prandtl and Busemann, and has been familiar to aerodynamists for some years; it is primarily for the purpose of making the technique more accessible to engineers that it is described in the present paper.

A rigorous mathematical derivation of the method of characteristics can be given; it can be shown in this way that by taking sufficiently small steps in the process, the result may be brought arbitrarily close to the exact continuous solution. It is only in this sense that the solution is approximate; its error can be made as small as desired. It is also possible to deduce the method from much more simple physical reasoning; this course will be pursued in the present paper and, it is hoped, will compensate in clarity for any lack of mathematical rigor.

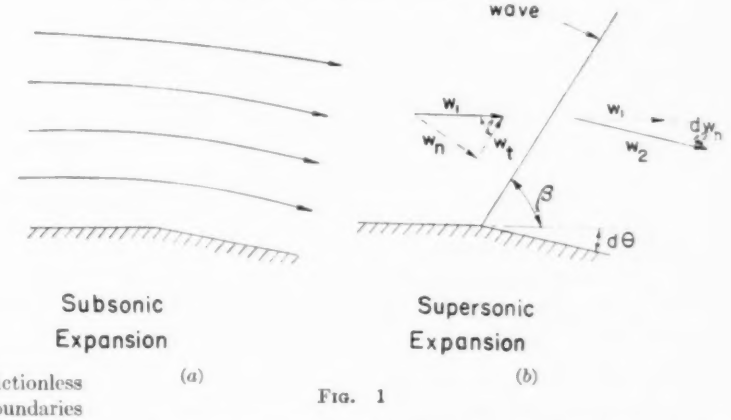

Fig. 1

The basic feature of a supersonic flow which distinguishes it from subsonic flow is the fact that a disturbance in the boundary of the flow makes its presence known only in roughly one half of the total flow field, that is, a disturbance produces a standing wave in the flow and the effect of the disturbance is felt only downstream of the wave. In Fig. 1(*a*) is shown the effect of a sudden expansion in the wall bounding a subsonic flow; it is seen that the effect is propagated symmetrically through the whole field.

The same disturbance in a supersonic flow will produce a standing wave, propagating in a downstream direction. In Fig. 1(*b*) is shown the resulting supersonic flow field. The initial velocity w_1, is undisturbed upstream from the wave and is changed to w_2 on the downstream side. If we thus construct a flow field by adding in the effect of one disturbance after another, proceeding in a downstream direction, the solution upstream will not be disturbed. It can be shown that a general supersonic flow field can be imagined to consist of an infinite number of such disturbance waves. The fundamental idea of the method of characteristics is to replace the infinite number of waves by a finite number which can then be treated separately. In the areas between waves, the velocity magnitude and direction are considered constant. Therefore it is necessary to replace the actual boundaries of the flow by approximate boundaries with a finite number

Presented at the National Meeting of the Applied Mechanics Division, Buffalo, N. Y., June 21–22, 1946, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1947, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

of disturbances. In other words, a curved boundary is replaced by a number of straight-line segments, with a definite angle between each.

Changes Through a Single Wave

The only mathematical treatment necessary is the computation of the flow changes produced by a single disturbance wave. The effect of the wave produced by the wall bend in Fig. 1(*b*) is to deflect the flow through an angle $d\theta$. It also produces a change in the speed and pressure of the flow, which are determined only by $d\theta$. These changes may be computed from the simple equations of motion for the fluid in differential form. If w_n is the component of w_1 normal to the wave, then conservation of mass for the flow across the wave requires that

$$\rho w_n = (\rho + d\rho)(w_n + dw_n) \quad [1]$$

or

$$w_n d\rho + \rho dw_n = 0$$

Let w_t be the component of w_1 parallel to the wave front; then conservation of momentum parallel to the wave requires that

$$\rho w_n w_t = (\rho + d\rho)(w_n + dw_n)(w_t + dw_t) \quad [2]$$

or

$$dw_t = 0$$

That is, the only velocity increment produced by the wave is normal to it. The momentum component normal to the wave is conserved if

$$\rho w_n dw_n + dp = 0 \quad [3]$$

Eliminating dw_n between Equations [1] and [3] gives

$$w_n^2 = \frac{dp}{d\rho} = a^2 \quad [4]$$

where a is the local speed of sound.

Thus the velocity component normal to the wave is the speed of sound. Use of the energy equation will show that the process across the wave is isentropic, and $dp/d\rho$ is computed using the isentropic law

$$p = \text{const}\ \rho^\gamma \quad [5]$$

Since $w_n = w \sin \beta$ where β is the wave angle, we have

$$\sin \beta = \frac{a}{w} = \frac{1}{\mathbf{M}} \quad [6]$$

where $\mathbf{M}$ is the local Mach number. The wave angle β is then called the "Mach angle." The increase in length of the velocity w_1 is given by

$$dw = dw_n \sin \beta \quad [7]$$

while the change in flow direction must be equal to

$$d\theta = \frac{dw_n \cos \beta}{w} \quad [8]$$

From Equations [7] and [8], the relation between increase in speed and change in flow direction is immediately found

$$\frac{dw}{w} = \tan \beta\, d\theta$$

or using Equation [6]

$$\frac{dw}{w} = \frac{d\theta}{\sqrt{\mathbf{M}^2 - 1}} \quad [9]$$

This equation is the only result necessary to perform the step-by-step computation through any number of waves. It must be observed, however, that $\mathbf{M}$ is a function of w which must include the variation in the speed of sound, a, with w. The Mach number and w are related by

$$\left(\frac{w}{a^*}\right)^2 = \frac{\gamma + 1}{\gamma - 1 + 2/\mathbf{M}^2} \quad [10]$$

where a^* is the "critical speed of sound," a constant for the entire flow. This may be deduced from the energy equation for the fluid (3). If this relation is used in Equation [9], with $\bar{w} = w/a^*$, then

$$d\theta = \sqrt{\frac{\bar{w}^2 - 1}{1 - \frac{\gamma - 1}{\gamma + 1}\bar{w}^2}} \cdot \frac{d\bar{w}}{\bar{w}} \quad [11]$$

With Equation [11] the successive flow changes through a series of bends in a wall, such as in Fig. 2, may be computed. If

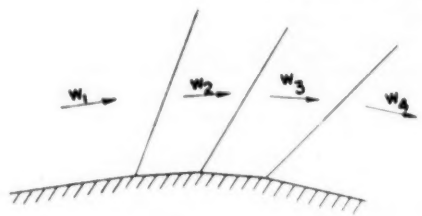

Fig. 2

$\bar{w}_1$ is given, the increments producing $\bar{w}_2$ and $\bar{w}_3$ are obtained from Equation [11]; it is necessary to compute only the Mach numbers corresponding to $\bar{w}_1$, $\bar{w}_2$, and $\bar{w}_3$ in order to draw the Mach wave at the proper angles, as given by Equation [6]. It should be pointed out that the waves described so far are "expansion waves," since the $d\theta$ shown will, according to Equations [9] and [3], produce a drop in pressure.

The evaluation of Equation [11] for every wave in the flow becomes a tedious computation, but may be avoided by noticing that Equation [11] may be integrated, resulting in a function $\theta = \theta(\bar{w})$. Since $\bar{w}$ is also a function of $\mathbf{M}$, we may finally express θ as a function of $\mathbf{M}$; the explicit relation becomes

$$\theta = \sqrt{\frac{\gamma + 1}{\gamma - 1}} \tan^{-1}\left[\sqrt{\frac{\gamma - 1}{\gamma + 1}}\sqrt{\mathbf{M}^2 - 1}\right] - \tan^{-1}\sqrt{\mathbf{M}^2 - 1} \quad [12]$$

The constant of integration has been chosen so that $\theta = 0$ at $\mathbf{M} = 1$. This is, of course, the relation obtained by Prandtl and Meyer (4), in computing the flow around a single sharp corner. The θ so defined is sometimes called the Prandtl-Meyer expansion angle. The function may be tabulated for small integral increments in θ, such as 1 deg. This is done in Table 1. It is now convenient to subdivide the boundaries of the flow in such a way that the angles between adjacent segments are integral multiples of 1 deg. It will also be convenient to let the Mach number in the initial flow region correspond exactly to one of the entries in Table 1. Then the Mach number resulting from the disturbance of any further waves in the flow can be read directly from the table. For instance, if, in Fig. 1(*b*), the initial velocity w_1, represents a Mach number of $\mathbf{M} = 2.022$, and $d\theta = 2$ deg, the Mach number following the wave will be $\mathbf{M} = 2.096$.

The foregoing computations will apply equally well to a wave originating at a disturbance on the upper boundary of the flow, as in Fig. 3. The only difference is that in this case the expansion

wave produces an upward deflection of the flow. It is seen that all disturbance waves will belong in one of two classes or families; those produced by disturbances on the lower wall, which we call the "lower family," and those produced by disturbances on the upper wall, which we may call the "upper family."

Intersection of Two Waves

The only fundamental problem now remaining in the computation of a supersonic flow field is the investigation of the flow following the intersection of two waves of opposite families. Such an intersection is indicated in Fig. 4. If $\mathbf{M}_1$ is given, then $\mathbf{M}_2$ and $\mathbf{M}_3$ are determined by $d\theta_1$ and $d\theta_2$, respectively. The important remaining physical fact is that the wave W_1 which produced an initial deflection of $d\theta_1$ in the flow will continue to produce the same deflection after it has intersected W_2, that is, W_1' produces also a deflection

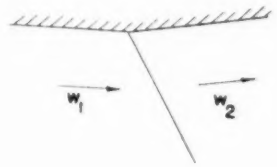

Fig. 3

$$\left.\begin{aligned} a + b &= N \\ (a - b)/2 &= \theta_a \end{aligned}\right\} \qquad [13]$$

It is now apparent that a wave of the upper family of strength $d\theta$ increases a by $2d\theta$, while a wave of the lower family increases b by $2d\theta$. The co-ordinate a records only changes due to the upper family and b records only changes due to the lower family. This is illustrated in Fig. 5 where both waves are assumed to be of strength $d\theta$.

The process of computing the flow change from one region to another, as in Fig. 4, is thus reduced to the purely mechanical process of making appropriate changes in a (or b) for each passage through a wave of the upper (or lower) family. The local speed and flow direction may be determined immediately from Equations [13]. The disturbance waves are drawn at the Mach angles determined by the local Mach number, as listed in Table 1. The accuracy of the construction will be improved by using the average of the wave angles corresponding to the Mach numbers before and after a wave. The angle must then be measured relative to the average flow direction. This average wave angle can

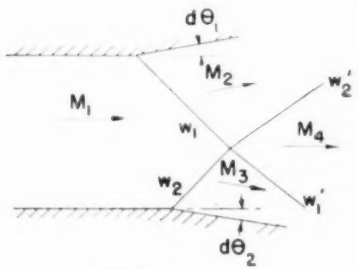

Fig. 4

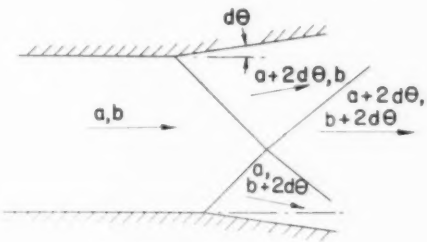

Fig. 5

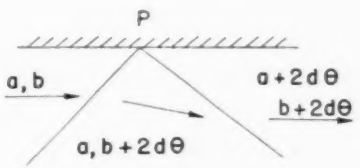

Fig. 6

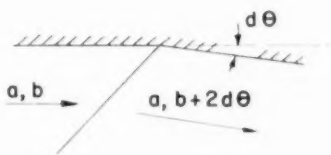

Fig. 7

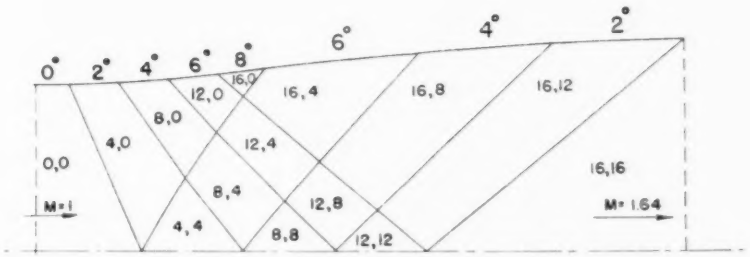

Fig. 8

$d\theta_1$. The same is true of W_2. The Mach number $\mathbf{M}_4$ is obtained from $\mathbf{M}_1$ by finding the θ corresponding to $\mathbf{M}_1$ in Table 1, and adding increments $d\theta_1$ and $d\theta_2$. It is seen that the flow which passes through W_2 and W_1' will experience the same Mach number change as that passing through W_1 and W_2'. The direction of the flow in region 4 will be determined by the fact that the flow has been deflected through an angle $(d\theta_1 - d\theta_2)$ upward, in going through either W_1 and W_2' or W_2 and W_1'. The only "graphical construction" of this elementary flow field lies in drawing the waves W_2' and W_1' at the Mach angles determined by $\mathbf{M}_2$ and $\mathbf{M}_3$, measured relative to the flow direction in regions 2 and 3.

It is desirable to have some notation for recording conveniently the Mach numbers and flow directions in each successive elementary flow field. Let the direction of the velocity vector in any flow region, referred to any initial datum direction, be denoted by θ_a. The speed or Mach number in any region may be described by the θ defined in Equation [12] and tabulated in Table 1; for reasons connected with the more rigorous mathematical development of the method it is actually convenient to adopt the speed index N, where $N = 2\theta$. Thus N is a function only of $\mathbf{M}$. We may now define the flow direction and Mach number in each region by a pair of numbers (a, b) having the following properties

be obtained directly by interpolation in Table 1.

Intersection of Wave and Wall

One more basic elementary wave pattern must be mentioned before proceeding with the design of a supersonic nozzle. If a wave from one wall strikes a straight segment of the opposite wall, it is reflected, but in a manner which must be computed. In Fig. 6 an expansion wave W_1 strikes the upper wall at P. It must be reflected in such a way that the flow is deflected again parallel to the wall; therefore the strength of W_1' (as measured by the deflection it produces) is the same as W_1. The reflected wave now belongs to the upper family, but is still an expansion wave. The angle of the reflected wave is not, of course, equal to the angle of the incident wave.

Had the wall to the right of P in Fig. 6 been inclined downward at angle $d\theta$, as in Fig. 7, that is, parallel to the flow in region 2, no reflected wave would be required to satisfy the boundary condition. This might be described as "canceling" the incoming wave since W_1 simply ends on the wall. It will be seen later that this is one of the fundamental principles required in the design of a supersonic nozzle.

The tools are now at hand to compute the flow through or to

design a supersonic nozzle. The principal elements of such a nozzle are shown in Fig. 8. The nozzle is considered to commence at the throat, across which it is assumed that the Mach number is uniformly 1; the validity of this assumption will depend on the shape of the subsonic contraction section which must precede the throat. An expanding section follows and then a return to a parallel section at the end of the nozzle. It is generally the object of the nozzle design to produce a uniform parallel flow in this exit section, which in our computational system means simply a flow with no disturbance waves present.

Nozzle Design

(*a*) *Maximum Expansion.* The simplest type of nozzle design is illustrated in Fig. 8. The shape of the initial expansion is arbitrary up to the point where the maximum expansion angle is reached, being governed generally by considerations of continuity with the curvature of the subsonic contraction. In Fig. 8 the diverging wall is represented by segments at angles of 2 deg to each other, and expanding up to a maximum angle of 8 deg. Four expansion waves are produced and their graphical construction follows the procedure previously outlined. The nozzle may be drawn symmetrically about the center line, or, as is done here, the center line is replaced by a solid wall; the flow solution must be the same in either case. The four initial expansion waves are reflected from the center line and return to the outer wall.

It is now that the fundamental idea of the nozzle design is applied; in order to achieve an ultimately wave-free supersonic flow, each of these expansion waves must be canceled at some time, using the principle illustrated in Fig. 7. At the point where the first returning expansion wave strikes the wall, the wall is deflected inward by an amount equal to the strength of the wave, in this case 2 deg. This is done with each of the other waves. When the last wave has been canceled, the walls have automatically become parallel again, and a uniform wave-free flow is produced. In this case the final Mach number will be **M** = 1.638. The wall shape following the point where the last expansion wave was produced is completely determined by the graphical construction.

It will be noticed that 8 deg is the largest expansion angle which could have been used to produce this Mach number without the introduction of compression waves and hence an actual recontraction in the nozzle. Thus the maximum permissible expansion angle for any nozzle design is exactly one half of the "Prandtl-Meyer" angle θ, corresponding to the final Mach number, or

$$\theta_{max} = N/4 \quad [14]$$

(*b*) *Less Than Maximum Expansion.* A design utilizing this maximum permissible expansion angle to produce a certain Mach number, will produce the shortest possible nozzle for a given initial rate of divergence (curvature). However, the same Mach number can be produced in a nozzle having any expansion angle

less than 8 deg by allowing the initial expansion waves to reflect a proper number of times from the wall. For instance, in Fig. 9 is shown a nozzle design for the same Mach number, using a maximum expansion angle of 4 deg. The elimination of 4 deg of expansion on the wall from the previous design requires the

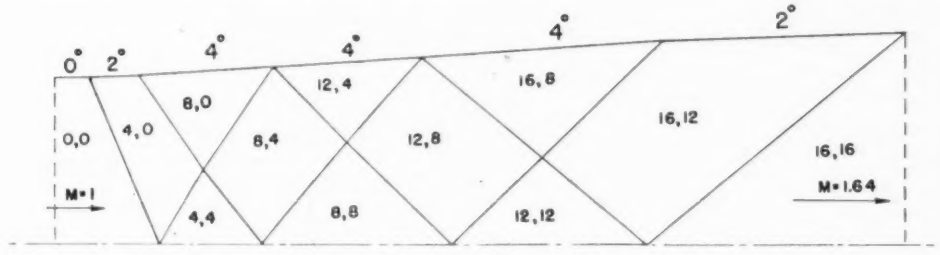

FIG. 9

reflection of two 2-deg waves, to supply the additional required expansion in the flow. Thus if the maximum permissible expansion angle is θ_{max}, and the expansion angle actually used is θ_0, the number n of reflected waves of strength $d\theta$ is given by

$$n = \frac{\theta_{max} - \theta_0}{d\theta} \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

In general, it cannot be said that either the design using θ_{max} or the design using a smaller expansion angle, is superior. If boundary-layer growth and friction losses are likely to be objectionable, it is obviously advantageous to use the shortest possible nozzle design. This point of view was apparently predominant in the German supersonic wind-tunnel designs. On the other hand, the longer a nozzle, the less critical is its design in so far as producing a uniform final velocity is concerned. If the expansion angle is small enough, almost any smooth curve connecting the throat to exit section will produce a reasonably uniform final velocity. Therefore it may be conservative design practice to use an expansion angle less than θ_{max}, say, one half to two thirds as large.

(*c*) *Steps in Nozzle Design.* The steps in nozzle design may be listed briefly as follows:

1 Determine from Table 1 the speed index N most closely corresponding to the desired design Mach number.

2 Determine the maximum permissible expansion angle θ_{max}, using Equation [14]. Choose a nozzle expansion angle θ_0, equal to or less than this.

3 Choose an expansion curve from the throat to θ_0 and divide this into suitable straight segments. The disturbance wave strength used might be 1 or 2 deg, depending upon the accuracy desired.

4 Construct the expansion waves produced by this section and their intersections and reflections from the center line. If θ_0 is less than θ_{max}, determine the necessary number of reflections from the wall using Equation [15].

5 Construct the section canceling all expansion waves, and producing a parallel flow.

The final nozzle shape should actually consist of a smooth curve faired through all the points of intersection of waves with the wall. This can be accomplished best on a plot with exaggerated vertical ordinates. It is important to note that a check on the over-all graphical construction may be obtained by computing the ratio of the exit area, A_e, produced by the construction to the throat area A^*, and comparing this with the theoretical area ratio deduced for one-dimensional flow, which is given by

$$\frac{A_e}{A^*} = \frac{1}{\mathbf{M}} \left\{ \frac{1 + \frac{\gamma - 1}{2} \mathbf{M}^2}{\frac{\gamma + 1}{2}} \right\}^{\frac{\gamma + 1}{2(\gamma - 1)}} \quad \ldots\ldots\ldots [16]$$

Since the flow in both throat and exit section is one-dimensional, these two area ratios should agree within the error of the graphical construction. It should be pointed out that the entire graphical construction is a very rapid and mechanically simple process, which can be carried out in a matter of only a few hours. The mechanical processes can be performed by a draftsman with no particular reference to their physical meaning.

(*d*) *Approximate Method.* One further approximation in the construction is sometimes possible, which will shorten the labor involved still more. It will be noted in both Fig. 8 and Fig. 9, that the flow pattern at a section through the point of maximum expansion consists of nearly uniformly spaced fields with constant Mach number. Thus the flow is almost uniformly radial at that section. Therefore it appears feasible to design a nozzle by starting at the section of maximum expansion, and assuming a uniform radial flow. This amounts to assuming the existence of uniformly spaced wave quadrilaterals with constant Mach number and flow direction varying uniformly. The number of waves which must be present is, of course, determined by the expansion angle used, and is given by

$$m = \frac{\theta_0}{d\theta} \quad \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

The design for the nozzle in Fig. 8, starting at the section of maximum expansion, and assuming uniform radial flow at that section, is shown in Fig. 10. Using this design procedure, it is necessary to connect the maximum expansion point with a throat of the correct size by a smooth curve representing the expansion

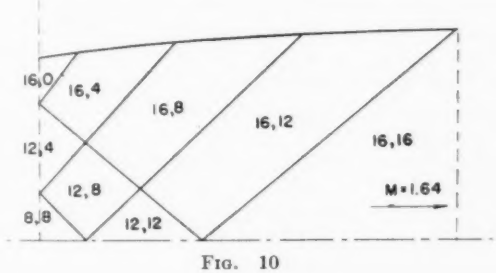

FIG. 10

section. It is clear that the accuracy of the assumption of uniform radial flow will depend to some extent upon the uniformity of the curvature of this section. The correct throat size must be computed in this case from Equation [16].

BOUNDARY-LAYER EFFECTS

The discussion so far has pertained to the approximate solution of the flow of a nonviscous fluid. In a real fluid some viscous effects must be present, but it can be shown that they are, for the most part, confined in a thin layer next to the walls of the flow, called the boundary layer. The real flow then consists essentially of a core of nonviscous flow, and thin layers of retarded

flow along the walls. It can be shown that the perfect fluid core behaves as though it were flowing between walls which lie somewhere in the boundary layer, inside the physical walls. These "effective walls" are displaced inside the true walls by a certain fraction of the boundary-layer thickness, called the "displacement thickness." The displacement thickness is also an important parameter in general boundary-layer theory (5); it is defined as the distance through which the wall of a channel carrying a perfect fluid would have to be displaced in order to produce the same reduction in mass flow that is caused by the actual boundary layer.

The nozzle computations made previously may now be considered to apply to a perfect fluid flowing between certain effective walls. The physical walls of a real flow which would

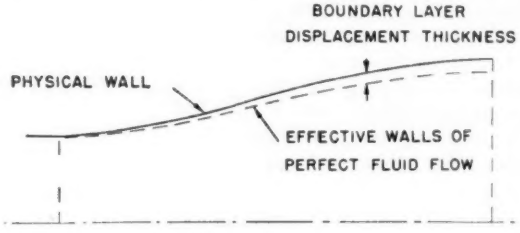

FIG. 11

have the same internal characteristics as the computed flow will lie exactly one displacement thickness outside of the effective walls (see Fig. 11). The displacement thickness increases from nearly zero at the throat to a value depending upon the Reynolds number, length, and Mach number in the nozzle. It continues to increase through the test section (following the exit section of the nozzle), which means that the actual nozzle walls must diverge slightly through the test section in order to maintain a constant velocity.

It should be noted that the boundary layer forms on all four walls of the nozzle; however, it is generally convenient to make boundary-layer corrections only to the top and bottom walls of a two-dimensional channel. As a first crude approximation, the total correction for all four walls might be divided between the top and bottom walls only. The detailed computation of the boundary-layer displacement thickness is outside the scope of the present paper, but some order of magnitude figures may be given for design purposes. Some theoretical estimates of the rate of boundary-layer growth have been made for the 2.5-in. supersonic wind tunnel at the Guggenheim Aeronautical Laboratory, California Institute of Technology, and comparisons made with boundary-layer profiles measured in the wind tunnel. The following rough figures will give an indication of the size of the effects obtained.

The rate of increase through a square test section is such that an expansion of the top and bottom walls by 0.007 to 0.010 in. per in. of length on each wall, will roughly provide the necessary compensation for all four walls. This figure has been found to be useful for a wide range of Reynolds numbers, from $\mathbf{R} = 5 \times 10^5$ to $\mathbf{R} = 5 \times 10^6$ based upon test section height, and for Mach numbers of the order of 1.5 to 2.5. The thickness of the boundary layer in a 2.5-in. wind-tunnel nozzle at a Mach number of 1.5 and Reynolds number of 5×10^5 is roughly 0.15 in.; of this, the displacement thickness is about 0.040 in. If the friction coefficient is assumed independent of Reynolds number, the displacement thickness would increase approximately linearly with the nozzle size. Increasing Mach number increases boundary-layer thickness, due essentially to the additional heating in it. In the 2.5-in. nozzle, the total boundary-layer thickness at $\mathbf{M} = 4$ is roughly 0.25 in.

TABLE 2 TYPICAL NOZZLE ORDINATES, MAXIMUM EXPANSION TO EXIT SECTION

						36.13	4.09	39.20	3.77	41.62	3.58
								39.80	3.62	42.79	3.29
										43.32	3.15
$\theta_0 = 7°$		9°		12°		13°		14°		15°	

It is also clear that the method in general may be applied to a wide variety of two-dimensional supersonic-flow problems, and that it forms a very powerful tool for investigation in this field.

CONCLUSIONS

Using the methods outlined in the paper, the graphical construction of a two-dimensional supersonic nozzle to produce uniform parallel flow at any desired Mach number is a relatively rapid and simple process. As an example of the application of the method, several nozzle shapes have been designed using the approximate method described, in which uniform radial flow is assumed at the maximum expansion section. These are given in Table 2; the abscissas x are measured from the nozzle exit section, and the ordinates y are measured from the nozzle center line. Only that part of the nozzle between exit section and maximum expansion angle is given. This section must be connected to a throat of the proper size (computed from Equation [16]) by a smooth curve of reasonably low curvature. The scale may be revised by changing x and y in the same ratio. It will be noticed that the expansion angles used, θ_0, correspond roughly to one half of the maximum permissible θ_{max}, so that the shape of the curve from throat to maximum expansion section should not be too critical. No correction for boundary layer has been made.

Analytical Design of Centrifugal Air Compressors

By C. CONCORDIA[1] and M. F. DOWELL[2]

The object of this paper is to describe a general method of design and analysis which has been developed for, and applied primarily to, the design of supercharger centrifugal impellers. The method has also been used as a systematic means for the analysis of such impellers as well as for the design of the corresponding diffusers and of gas-turbine compressors and turbines. The development was undertaken with the idea of obtaining, as nearly as possible, a self-sufficient and self-contained rational design method which would be influenced as little as possible by preconceived notions of what the impeller blades should look like. The method is also complete in the sense that it is not used merely as a guide to the character of the blade shape, e.g., to determine limiting curvatures. Instead, one starts from and uses the basic laws of the fluid motion to determine the required flow path and thus the complete blade shape. On the other hand, the fullest use has been made of available experience and test results as checks of the theory.

Nomenclature

The following nomenclature is used in the paper:

- ρ = mass density of fluid, lb-sec^2/ft^4
- t = time, sec
- r = radial distance to air particle, ft
- θ = angular position of air particle, radians
- $\omega = d\theta/dt$ = angular velocity of air, radians per sec
- ω_w = angular velocity of impeller, radians per sec
- $\alpha = d\omega/dt = d^2\theta/dt^2$ = angular acceleration of air, radians per sec^2
- p = pressure, psf
- B = angular position of blade element $= \theta - \omega_w t$, radians
- z = axial distance, ft
- $v_r = dr/dt$ = radial component of air velocity, fps
- $v_z = dz/dt$ = axial component of air velocity, fps
- v_{s+r} = resultant of axial and radial velocities, fps
- ω_1, ω_2 = initial (entrance) and final (exit) angular velocities, respectively, of air, radians/sec
- $\omega_{rel} = \omega - \omega_w$ = angular velocity of air relative to the wheel, radians/sec
- r_1, r_2 = initial and final radii respectively of flow line, ft

Subscripts b, m, and o refer to back wall, median flow line, and open face as defined in Fig. 1

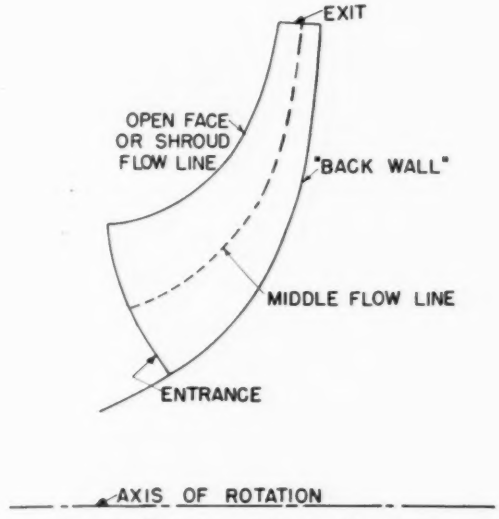

Fig. 1 Tangential View of Impeller
(Section in axial-radial plane.)

- μ = fluid viscosity
- δ = boundary layer thickness
- $p' = p - p''$ (see Equation [13])

Description of Method

The procedure has been to set up first the equations of equilibrium of an air particle in terms of a system of cylindrical co-ordinates suited to the form of the centrifugal compressor to be studied. The three equations of equilibrium for an element of a compressible perfect fluid of density ρ and pressure p, in cylindrical co-ordinates r, θ, and z, are

Tangential acceleration

$$\rho\left(r\frac{d^2}{dt^2}\theta + 2\frac{dr}{dt}\frac{d\theta}{dt}\right) = \rho\,(r\alpha + 2v_r\omega) = -\frac{\partial p}{r\partial\theta} \quad [1]$$

Radial acceleration

$$\rho\left(\frac{d^2}{dt^2}r - r\left(\frac{d\theta}{dt}\right)^2\right) = \rho\left(\frac{d}{dt}v_r - r\omega^2\right) = -\frac{\partial p}{\partial r} \quad [2]$$

Axial acceleration

$$\rho\frac{d^2}{dt^2}z = \rho\frac{d}{dt}v_z = -\frac{\partial p}{\partial z} \quad [3]$$

These equations are simply an expression of Newton's second law and are assumed to hold along any streamline within the fluid. In order to solve these equations without further approximation it would be necessary to integrate them over the whole space within any one impeller passage and consider proper boundary conditions along the passage walls. This has been avoided by the distribution of the boundary forces within the fluid,[3] as for

an infinite number of blades. The condition of the fluid is then in the first approximation independent of angle and the various streamlines may be separately considered.

The determination of blade shapes and passages by means of these equations is as follows:

The equation of tangential force, Equation [1], is regarded as the most significant since it exhibits the primary effect of the impeller on the air in imparting a rotary motion by means of the tangential pressure gradient between the blades. In this equation, $\partial p/\partial\theta$ is replaced by $\Delta p/\Delta\theta$ where Δp is the pressure difference across each blade at any point along the path (the blade loading), and $\Delta\theta$ is the angular distance between adjacent blades. Thus Equation [1] becomes

$$\rho\,(r\alpha + 2\,v_r\omega) = -\frac{\Delta p}{r\,\Delta\theta} \qquad [4]$$

This equation is used to calculate step by step the angular acceleration α, the angular velocity ω, and finally the relative angular position B of an air particle as it travels through the impeller, for a given blade loading Δp, density distribution ρ, and radial component of velocity v_r. The basic premise of this procedure is that blade loading is the most significant factor, so that a given blade loading is desirable as compared with some other kind of loading.

For preliminary calculations the desirable distribution of pressure across the blade as a function of radius was chosen on a common-sense basis by following the rule that the air should be accelerated gradually, with the force starting at zero and increasing to a more or less uniform maximum value over the middle portion of the blade and then decreasing to a small (but not necessarily exactly zero) value at the exit. Thus shocks at entrance and exit, as well as pulsations of pressure at the entrance to the diffuser, are minimized, and on the other hand no portion of the blade escapes its proper share of the work.

It will be shown later how other criteria of good blade loading have also been applied. In the foregoing discussion the whole passage is regarded as lumped into a single flow line with a force proportional to $\Delta p/\Delta\theta$ acting on the air. From the mathematical point of view, the original partial differential equation has been reduced to an ordinary differential equation solvable by a step-by-step process or by means of the differential analyzer.

In Equation [1] it is evident that ρ and v_r must also be specified. The procedure has been to estimate ρ first from available test results and finally from pressure-rise curves calculated from the radial- and axial-force equations. From another point of view, the ratio of blade loading to density ($\Delta p/\rho$) may be regarded as the quantity specified so that it is not necessary for the present to know ρ. The velocity v_r does not have to be guessed but may be independently assigned, since when ρ is known the passage contour in the axial-radial plane, that is, in the tangential view as shown in Fig. 1, may be determined by means of the equation of continuity to produce any desired axial-radial component v_{z+r} of velocity. In this sense the flow line is regarded as a middle or median line, and the velocity as an average velocity, since we know that in actuality there is a variation of velocity across the passage. The v_r for any particular shape of median flow line and assigned v_{z+r} may be found by measuring the slope of the flow line in the $z + r$ plane directly from a sketch such as that in Fig. 1.

Calculations have shown that the blade shape so determined is rather insensitive to variations in the density distribution, but on the other hand the radial component of velocity is very important. The practical result is that the axial-radial passage contour may be and has been used as a control of the blade shape for any specified loading, and conversely one must remember that if the axial-radial contour is changed the blade shape should be changed correspondingly. There may evidently be an infinite number of properly co-ordinated axial-radial passage contours and blade shapes, all presumably having reasonably good performance.

Application of Formulas to Impeller Design

One of the first applications of these equations was to an impeller having a nearly uniform radial velocity. The resulting blade shape, in its axial view, Fig. 2, has a backward curvature at the entrance and the exit (because of the light blade loading at entrance and exit) and a forward curvature in its middle portion. As such reversals of curvature are undesirable from the standpoint of construction, a general study of blade shape as affected by the radial component of velocity as well as by other factors was undertaken.

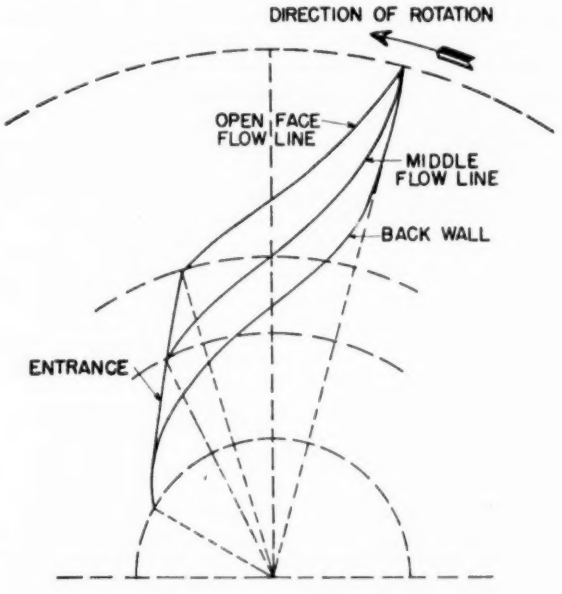

Fig. 2 Axial View of Radial-Flow Impeller

Some preliminary work was done by hand step-by-step integration of Equation [4] and this indicated almost at once that a proper reduction of the radial component of velocity at the inlet could eliminate the initial backward curvature. The entrance velocity thus should be principally axial and should turn around more or less gradually to a nearly radial exit, so that the impeller changes gradually from axial to radial.

A continuation of the work by a study of several hundred specific cases on the differential analyzer has shown that a proper axial-radial velocity distribution can result in a simple blade shape as far as the median flow line is concerned, but has brought out the fact that the passage contour (in the tangential view) necessary to produce the simplest median flow line (in the axial view) may have certain undesirable features, and moreover may not correspond to the simplest flow lines along these contours.

As just implied, following the determination of the middle flow line, we must calculate the two extreme flow lines, i.e., along the back wall (see Fig. 1) and along the open face (or shroud, if any). To do this we must estimate a velocity component v_r along these lines. This is done, as in the case of the median ρ, first by experience and finally from a consideration of the fact that zero circulation should exist within the fluid up the streamline along the open face or back wall and back down the middle line. This calculation of circulation cannot be made until a blade shape and the corresponding angular velocities have been calculated, as until

then we know neither the relative velocities nor the length of the path.

It is also necessary to have in some sense an equality of over-all effect on the fluid among the various flow lines. In the designs made so far, this has been accomplished by making the work done on the fluid equal for all flow lines, which simply means that the tangential components of exit velocity must be inversely proportional to the exit radii,[4] or that the angular velocities at the exit must be inversely proportional to the square of the radii

$$\left.\begin{aligned} v_{\theta 2b}\, r_{2b} &= v_{\theta 2m}\, r_{2m} = v_{\theta 2o}\, r_{2o} \\ \text{or} \qquad \omega_{2b}\, r_{2b}^2 &= \omega_{2m}\, r_{2m}^2 = \omega_{2o}\, r_{2o}^2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [5]$$

As a final check the circulation around the blade along the three flow lines is calculated to see if it varies by any significant amount.

It was stated previously that the variation of density ρ through the impeller is computed from the axial- and radial-force equations. Actually, these Equations [2] and [3] require some modification in order to put them into the best form for computation.

According to the original assumption, there is everywhere within the fluid a pressure gradient ($\partial p/\partial\theta$), or ($\Delta p/\Delta\theta$). This corresponds physically to the assumption of an infinite number of blades, and as shown in Fig. 3, the effect of the gradient is

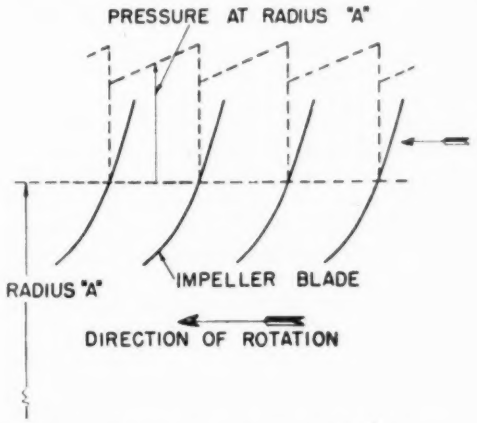

FIG. 3 VARIATION OF PRESSURE WITH ANGLE

canceled each time one passes through a blade, so that there is no net pressure variation in the tangential (θ) direction. This shows that if one is to integrate the pressure gradient from entrance to exit, one must take care to avoid passing through a blade if the proper pressure rise is to be obtained. The differential pressure rise may be written as

$$dp = \frac{\partial p}{\partial r}\, dr + \frac{\partial p}{\partial z}\, dz + \frac{\partial p}{\partial \theta}\, d\theta \ldots\ldots\ldots\ldots [6]$$

Substituting for $\partial p/\partial r$ and $\partial p/\partial z$ from Equations [2] and [3]

$$dp = \rho \left[r\omega^2 dr - \frac{dv_r}{dt}\, dr - \frac{dv_z}{dt}\, dz \right] + \frac{\partial p}{\partial \theta}\, d\theta \ldots\ldots [7a]$$

In this expression $dr/dt = v_r$ and $dz/dt = v_z$, thus

$$dp = \rho\, [r\omega^2 dr - v_r\, dv_r - v_z dv_z] + \frac{\partial p}{\partial \theta}\, d\theta \ldots\ldots [7b]$$

or, since

$$v_r^2 + v_z^2 = v_{z+r}^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [7c]$$

$$dp = \rho\, (r\omega^2 dr - v_{z+r}\, dv_{z+r}) + \frac{\partial p}{\partial \theta}\, d\theta \ldots\ldots\ldots [7d]$$

Finally, in order to avoid passing through an impeller blade $d\theta$ must be taken equal to dB, the change in blade angle, while $\partial p/\partial\theta$ is replaced by $\Delta p/\Delta\theta$, so that one obtains

$$dp = \rho\, [r\omega^2 dr - v_{z+r}\, dv_{z+r}] + \frac{\Delta p}{\Delta \theta}\, dB \ldots\ldots\ldots [8]$$

This equation may be evaluated for each interval along the flow path, as all the quantities are now known, that is, ρ, v_{z+r}, and $\Delta p/\Delta\theta$ were previously assigned in order to solve Equation [4], ω is found from the step-by-step solution of Equation [4], and B is found by numerically integrating ($\omega - \omega_w$), the angular velocity relative to the impeller, with respect to time.

Having found p by summation of the dp of Equation [8], one may find a new ρ curve from a suitable relation $(\rho/\rho_0)^\gamma = (p/p_0)$. Experience has shown that the values of (dp) found from Equation [8] must be multiplied by a factor of from 70 to 80 per cent to check test values. This is presumably because of the fact that losses have been neglected. Although more complete expressions including the effect of surface friction have been developed, we have preferred to depend directly on estimates based upon tests for the magnitude of the pressure rise, using Equation [8] only to determine the shape of the curve. The calculated pressures are also useful in a relative sense to compare the performance of different impellers.

In the same way Equation [4] has not been modified, since the effect of friction is merely to increase the required blade loading without significantly changing its shape. These two simplifications are legitimate because of the fact that we are not trying to determine the performance, i.e., the efficiency and pressure ratio, of a given impeller, but rather are trying to determine directly the optimum design having maximum efficiency for any assigned pressure ratio.

It might have been supposed that the pressure rise could be computed more simply by the relation

$$dp = -\rho v\, dv \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

where v is the total velocity of the air relative to the impeller. However, the form, Equation [8], is believed to have the advantages of convenience and of showing clearly the fundamental design components which contribute to the pressure rise. For example, the first term $\rho\, r\omega^2 dr$ represents the centrifugal pressure rise and may be compared to a similar term $\rho\, r\omega_w^2 dr$ which represents the corresponding pressure rise in a straight radial-blade impeller. The second term $-\rho\, v_{z+r}\, dv_{z+r}$ is the pressure rise due to the fluid flow through the impeller neglecting the effects of the blades (that is, it represents the impeller as an annular diffusing passage), and thus shows directly the effect of changes in the shape of the axial-radial cross section. The third term shows the direct action of the blades in pushing on the air and is the only term which would exist in a purely axial-flow fan with constant axial velocity.

In evaluating the total circulation within the fluid passage a path, Figs. 1 and 2, is chosen up the back wall, across the impeller exit (this portion is not necessarily negligible, since the exit velocity is not necessarily normal to the exit cross section), down the open face, and down the entrance. The integral of the component of relative velocity (in line with this path) with respect to path length is taken and evaluated numerically. This integral is the circulation in co-ordinates moving with the impeller, so to it must be added $+ 2A\omega_w$ in order to obtain the circulation with respect to co-ordinates fixed in space, where A is the net

[4] "Energy Transfer Between a Fluid and a Rotor for Pump and Turbine Machinery," by S. A. Moss, C. W. Smith, and W. R. Foote. Trans. A.S.M.E., vol. 64, 1942, pp. 567–597.

projected area of the blade in the axial view as shown in Fig. 2. To obtain this projected area we must consider negative as well as positive areas if the projections of the back wall and open face lines overlap. With the conventions chosen in Fig. 2, a positive area is obtained if the enclosed portion is on the left as one proceeds along the path (see Fig. 2).

In evaluating the total circulation about the blade along each of the three flow lines, the pressure loading Δp has been used to compute the corresponding difference of velocity, and this has been numerically integrated along each path.

Differential Analyzer Simplifies Computing Process

It is evident from the foregoing description that this design method is straightforward and simple in theory but entails a considerable amount of numerical work. In principle, a sort of successive approximation solution of the force equations in the three dimensions for each flow line and a successive consideration of the three flow lines must be made. In practice, however, the relative unimportance of the density distribution allows some separation of the equations so that the blade shape may be found for many cases without checking each flow line to see if the pressure rise has exactly the assumed shape. This fact has permitted the saving of a great deal of time by use of the differential analyzer[5] for some of the calculations.

Determination of Optimum Blade Loading

Since the basis of most of the work is the shape of the curve of pressure difference across the blade, the question of what is the best pressure loading is of prime importance. This question has been approached in three ways: (1) As just noted, by the common-sense consideration that the pressure should be small at entrance and exit and should not have any reversals of curvature; (2) by comparisons of calculated pressure loadings for several impellers which have already been tested; and (3) by a consideration of the possibility of boundary-layer separation.

The application of method (1) needs no further discussion.

For method (2) an instrument, Fig. 4, was built and has been

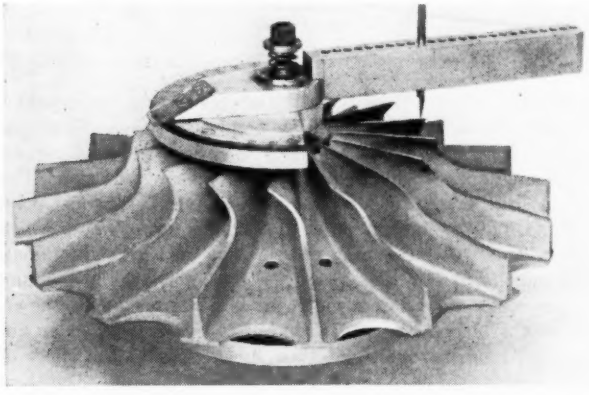

Fig. 4 Device for Measurement of Impeller-Blade Contours

used for the detailed measurement of the blade contours. From these measurements and for given impeller speeds and flow conditions, the blade loadings are computed by Equation [4]. Calculations have been made for operating conditions of both good and poor performance so that a correlation of performance and blade loading could be made.

Method (3) is the assignment of the blade loading in such a way that separation is avoided. This can be done only indirectly. The procedure has been to plot the curves of pressure for both surfaces of the blade, taking as a first approximation

$$p_s = p \pm (\Delta p/2) \quad [10]$$

where the two values of p_s are the surface pressures and p is the pressure calculated as described in connection with Equation [8]. The criterion of separation involves the boundary-layer thickness, density, relative velocity, pressure gradient along the flow path, and the impeller rotational speed. One may, as an approximation, write that in order to avoid separation we must have[6]

$$\frac{\delta\,(dp'/ds)}{\rho\, v^2} < \frac{K}{R_\delta} \quad [11]$$

where s is the distance along the flow path, v is the relative velocity, K is a constant, R_δ $(= v\delta\rho/\mu)$ is Reynolds number for the boundary layer, and μ is the fluid viscosity.

Equation [11] may also be written in the form

$$\frac{dp'}{ds} < \frac{K\,\mu\, v}{\delta^2} \quad [12]$$

In the present case the "pressure gradient" (dp'/ds) is not the actual pressure gradient but a corrected gradient found by subtracting from the actual gradient a centrifugal-pressure gradient to which we are entitled by virtue of the impeller rotation; or, from the actual pressure we subtract a centrifugal pressure p''

$$(p'' = \omega_w^2 \int_{r_0}^{r} \rho\, r\, dr) \quad [13]$$

before computing the gradient. This pressure p'' may be regarded as representing that developed in a rotating impeller having no flow, and for which there will of course be no separation regardless of the magnitude of the pressure gradient.

For the centrifugal impellers considered this centrifugal-pressure gradient has been extremely important, being in most cases 4 or 5 times as great as the residual-pressure gradient (dp'/ds) which tends to produce separation. Thus a proper estimate of the separation condition depends much more upon a proper calculation of the pressure-rise distribution than upon an exact knowledge of the boundary-layer thickness or of the quantity K. Moreover, it is evident that the best shape of loading curve will bear little resemblance to the best shape for an airfoil in a free stream, and will also vary widely depending upon other features of the design.

Discussion of Results and Conclusions

The studies made by the methods outlined have led to an improved understanding of the proper and necessary correlation between the over-all passage contour (as projected in the axial-radial plane) and the blade shape. The inherent relations among the three principal flow lines considered, and the necessity for a proper consideration of all three, are brought out. In addition, the effect of various factors such as density, shape, and magnitude, Fig. 5, of blade loading, initial spin, and design speed have been determined, as well as the best blade shapes for certain specific designs.

One might loosely classify the method as an attempt to solve the complete aerodynamic-design problem roughly, rather than any one part of it exactly. The partial differential equations of equilibrium have been reduced to a series of one-dimensional equations and solved in succession. The equations of continuity and of circulation have been applied to the whole passage as a unit (or at most in two parts). The merits of these assumptions must be judged by the results obtained, and on this basis they have

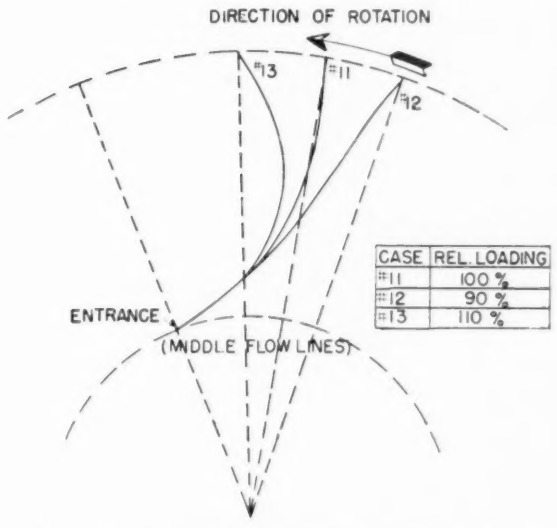

FIG. 5(a) AXIAL VIEW OF CENTRIFUGAL IMPELLERS; EFFECT OF MAGNITUDE OF BLADE PRESSURE LOADING ON BLADE SHAPE

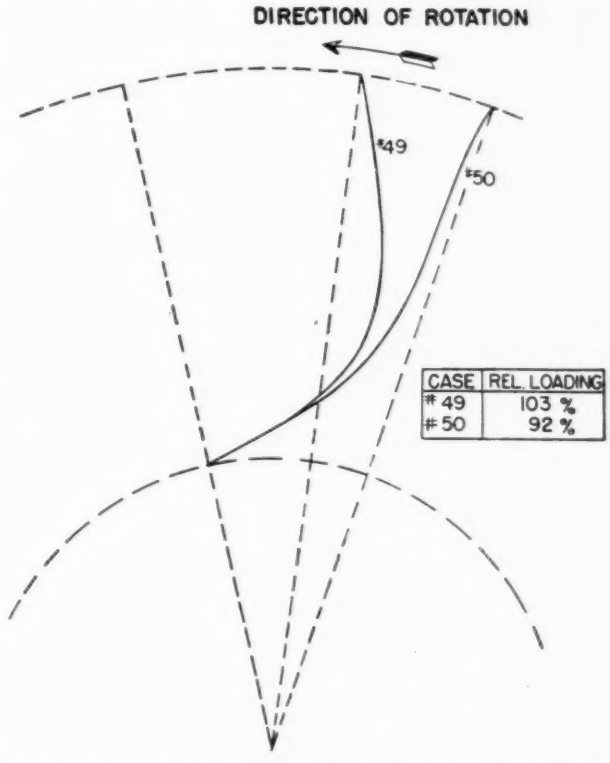

FIG. 5(b) AXIAL VIEW OF MIDDLE FLOW LINES OF CENTRIFUGAL IMPELLERS; EFFECT OF MAGNITUDE OF BLADE PRESSURE LOADING ON BLADE SHAPE

been amply justified. Tests on several impellers have shown considerable increases in efficiency, flow capacity, and maximum attainable pressure ratio.

Not the least of the benefits has come from the systematic analysis of all types of impellers. It has been possible on more than one occasion to explain differences in performance among various experimental impellers which seemed practically alike on even a careful qualitative inspection, since the analysis provides a means of looking at the fundamental physical effects of design changes rather than merely at the geometrical dimensions themselves. This form of analysis may be compared to the methods of smoke and dust precipitation, since a more or less even precipitation is taken as a criterion of good performance. However, in the analytical method one may take on paper any speed, however high, as the design speed, as opposed to the test method which may be used only at moderate speeds, and also one may obtain a quantitative idea of the magnitude and detailed distribution of the loading over the blade surface, so that the optimum loading from the aerodynamic standpoint may be approached.

ACKNOWLEDGMENT

The authors are indebted to Miss Helen Poulos for innumerable calculations, to Dr. J. R. Weske for referring them to the work of Ruden, to Dr. H. Poritsky for several discussions of separation and boundary-layer phenomena, and to the staff of the General Electric Company who operate the differential analyzer.

Forced Torsional Vibrations With Damping: An Extension of Holzer's Method

By J. P. DEN HARTOG[1] AND J. P. LI[2]

An extension of Holzer's method is given for the case of damped systems of discreet as well as of uniformly distributed inertias and flexibilities. For discreet systems the modification in the Holzer table consists of replacing I by $I - jc_0/\omega$, and of replacing k by $k + j\omega c_i$, whereby most numbers in the tables become complex. The meaning of the real part of any complex number is that quantity which is in time-phase with the motion at the free end, while the imaginary part is 90 deg out of time-phase with that motion. For distributed systems the results are given by Equations [12] and [12a] for a free forward end; by Equations [13] and [13a] for a damped forward end, while the letters a and b appearing in these results are defined by Equations [8] and [8a].

1 Nomenclature

The following nomenclature is used in the paper:

a, b . . . . numbers depending on system constants, defined by Equations [8] and [8a] or by [9]

A, B, C, D
C_1, C_2, C_3, C_4 } . . . . integration constants

c . . . . torsional damping constant

I . . . . moment of inertia

j . . . . imaginary unit

k . . . . torsional spring constant

l . . . . length of shaft

p . . . . roots, defined by Equation [8]

P, Q . . . . angular displacement functions of x, being the in-phase (real) and the quadrature (imaginary) components of that angle

x . . . . distance along shaft, between 0 and l

φ . . . . angle of torsional displacement

ω . . . . frequency

Subscripts:

1 . . . . per unit length (in a distributed system)

i . . . . inner or internal (damping)

o . . . . outer or external (damping to ground)

$n, (n-1)$ . . . . running number of disk

2 Scope and Object of This Paper

In the calculation of the free and forced vibrations of torsional systems with small damping, the method of Holzer is widely used. It consists of determining the shapes and frequencies of the free vibrations, disregarding damping. The damping is subsequently taken into consideration by equating its energy dissipation during one cycle to the work done by the exciting forces during that cycle Obviously this method is satisfactory and reliable only when the natural frequency and particularly the vibrating shape of the system are practically independent of damping. In most practical systems this is true enough, justifying the widespread use of this simple method of calculation. Exceptions occur in cases where two flywheels in the middle of the system are coupled to each other by a dashpot only, or by a dashpot transmitting a torque which is considerable compared to the spring torque transmitted between these two flywheels.

An old practical example of this condition is the Lanchester damper or the sprung "damped dynamic vibration absorber." Other cases are hydraulic or inductive electric couplings tying two parts of the system together, as they occur in ship drives. In all such cases the energy dissipation in the device obviously is zero for zero damping. But the energy dissipation is also zero for large (infinite)damping, because then the two halves of the coupling are rigidly tied together by the dashpot, which changes the shape of the vibration altogether. These devices are used in practice with a damping between zero and infinity so that the damping torque as well as the relative motion are considerable, resulting in a maximum energy dissipation. The shape of the vibration then is somewhere between that for zero damping and solid coupling and differs considerably from either. For such cases the simple Holzer method breaks down and it is necessary to consider the damping directly with all its complications of changing phase angles.

In his original publication,[3] Holzer gave the method of Section 3 of this paper in great detail. It is here repeated in a simplified manner. For engine systems with a large number (six or more) of identical cylinders, it is advantageous to consider the engine as a uniformly distributed elasticity and inertia. For zero damping this leads to the Lewis method,[4] which in principle is also given in Holzer's book.[3] The calculations for a system with uniformly distributed elasticity, inertia, and damping are given by Holzer[3] only for the case of free vibration and in a very complicated manner. In this paper, the forced vibrations of such systems are investigated, which is believed to be a new contribution.

3 The Holzer Table for Damped Systems

The discussion is based on the usual engine idealization where the moving parts of each crank are replaced by an equivalent flywheel and an equivalent torsional stiffness. The damping is assumed to be linear and can consist of two parts represented by (a) a dashpot between each flywheel and ground and (b) dashpots between each flywheel and the one or two neighbor flywheels. The damping constants corresponding to these two types are designated as c_o, for "outer" or external damping and c_i for "inner" or internal damping.

The Newton equation of motion for the nth disk (Fig. 1) is

$$I_n\ddot{\varphi}_n + k_n(\varphi_n - \varphi_{n+1}) + k_{n-1}(\varphi_n - \varphi_{n-1}) + c_{no}\dot{\varphi}_n + c_{ni}(\dot{\varphi}_n - \dot{\varphi}_{n+1}) + c_{n-1,i}(\dot{\varphi}_n - \dot{\varphi}_{n-1}) = 0 \ldots . [1]$$

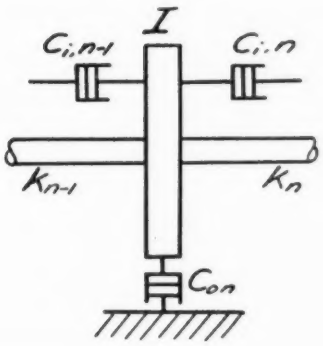

FIG. 1

The method used by Holzer consists of finding the end torque necessary to cause a steady-state *forced* vibration of an assumed frequency ω at unit amplitude at the other end. With damping the steady-state motions at the various disks are still harmonic motions at frequency ω, but they no longer have the same phase from disk to disk, or

$$\varphi_n = A_n \sin \omega t + B_n \cos \omega t \quad \ldots\ldots [2]$$

for which we can use the shorthand notation $\varphi_n = A_n + jB_n$. Differentiation of Equation [2] amounts to multiplication by $j\omega$ of the shorthand notation and two differentiations amount to multiplication by $-\omega^2$ of the shorthand notation. Substituting Equation [2] into [1] gives

$$(-I_n\omega^2 + j\omega c_{no})\varphi_n + (k_n + j\omega c_{ni})(\varphi_n - \varphi_{n+1}) + (k_{n-1} + j\omega c_{n-1,i})(\varphi_n - \varphi_{n-1}) = 0 \quad \ldots [3]$$

This equation differs from the undamped one only in that $I_n\omega^2$ is replaced by $I_n\omega^2 - j\omega c_{no}$, and in that k_n is replaced by $k_n + j\omega c_{ni}$.[5] The computations of the Holzer table are identical with those of the undamped case, except that, as a result of the two foregoing replacements, most numerical figures in the table are complex.

In the undamped case the end torque or "remainder torque" is a real number, which means that the torque is in phase with the motion at the opposite end. Here the remainder torque is a complex quantity, containing components in phase with and in quadrature to the motion at the other end. In the undamped case, there are certain frequencies ω for which the remainder torque becomes zero, which means that the system can have a steady-state vibration without any external excitation. With the presence of damping, this obviously can no longer be the case. The remainder torque never becomes zero, but, for certain values of ω, it becomes a minimum, and we may define these frequencies as the "damped natural frequencies," which for small damping differ but slightly from the undamped, true, natural frequencies.

This modified form of the Holzer table appears in a few examples later in the paper.

4 Systems With Uniformly Distributed Inertia, Elasticity, and Damping

The differential equation of torsional vibration for a shaft with uniformly distributed inertia, elasticity, internal and external damping is

$$I_1\ddot{\varphi} + c_{1o}\dot{\varphi} = k_1\varphi'' + c_{1i}\dot{\varphi}'' \quad \ldots\ldots [4]$$

where dots mean $\partial/\partial t$ and dashes mean $\partial/\partial x$, as usual. The angle will not have the same time phase along the length of the shaft so that we assume the solution in the form

$$\varphi = P(x) \sin \omega t + Q(x) \cos \omega t \quad \ldots\ldots [5]$$

where P and Q are real functions of x only. This represents a forced vibration of frequency ω, the forcing torque to be applied at the end of the shaft. Note that Equations [5] and [4] are generalizations of [2] and [1], respectively.

Substitute the assumption, [5] into [4], and set the terms proportional to sin ωt and cos ωt independently equal to zero

$$\left.\begin{aligned} I_1\omega^2 P + k_1 P'' + c_{1o}\omega Q - c_{1i}\omega Q'' &= 0 \\ I_1\omega^2 Q + k_1 Q'' - c_{1o}\omega P + c_{1i}\omega P'' &= 0 \end{aligned}\right\} \quad \ldots\ldots [6]$$

Since these are linear differential equations in $P(x)$ and $Q(x)$, we set, as usual

$$P = P_0 e^{px} \qquad Q = Q_0 e^{px}$$

and substitute

$$\left.\begin{aligned} (I_1\omega^2 + k_1 p^2)P_0 + (c_{1o}\omega - c_{1i}\omega p^2)Q_0 &= 0 \\ (-c_{1o}\omega + c_{1i}\omega p^2)P_0 + (I_1\omega^2 + k_1 p^2)Q_0 &= 0. \end{aligned}\right\} \quad \ldots\ldots [7]$$

In this homogeneous set of algebraic equations in P_0 and Q_0, the determinant must be zero or

$$(I_1\omega^2 + k_1 p^2)^2 = -(c_{1o}\omega - c_{1i}\omega p^2)^2$$

which is an equation of the fourth degree in p, having the four roots

$$p_{1,2,3,4} = \pm \sqrt{\frac{-I_1\omega^2 \pm j\omega c_{1o}}{k_1 \pm j\omega c_{1i}}} \quad \ldots\ldots [8]$$

for which we can write

$$p_{1,2,3,4} = \pm a \pm jb \quad \ldots\ldots [8a]$$

where a and b in each case can be found numerically from I_1, k_1, c_{1o}, c_{1i}, and ω in the simplest manner semigraphically in the complex plane diagram, but for the sake of completeness they are given explicitly

$$\left.\begin{aligned} b^2 &= \frac{\sqrt{(-k_1 I_1\omega^2 + c_{1i}c_{1o}\omega^2)^2 + (k_1 c_{1o}\omega + I_1 c_{1i}\omega^3)^2} + {}^1/_2(k_1 I_1\omega^2 - c_{1i}c_{1o}\omega^2)}{k_1^2 + c_{1i}^2\omega^2} \\ a^2 &= \frac{1}{2b} \cdot \frac{k_1 c_{1o}\omega + I_1 c_{1i}\omega^3}{k_1^2 + c_{1i}^2\omega^2} \end{aligned}\right\} \quad \ldots [9]$$

Also from Equation [7] it follows that the ratio P_0/Q_0 must be

$$\frac{P_0}{Q_0} = -\frac{c_{1i}\omega p^2 - c_{1o}\omega}{I_1\omega^2 + k_1 p^2}$$

and upon substitution of the values Equation [8a] for p this is found to be

$$\frac{P_0}{Q_0} = +j \quad \text{for the roots } p = a + jb \text{ and } p = -a - jb$$

$$\frac{P_0}{Q_0} = -j \quad \text{for the roots } p = a - jb \text{ and } p = -a + jb$$

Thus the P and Q functions become

$$\left.\begin{aligned} P &= C_1 e^{(a+jb)x} + C_2 e^{(-a-jb)x} + C_3 e^{(a-jb)x} + C_4 e^{(-a+jb)x} \\ Q &= -jC_1 e^{(a+jb)x} - jC_2 e^{(-a-jb)x} + jC_3 e^{(a-jb)x} + jC_4 e^{(-a+jb)x} \end{aligned}\right\} . [10]$$

Since from the physics of the situation the functions P and Q

[5] A similar result is shown in Equation [24] of the paper, "Torsional Vibration in Geared-Turbine Propulsion Equipment," by H. Poritsky and C. S. L. Robinson, *Journal of Applied Mechanics*, Trans. A.S.M.E., vol. 62, 1940, p. A-117.

must be real functions of x, it is useful to rewrite these expressions, splitting them into real and imaginary parts. After a little algebra Equations [10] can thus be written as

$$P = \cos bx[A \cosh ax + B \sinh ax] + j \sin bx[C \cosh ax + D \sinh ax]$$

$$Q = \sin bx[B \cosh ax + A \sinh ax] - j \cos bx[D \cosh ax + C \sinh ax]$$

The integration constants A to D may be real, imaginary, or complex, but P and Q must be real. This can be accomplished either by making $C = D = 0$ and A and B real, or also by making $A = B = 0$, with C and D purely imaginary. Either supposition leads essentially to the same solution, which is

$$\varphi = [A \cosh ax + B \sinh ax] \cos bx \sin \omega t + [A \sinh ax + B \cosh ax] \sin bx \cos \omega t \quad \ldots\ldots [11]$$

in which A and B are arbitrary (real) constants, while a and b are formally defined by Equations [9], although numerically they can be computed more easily from Equations [8] and [8a].

The constants A and B are determined by the condition of the end $x = 0$. For the usual case of a free end $\varphi' = 0$ and $\varphi = 1.000$, we have

$$\varphi = 1.000[\cosh ax \cos bx \sin \omega t + \sinh ax \sin bx \cos \omega t] \quad [12]$$

For the less frequent case of a built-in end or for an infinite flywheel at the end, the boundary conditions are $\varphi = 0$ and $\varphi' = 1.000$, so that

$$\varphi = \frac{1.000}{\sqrt{a^2 + b^2}} \cdot [\sinh ax \cos bx \sin \omega t + \cosh ax \sin bx \cos \omega t] \quad [13]$$

The torque $M(x)$ along the shaft in general is

$$M(x) = k_1\varphi'(x) + c_{1i}\dot{\varphi}'(x) \quad \ldots\ldots [14]$$

and in particular for the case of a free end at $x = 0$

$$M(x) = \sin \omega t[(k_1a - \omega c_{1i}b) \sinh ax \cos bx - (k_1b + \omega c_{1i}a) \cosh ax \sin bx] + \cos \omega t[(k_1b + \omega c_{1i}a) \sinh ax \cos bx - (k_1a - \omega c_{1i}b) \cosh ax \sin bx] \quad \ldots\ldots [12a]$$

For the case of a damped end at $x = 0$, we have

$$M(x) = \frac{\sin \omega t}{\sqrt{a^2 + b^2}}[(k_1a - \omega c_{1i}b) \cosh ax \cos bx - (k_1b + \omega c_{1i}a) \sinh ax \sin bx] + \frac{\cos \omega t}{\sqrt{a^2 + b^2}}[(k_1b + \omega c_{1i}a) \cosh ax \cos lx + (k_1a - \omega c_{1i}b) \sinh ax \sin bx] \ldots. [13a]$$

To find the remainder torque or the amplitude at the end l of the shaft, the quantity x has to be replaced by l in Equations [12], [12a], [13], or [13a] as the case may be.

It is important that the results of Equations [12], [13], [12a], and [13a] are all in terms of real quantities, immediately fit for numerical computations. The only complex quantities used are in Equations [8] and [8a] for the determination of a and b. The results so given are not in the form we are accustomed to for the nondamped case. It is possible to write the solution of the differential Equation [4] in a form directly comparable to the undamped case, but at the expense of being full of complex quantities not directly fit for numerical computation. This form is written below for the case of a free end

$$\varphi(x) = \cos \Phi \frac{x}{l} \qquad \varphi(l) = \cos \Phi$$

$$M(l) = [K + j\omega C_i]\Phi \sin \Phi$$

where

$$\Phi = \sqrt{\frac{I\omega^2 - j\omega C_0}{K + j\omega C_i}}$$

and

$$\left.\begin{aligned} I &= lI_1 \\ K &= k_1/l \\ C_0 &= lc_{10} \\ C_i &= c_{1i}/l \end{aligned}\right\} \text{are the system constants for the entire system of length } l.$$

This result for zero damping reduces immediately to Lewis' solution.

5 Example With Discreet Masses

As a first example, consider the system in Fig. 2, consisting of four equal inertias of 10^4 lb-in-sec,^{2} coupled by two stiffnesses of 10^6 in-lb/radian, a stiffness of 0.5×10^6 in-lb/radian, and by a central dashpot of constant c_i, which we propose to give several numerical values. For $c_i = 0$, the system falls into separate parts with the one natural frequency $\omega^2 = 200$. For $c_i = \infty$, the two central masses are united, and the same motion at $\omega^2 = 200$ is possible, but in addition there is a natural motion with a node in the center at $\omega^2 = 100$. Table 1 is a sample Holzer table.

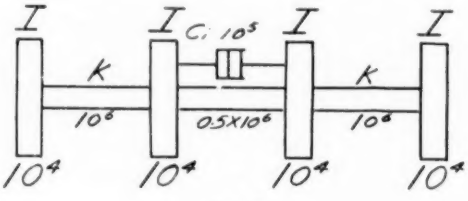

Fig. 2

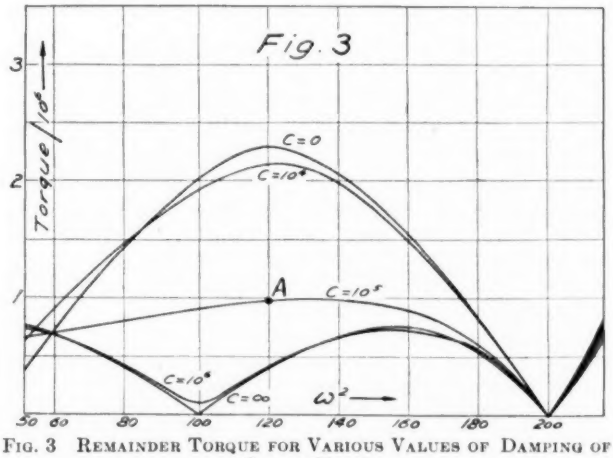

Fig. 3 Remainder Torque for Various Values of Damping of System Fig. 2

TABLE 1 SAMPLE HOLZER TABLE FOR EXAMPLE WITH DISCREET MASSES[a]

No.	$\frac{I\omega^2 - j\omega c_0}{10^6}$	φ	$\frac{(I\omega^2 - j\omega c_0)\varphi}{10^6}$	$\Sigma/10^6$	$\frac{k + j\omega c_i}{10^6}$	$\frac{\Sigma}{k + j\omega c_i}$
1	$1.200 + 0.000j$	$1.000 + 0.000j$	$1.200 + 0.000j$	$1.200 + 0.000j$	$1.000 + 0.000j$	$1.200 + 0.000j$
2	$1.200 + 0.000j$	$-0.200 + 0.000j$	$-0.240 + 0.000j$	$0.960 + 0.000j$	$0.500 + 1.095j$	$0.331 - 0.725j$
3	$1.200 + 0.000j$	$-0.531 + 0.725j$	$-0.637 + 0.870j$	$0.323 + 0.870j$	$1.000 + 0.000j$	$0.323 + 0.870j$
4	$1.200 + 0.000j$	$-0.854 - 0.145j$	$-1.025 - 0.174j$	$-0.702 + 0.696j$	.....	.....

[a] In this table $c_i = 10^6$; $\omega^2 = 120$; $\omega = 10.95$.

The absolute value of the remainder torque is

$$| -0.702 + 0.696j | 10^6 = 0.988 \times 10^6$$

plotted as point A in Fig. 3.

The results of a large number of similar calculations are shown likewise in that figure, from which it can be seen that $c = 10^4$ is a "small" damping; $c = 10^6$ is a "large" damping, while $c = 10^5$ is an intermediate value.

6 Example With Uniformly Distributed Characteristics

Consider a system of six equal inertias, each $I = 10^3$ lb-in-sec^2, coupled by five shafts each of $k = 10^7$, having dashpots c_0 from each inertia to ground and dashpots c_i between inertias. Table 2 is a sample Holzer table for this problem.

TABLE 2 SAMPLE HOLZER TABLE FOR EXAMPLE WITH UNIFORMLY DISTRIBUTED CHARACTERISTICS[a]

No.	$\frac{I\omega^2 - j\omega c_0}{10^6}$	φ	$\frac{I\omega^2 - j\omega c_0}{10^6}$	$\Sigma/10^6$	$\frac{k + j\,\omega c_i}{10^6}$	$\frac{\Sigma}{k + j\omega c_i}$
1	$1.000 - 0.316j$	1.000	$1.000 - 0.316j$	$1.000 - 0.316j$	$10.000 + 0.632j$	$0.098 - 0.038j$
2	$1.000 - 0.316j$	$0.902 + 0.038j$	$0.914 - 0.247j$	$1.914 - 0.563j$	$10.000 + 0.632j$	$0.187 - 0.068j$
3	$1.000 - 0.316j$	$0.715 + 0.106j$	$0.749 - 0.120j$	$2.663 - 0.683j$	$10.000 + 0.632j$	$0.261 - 0.085j$
4	$1.000 - 0.316j$	$0.454 + 0.191j$	$0.515 + 0.047j$	$3.178 - 0.636j$	$10.000 + 0.632j$	$0.312 - 0.083j$
5	$1.000 - 0.316j$	$0.142 + 0.274j$	$0.228 + 0.229j$	$3.406 - 0.407j$	$10.000 + 0.632j$	$0.336 - 0.062j$
6	$1.000 - 0.316j$	$-0.194 + 0.336j$	$-0.089 + 0.398j$	$3.317 - 0.009j$	.....	.....

[a] In this table, $I = 10^3$; $k = 10^7$; $c_0 = 10^4$; $c_i = 2 \times 10^4$; $\omega^2 = 1000$.

The engine can also be considered as a uniformly distributed beam and treated by means of Equations [12], [12a], [8], and [8a] in which, by taking the length of one crank throw as the unit of length, we have

$$I_1 = 10^3 \qquad k_1 = 10^7 \qquad c_{i1} = 10^4 \qquad c_{i1} = 2 \times 10^4 \qquad l = 6$$

Assuming the same frequency $\omega^2 = 1000$ as in the previous Holzer table, we find by graphical construction and computation in the complex plane from Equations [8]and [8a]

$$al = 1.914 \qquad bl = 0.355$$

Substituting these values into Equation [12] and using tables for the hyperbolic and trigonometric functions, we can plot the shape $\varphi(x)$ of the vibration and compare it with the result φ in the third column of the Holzer table. In Fig. 4, the real (in phase) and imaginary (in quadrature) parts of the two solutions are plotted, and it is seen that very good agreement is obtained if each discreet inertia is placed in the middle of the corresponding distributed length so that the distributed shaft protrudes half a crank throw beyond the first and last inertias. Also, by substituting into Equation [12a], the shaft torque distribution is found as a complex quantity, which should be compared to the fifth column in the Holzer table, and again Fig. 5 shows good agreement.

The remainder torque of the system was calculated for a range of frequencies by means of Equations [12a], [8], and [8a], and the result is shown in Fig. 6. The damping in this case is so large that the second critical frequency is hardly recognizable.

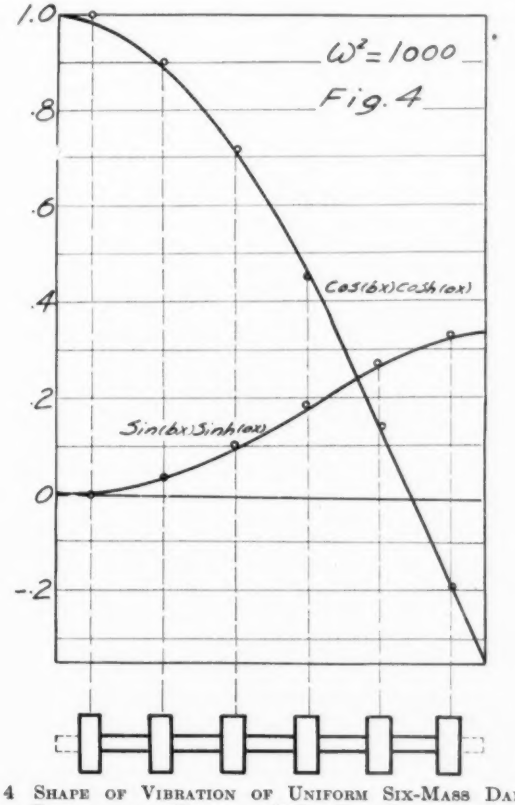

Fig. 4 Shape of Vibration of Uniform Six-Mass Damped System, Calculated by Equation [12] in Full Lines, and by the Holzer Table in Circled Points

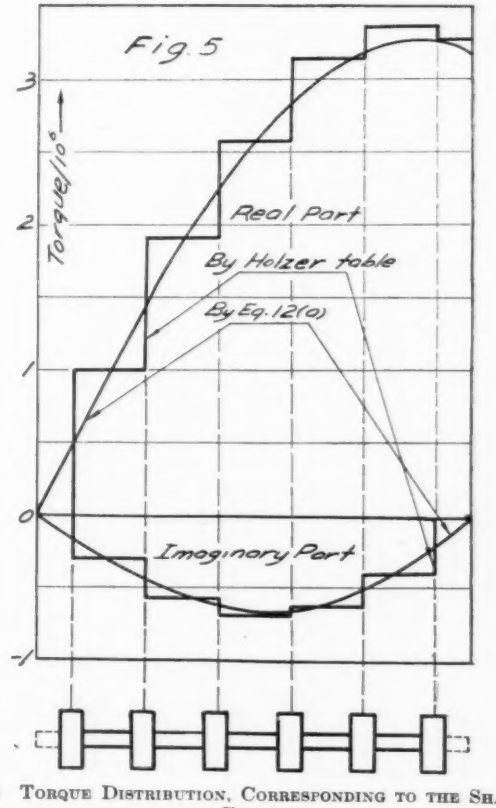

Fig. 5 Torque Distribution, Corresponding to the Shape in Fig. 4

(Curved line is Equation [12a], and stepped line is the Holzer table.)

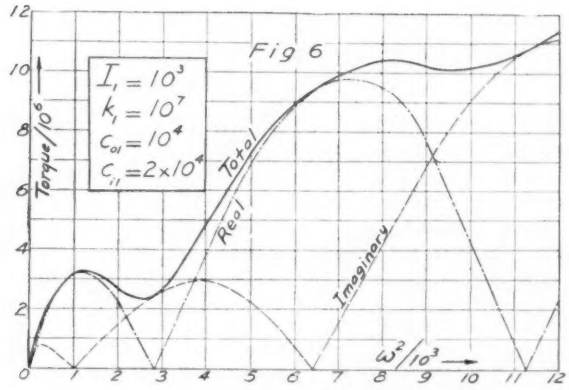

FIG. 6 REMAINDER TORQUE PLOTTED VERSUS SQUARED FREQUENCY FOR A UNIFORMLY DISTRIBUTED SYSTEM

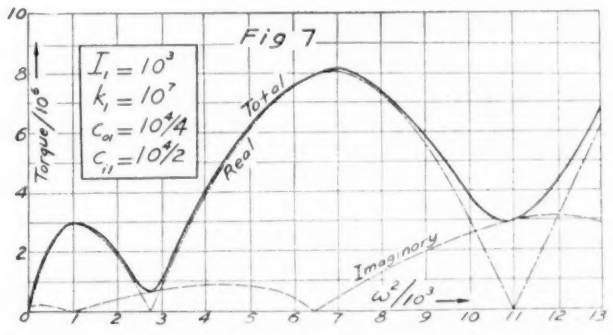

FIG. 7 SAME AS FIG. 6, EXCEPT THAT DAMPING IS 4 TIMES SMALLER

The system was again calculated for a damping 4 times as small internally as well as externally, and the remainder torque is shown in Fig. 7. In this case the shape of the vibration is not seriously affected by the damping, and it has been verified that the remainder torques at the two natural frequencies $\omega^2 = 2730$ and $\omega^2 = 10{,}920$ can be calculated with reasonable accuracy by the familiar method of dissipation-energy input-balance. However, this is not so for Fig. 6, and it is for such cases of large damping that the method just described becomes useful.

Orthogonal Functions Used in the Solution of Linear Difference Problems

By S. U. BENSCOTER,[1] HAMPTON, VA.

A method of solution of linear difference equations is presented in which the solution is assumed in terms of a finite set of orthogonal functions which satisfy the boundary conditions. A formula for the latent roots of the matrix of the system of equations is obtained. A simple formula is then derived for the reciprocal matrix in terms of the latent roots and latent vectors. A simple numerical example is presented.

Nomenclature

The following nomenclature is used in the paper:

m = bending moment
n = an integer
x = number of support
ϕ = primary flexibility
γ = secondary flexibility
δ = angular dislocation
λ = latent root

Introduction

The possibility of expressing the reciprocal of a matrix in terms of its latent roots and vectors is well known. The use of this procedure in solving a system of nonhomogeneous linear algebraic equations has found little practical application. This is due to the fact that there are many methods of solving such a system of equations, and of computing the reciprocal matrix, which require less time. However, in the case of linear difference problems, the use of the latent roots and vectors may provide a more rapid method of determining the reciprocal matrix than any other available procedure. This is due to the fact that a simple formula for the latent roots can be developed for a certain class of problems. The use of orthogonal functions, which are the latent vectors of a matrix, in the solution of general indeterminate structures has been developed by Prof. J. B. Wilbur.[2] The method of solution to be presented will be given in application to a specific problem in structural analysis rather than using generalized mathematical form.

Difference Equation and Boundary Condition

In the analysis of a continuous beam resting on a series of simple supports, which are fixed against translation, an equation of three moments may be associated with each support, except the first and last supports. A difference problem arises when every beam span is of identical physical construction. The individual spans need not be prismatic or symmetrical about their own center lines. Consider the two spans adjacent to the support numbered x of a beam of many spans as shown in Fig. 1(*a*). The flexibility matrix for each of the spans is shown. The flexibility matrix is symmetrical in accord with Maxwell's law of reciprocal displacements. The equation associated with the support numbered x is

$$\gamma m_{x-1} + (\phi_a + \phi_b) m_x + \gamma m_{x+1} = -\delta_x \quad [1]$$

The quantity δ_x is the angular dislocation which would occur at the x th support if the beam were cut at this support, and the two adjacent supports, to give simple beam action in the two adjacent spans. This angular dislocation is illustrated in Fig. 1(*b*).

The boundary conditions may be explained by reference to the three-span beam shown in Fig. 2. The loading is arbitrary. The determinate, indeterminate, and resultant moment diagrams are shown. It is apparent that the boundary conditions on the set of joint moments, which are governed by the equations of three moments, are that the value at the first and last support shall be zero. If x is the number of the support, the boundary conditions are that $m_x = 0$ when $x = 0$ and $x = 3$. The functions $\sin \frac{n\pi x}{3}$ satisfy these conditions for all integral values of n.

Method of Solution

The method of solution will be explained by reference to a four-span beam as shown in Fig. 3(*a*). The solution may be assumed in the form

$$m_x = \sum_{n=1}^{3} a_n \sin \frac{n\pi x}{4} \quad [2]$$

The number of terms in the series to be used is equal to the number of unknowns to be determined. Equation [2] corresponds to three linear algebraic equations which may be written in the following matrix form

$$\begin{bmatrix} m_1 \\ m_2 \\ m_3 \end{bmatrix} = \sin \begin{bmatrix} \pi/4 & 2\pi/4 & 3\pi/4 \\ 2\pi/4 & 4\pi/4 & 6\pi/4 \\ 3\pi/4 & 6\pi/4 & 9\pi/4 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} \quad [3]$$

$$= \begin{bmatrix} \sqrt{2}/2 & 1 & \sqrt{2}/2 \\ 1 & 0 & -1 \\ \sqrt{2}/2 & -1 & \sqrt{2}/2 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} \quad [4]$$

The m_x values are hereby expressed as linear functions of the a_n values. It will be necessary to have the a_n values expressed as linear functions of the m_x values at a later step in the analysis. Solving for the a_n values in terms of the m_x values is greatly simplified by the fact that the columns of the square matrix of coefficients are orthogonal column vectors. This is true because the solution has been assumed in terms of orthogonal functions which have been evaluated only at equally spaced values of the angle variable.

Equation [4] may be written in contracted matrix form as

$$[m] = [S][a] \quad [5]$$

where $[m]$ is the column vector of m_x values, $[a]$ is the column vector of a_n values, and $[S]$ is the square matrix of coefficients. It should be noted that the matrix $[S]$ is symmetrical and that all of its column vectors have the same norm, and hence the same

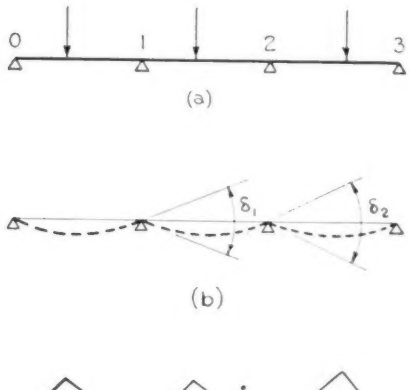

FIG. 2 CONTINUOUS-BEAM MOMENT DIAGRAMS

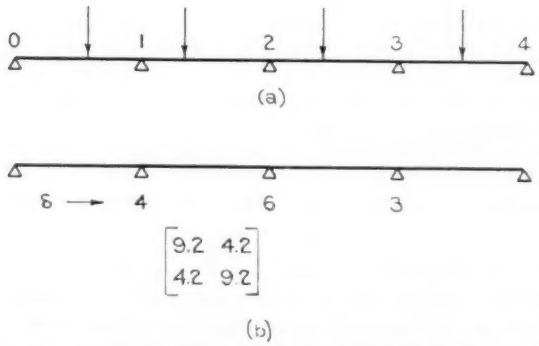

FIG. 3 FOUR-SPAN CONTINUOUS BEAM

normalizing factor. Because of these facts the product of $[S]$ by itself gives a scalar matrix which may be written as a scalar factor times the identity matrix

$$[S][S] = 2[I] \quad [6]$$

This equation is easily checked by using the "row by column" rule for matrix multiplication. Multiplying Equation [5] through by $[S]$ gives

$$[S][m] = 2[I][a] = 2[a] \quad [7]$$

or

$$[a] = {}^1/_2[S][m] \quad [8]$$

Thus it is seen that the a_n values are expressed as linear functions of the m_x values by a set of coefficients which are just one half of the values of the elements of $[S]$.

In order to substitute the assumed solution into the difference equation, it is necessary to compute m_{x-1} and m_{x+1}. This is done by substituting $x - 1$ and $x + 1$ into Equation [2] for x

$$m_{x-1} = \Sigma a_n \left[\sin \frac{n\pi x}{4} \cos \frac{n\pi}{4} - \cos \frac{n\pi x}{4} \sin \frac{n\pi}{4} \right] \quad [9]$$

$$m_{x+1} = \Sigma a_n \left[\sin \frac{n\pi x}{4} \cos \frac{n\pi}{4} + \cos \frac{n\pi x}{4} \sin \frac{n\pi}{4} \right] \quad [10]$$

Substitution of Equations [2], [9], and [10] into Equation [1] gives

$$(\phi_a + \phi_b) \Sigma a_n \sin \frac{n\pi x}{4} + 2\gamma \Sigma a_n \cos \frac{n\pi}{4} \sin \frac{n\pi x}{4} = -\delta_x \quad [11]$$

Combining terms gives

$$\Sigma a_n \left(\phi_a + \phi_b + 2\gamma \cos \frac{n\pi}{4} \right) \sin \frac{n\pi x}{4} = -\delta_x \quad [12]$$

Let

$$\lambda_n = \phi_a + \phi_b + 2\gamma \cos \frac{n\pi}{4} \quad [13]$$

Then

$$\Sigma a_n \lambda_n \sin \frac{n\pi x}{4} = -\delta_x \quad [14]$$

This equation corresponds to three linear equations expressing the δ_x values as linear functions of the quantities $a_n\lambda_n$. The coefficients of these linear equations again form the matrix $[S]$. In expanded matrix form the equations may be written

$$\begin{bmatrix} \sqrt{2}/2 & 1 & \sqrt{2}/2 \\ 1 & 0 & -1 \\ \sqrt{2}/2 & -1 & \sqrt{2}/2 \end{bmatrix} \begin{bmatrix} a_1\lambda_1 \\ a_2\lambda_2 \\ a_3\lambda_3 \end{bmatrix} = \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix} \quad [15]$$

In contracted matrix form this equation becomes

$$[S][a\lambda] = -[\delta] \quad [16]$$

The column vector $[a\lambda]$ must be separated in the following manner

$$[a\lambda] = \begin{bmatrix} a_1\lambda_1 \\ a_2\lambda_2 \\ a_3\lambda_3 \end{bmatrix} = \begin{bmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = [\Lambda][a] \quad [17]$$

The matrix $[\Lambda]$ is a diagonal matrix of λ_n values. Equation [16] becomes

$$[S][\Lambda][a] = -[\delta] \quad [18]$$

The column vector $[a]$ may be eliminated by substituting Equation [8]

$${}^1/_2[S][\Lambda][S][m] = -[\delta] \quad [19]$$

Inspection of the columns of $[S]$ shows that the normalizing

factor is $\sqrt{2}$. It is convenient to introduce the matrix $[T]$ defined by

$$[T] = \frac{1}{\sqrt{2}}[S] \quad [20]$$

The matrix $[T]$ is its own reciprocal as may be seen from Equation [6]

$$[T][T] = [I] \quad [21]$$

The columns of $[T]$ are orthonormal (normalized orthogonal) column vectors. The matrix $[T]$ is called an orthogonal matrix, although it would seem more reasonable to call it an orthonormal matrix in agreement with the type of column vectors which it contains.

Equation [19] may now be written

$$[T][\Lambda][T][m] = -[\delta] \quad [22]$$

It is now necessary to return to the original system of equations which is to be solved. Referring to Equation [1], it may be seen that the system of equations may be written in the following matrix form

$$\begin{bmatrix} \Sigma\phi & \gamma & 0 \\ \gamma & \Sigma\phi & \gamma \\ 0 & \gamma & \Sigma\phi \end{bmatrix} \begin{bmatrix} m_1 \\ m_2 \\ m_3 \end{bmatrix} = - \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix} \quad [23]$$

where

$$\Sigma\phi = \phi_a + \phi_b \quad [24]$$

This matrix equation may be written in the following contracted form

$$[\Phi][m] = -[\delta] \quad [25]$$

In this equation $[\Phi]$ is the square matrix of coefficients. Comparing Equation [25] with Equation [22], it is seen that the matrix $[\Phi]$ has been replaced by a product of matrixes

$$[\Phi] = [T][\Lambda][T] \quad [26]$$

From this transformation it is seen that the matrixes $[\Phi]$ and $[\Lambda]$ are similar. Hence the diagonal elements of $[\Lambda]$ are the latent roots of $[\Phi]$, and the columns of $[T]$ are the latent vectors of $[\Phi]$. In characteristic value problems, which are governed by homogeneous equations, the latent roots of the matrix are very useful in obtaining the solution and are given by the simple formula of Equation [13]. In the present problem, the elements of $[\delta]$ are considered to be a set of unrelated constants which are not a function of the independent variable. A solution for $[m]$ in terms of $[\delta]$ involves the use of the reciprocal of the coefficient matrix $[\Phi]$.

Multiplying through Equation [25] by $[\Phi]^{-1}$ gives

$$[m] = -[\Phi]^{-1}[\delta] \quad [27]$$

A convenient formula for the rapid calculation of $[\Phi]^{-1}$ is obtained from Equation [26]. A law of matrix algebra states that the reciprocal of a product of matrixes is equal to the product of their reciprocals in reverse order. Since $[T]$ is its own reciprocal the formula becomes

$$[\Phi]^{-1} = [T][\Lambda]^{-1}[T] \quad [28]$$

The reciprocal of a diagonal matrix is obtained by replacing each diagonal element by its own reciprocal. Hence $[\Lambda]^{-1}$ is given in expanded form as follows

$$[\Lambda]^{-1} = \begin{bmatrix} 1/\lambda_1 & 0 & 0 \\ 0 & 1/\lambda_2 & 0 \\ 0 & 0 & 1/\lambda_3 \end{bmatrix} \quad [29]$$

Thus it is seen that a simple and rapid method of computing the reciprocal matrix becomes available through the use of orthogonal functions. The practical benefit of the method shows up more effectively with higher-order difference equations. The final formula for $[m]$ is obtained by substituting Equation [28] in Equation [27]

$$[m] = -[T][\Lambda]^{-1}[T][\delta] \quad [30]$$

It is of interest to note that the matrix $[T]$ is a standard universal matrix applicable to all beams. The effect of the physical properties of the beam is contained entirely in $[\Lambda]^{-1}$ which may be quickly computed for any given beam.

Numerical Example

Consider the four-span beam shown in Fig. 3(*b*). A set of δ values is shown directly beneath the intermediate supports. It is assumed that these values have been computed from the loading and beam properties. The flexibility values for a span are assumed to be as shown in the matrix beneath the beam. The individual beam spans are assumed to be nonprismatic but symmetrical about their own center line. This means that $\phi_a = \phi_b$.

The system of equations to be solved is as follows

$$\begin{bmatrix} 18.4 & 4.2 & 0 \\ 4.2 & 18.4 & 4.2 \\ 0 & 4.2 & 18.4 \end{bmatrix} \begin{bmatrix} m_1 \\ m_2 \\ m_3 \end{bmatrix} = - \begin{bmatrix} 4 \\ 6 \\ 3 \end{bmatrix} \quad [31]$$

The matrix $[T]$ may be determined as

$$[T] = \begin{bmatrix} 0.5 & 0.707 & 0.5 \\ 0.707 & 0 & -0.707 \\ 0.5 & -0.707 & 0.5 \end{bmatrix} \quad [32]$$

The latent roots are computed as

$$\lambda_1 = 18.4 + 8.4 \cos \frac{\pi}{4} = 24.34$$

$$\lambda_2 = 18.4 + 8.4 \cos \frac{\pi}{2} = 18.4$$

$$\lambda_3 = 18.4 + 8.4 \cos \frac{3\pi}{4} = 12.46$$

Calculating the reciprocals of these numbers gives the matrix $[\Lambda]^{-1}$

$$[\Lambda]^{-1} = \begin{bmatrix} 0.0411 & 0 & 0 \\ 0 & 0.0543 & 0 \\ 0 & 0 & 0.0803 \end{bmatrix} \quad [33]$$

The reciprocal matrix is computed in two steps

$$[\Lambda]^{-1}[T] = \begin{bmatrix} 0.205 & 0.290 & 0.0205 \\ 0.0384 & 0 & -0.0384 \\ 0.0401 & -0.0567 & 0.0401 \end{bmatrix} \quad [34]$$

$$[\Phi]^{-1} = [T][\Lambda]^{-1}[T] = \begin{bmatrix} 0.0574 & -0.0139 & 0.0032 \\ -0.0139 & 0.0606 & -0.0139 \\ 0.0032 & -0.0139 & 0.0574 \end{bmatrix} \quad [35]$$

The bending moments are given by

$$\begin{bmatrix} m_1 \\ m_2 \\ m_3 \end{bmatrix} = - [\Phi]^{-1} \begin{bmatrix} 4 \\ 6 \\ 3 \end{bmatrix} = - \begin{bmatrix} 0.1558 \\ 0.2663 \\ 0.1016 \end{bmatrix} \quad [36]$$

For any other loading condition a new set of $[\delta]$ values can be determined and multiplied by $[\Phi]^{-1}$ to obtain an immediate solution.

Conclusion

By assuming the solution of a linear difference problem in terms of appropriate orthogonal functions, which satisfy the boundary conditions, a simple method becomes available for computing the latent roots and vectors of the matrix of the system of equations. The transformation matrix of latent vectors is a universal matrix of elements which are not dependent upon the properties of the structure. The reciprocal matrix may be computed rapidly from the latent roots and vectors.

A Note on the Damped Vibration Absorber

By JOHN E. BROCK,[1] ST. LOUIS, MO.

IN THE following, formulas for optimum damping for three cases of the dynamic vibration absorber with damping are presented and the method of derivation is indicated. The writer is prejudiced against notes and papers which are not self-contained and self-explanatory; in the present instance, however, it would require twenty paragraphs of material readily available elsewhere to introduce three paragraphs of new results. Accordingly, reference is made to the book, "Mechanical Vibrations," by J. P. Den Hartog.[2] Using the notation employed by Den Hartog, and referring to the figures accompanying his text, the following remarks apply:

1 *Case of Optimum Tuning.* In this case, $f = 1/(1 + \mu)$, and the abcissas of points P and Q of the $(g, x_1/x_{st})$ diagram are, respectively

$$g_1 = \sqrt{\frac{1 - \sqrt{\mu/(2 + \mu)}}{1 + \mu}}\ ; \quad g_2 = \sqrt{\frac{1 + \sqrt{\mu/(2 + \mu)}}{1 + \mu}} \ldots [1]$$

while the common ordinate is

$$\left(\frac{x_1}{x_{st}}\right)_{g = g_1} = \left(\frac{x_1}{x_{st}}\right)_{g = g_2} = \sqrt{1 + \frac{2}{\mu}} \ldots [2]$$

In order to cause the curve of (x_1/x_{st}) vs. g to pass horizontally through point P, we first require that it pass through a point P' of abscissa $g = \sqrt{\frac{1 - \sqrt{\mu/(2 + \mu)} + \delta}{1 + \mu}}$ and ordinate $(x_1/x_{st}) = \sqrt{1 + \frac{2}{\mu}}$, and then let δ approach zero as a limit. Solving Den Hartog's equation [57] for $(c/c_c)^2$, we get

$$\left(\frac{c}{c_0}\right)^2 = \frac{(f^2 - g^2) - (x_1/x_{st})^2\left\{\mu f^2 g^2 - (1 - g^2)(f^2 - g^2)\right\}^2}{4g^2\left\{(x_1/x_{st})^2\left[1 - (1 + \mu)g^2\right]^2 - 1\right\}} \ldots [3]$$

If $g = \sqrt{\frac{1 - \sqrt{\mu/(2 + \mu)} + \delta}{1 + \mu}}$, $(x_1/x_{st}) = \sqrt{1 + \frac{2}{\mu}}$ is substituted in Equation [3], we obtain a result of the form

$$\left(\frac{c}{c_0}\right)^2 = \frac{A_0 + A_1\delta + A_2\delta^2 + A_3\delta^3 + \ldots}{B_0 + B_1\delta + B_2\delta^2 + B_3\delta^3 + \ldots} \ldots [4]$$

Since Equation [3] assumes the indeterminate form 0/0 if $\delta = 0$, it is clear that $A_0 = B_0 = 0$ and that our desired result is given by

$$(c/c_0)^2 = A_1/B_1 \ldots [5]$$

Performing the indicated operations and rationalizing the result, we obtain

$$(c/c_0)^2 = \frac{\mu\left[3 - \sqrt{\mu/(2 + \mu)}\right]}{8(1 + \mu)^3} \ldots [6]$$

By a similar process, we obtain

$$(c/c_0)^2 = \frac{\mu\left[3 + \sqrt{\mu/(2 + \mu)}\right]}{8(1 + \mu)^3} \ldots [7]$$

for a horizontal tangent at point Q. Clearly, a convenient average value is

$$(c/c_0)^2 = \frac{3\mu}{8(1 + \mu)^3} \ldots [8]$$

2 *Case of Constant Tuning.* In this case, $f = 1$, and the abscissas of points P and Q are, respectively

$$g_1 = \sqrt{1 - \sqrt{\mu/(2 + \mu)}}\ ; \quad g_2 = \sqrt{1 + \sqrt{\mu/(2 + \mu)}} \ldots [9]$$

while the ordinates are, respectively

$$\left(\frac{x_1}{x_{st}}\right)_{g = g_1} = \frac{1}{(1 + \mu)\sqrt{\mu/(2 + \mu)} - \mu}\ ;$$

$$\left(\frac{x_1}{x_{st}}\right)_{g = g_2} = \frac{1}{(1 + \mu)\sqrt{\mu/(2 + \mu)} + \mu} \ldots [10]$$

It is seen that the ordinate of point P is greater than that of point Q. Accordingly, it is desired that the $(g, x_1/x_{st})$ curve pass horizontally through point P for optimum damping. Employing the process used previously, we obtain

$$(c/c_0)^2 = \frac{\mu(3 + \mu)\left[1 + \sqrt{\mu/(2 + \mu)}\right]}{8(1 + \mu)} \ldots [11]$$

3 *Case of Lanchester Type Damper (Viscous Damping).* In this case, $f = 0$, and the abscissas of points P and Q are, respectively

$$g_1 = 0; \quad g_2 = \sqrt{2/(2 + \mu)} \ldots [12]$$

while the ordinates are

$$\left(\frac{x_1}{x_{st}}\right)_{g = g_1} = 1; \quad \left(\frac{x_1}{x_{st}}\right)_{g = g_2} = 1 + 2/\mu \ldots [13]$$

Employing the process used previously in order the make the curve pass horizontally through point Q, we obtain

$$(c/c_0)^2 = \frac{1}{2(1 + \mu)(2 + \mu)} \ldots [14]$$

for optimum damping.

An Improved Fuse Escapement for the Mark 18 and Other U. S. Navy Mechanical Time Fuses

By F. G. KELLY and J. L. ZAR,[1] WEST ORANGE, N. J.

Theoretical shortcomings of previous Army and Navy fuse escapements are pointed out. The development of a new escape wheel and lever is described, in which spurious torques due to the fall of escape-wheel teeth against the pallets are eliminated; and a tooth shape is derived which delivers accelerating impulses symmetrically about the neutral position of the lever. Fuses with the new escapement have a timing rate which is independent of driving torque over the range of torques encountered; they can be assembled with one size of wheel and lever and with no hand-matching, function at low driving torques, and have given improved firing-test performance.

THIS paper describes a revision of the conventional wheel and oscillating-lever type of time-fuse escapement. A typical mechanical time fuse is shown in Fig. 1 and its mechanism is illustrated by the schematic diagram, Fig. 2.[2] Fig. 3 shows the revised escapement, approximately 4 times full size, illustrating the working engagement.

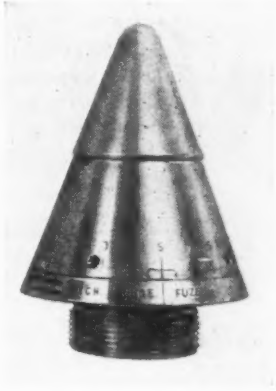

FIG. 1 TYPICAL MECHANICAL TIME FUSE

Development of this escapement was undertaken for the following reasons:

(*a*) *To Produce a Better Timekeeper.* The rate of the original Mark 18 escapement is relatively sensitive to driving torque. Since the driving torque diminishes as the fuse runs out, there is a timing error which increases rapidly with the time of flight. Fig. 4 shows the timing error in seconds versus running time for an average Mark 18 fuse, operating at constant spin. The timing of this escapement varies between the curves "fast limit" and "slow limit" in Fig. 4.[3] Since this characteristic is not the same for each fuse, there results a scattering of the firing time from this cause which may amount to ±0.10 sec after 45 sec of flight.[4] The new escapement was designed with a view toward minimizing the torque sensitivity or flattening the curve in Fig. 4.

(*b*) *To Reduce the Cost and Time of Manufacture.* The Mark 18 fuse design required very exact escapement dimensions. In its manufacture, hand-matching of escape levers and wheels was required because, with the closest tolerances that could be maintained in production, the parts could not be made accurately enough. Ten sizes of wheels were necessary, varying in steps of 0.001 in. in diam. Selection of the proper size of wheel for each individual fuse was left to the judgment of a skilled operator. In those cases where a poorly matched escapement was selected, the error was not detected until the fuse was completely assembled and tested. Consequently, there was a small percentage of rejects due to faulty escapements which had to be reworked. The second object of this development was to obtain an escapement in which a single size of wheel would serve for all fuses.

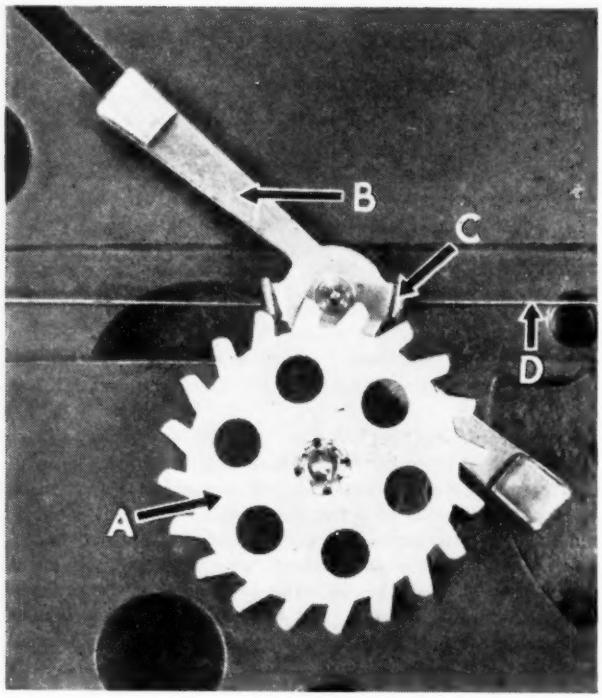
[2] Acknowledgment is made to the Encyclopedia Britannica for permission to reproduce Fig. 2, which was taken from the Encyclopedia, fourteenth edition, vol. 1, p. 826.



[3] The curve marked "fast limit" is the Navy's fast tolerance limit at the time of this development. The other two curves are taken from dynamic test data on actual fuses. In these, the initial rate was purposely made fast to compensate for the normal slowing of the escapement toward the end of its run.

[4] In actual firing, the dispersion in timing is more than this due to the effects of centrifugal force, which diminish during fuse flight. These effects are important but are not discussed in this report because those parts which are sensitive to spin were not changed. The new escapement has approximately the same spin dependence as the Mark 18.

FIG. 3 NEW ESCAPEMENT IN OPERATING ENGAGEMENT, APPROXIMATELY 4 TIMES FULL SIZE

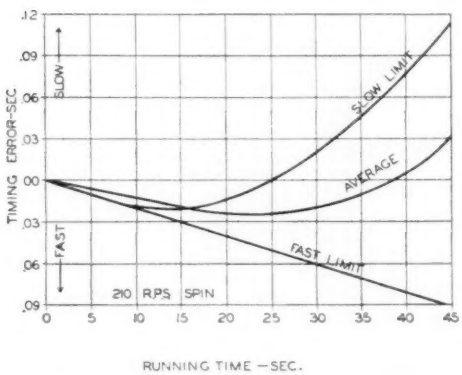

FIG. 4 TIMING ERROR OF MARK 18 FUSE AT CONSTANT SPIN

DEVELOPMENT

This work has been limited to revisions of the standard fuse escapement because it was necessary to incorporate the results into large quantity fuse production with a minimum of changes.

The first considerations were toward developing the best possible time-keeping properties. Later considerations were toward producing the broadest and deepest tooth which the pallet amplitude would permit, and the least critical tooth form. These last objectives were to minimize the effects of manufacturing variations on the operation of the escapement, and to obtain the maximum possible depth of engagement for maximum safety of operation.

In a fuse, the escape lever and hairspring approximate a simple harmonic oscillator maintained in continuous oscillation by impulses supplied through contact of the escape wheel with the pallets. It is well known (1, 2, 3)[5] that if the frequency of a mechanical oscillating system is to be made independent of variations in driving force, the driving impulses should arrive, on the average, when the mass is passing through its neutral position. This is the position of greatest velocity when the lever is moving. It is also the rest position when the lever is stationary. If this condition is met the frequency of oscillation is independent of the driving force and the escapement is a good timekeeper.

Analyses of the Navy and Army escapements have been made to determine how the driving impulses act and any other causes for their relatively high sesnsitivity to variation in driving torque.

MARK 18 OR NAVY ESCAPEMENT

A limited analysis of the Mark 18 escapement for causes contributing to its torque sensitivity is given here. Reference is made to Fig. 5 in which the escape pallets are shown in their neutral positions. The escape-wheel teeth are shown in a position where the trajectory of the tips of the pallets can touch the base circle.[6] Left and right sides are both shown in this same phase of escapement for convenience, but are actually $^1/_2$ cycle apart in time.

In the Mark 18 escapement there are several impulses of momentum delivered to the lever during each oscillation cycle. What may be thought of as the normal driving impulse is the

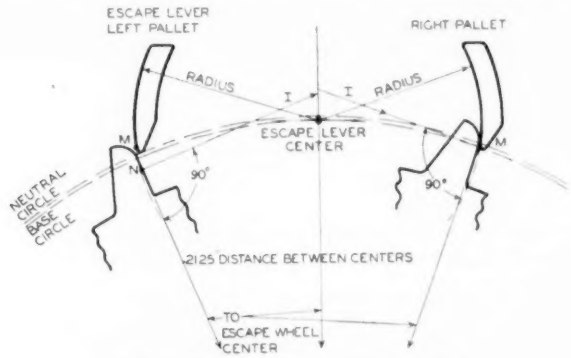

FIG. 5 MARK 18 ESCAPEMENT ACTION
(The fall impulses *I*, act above the escape-lever center.)

force of the escape-wheel tooth against the pallet as the curved portion of the tooth moves under it. Torque on the lever results from the slope of the tooth contour. Referring to Fig. 5, it will be seen that the curved or working portion of the tooth occurs almost entirely above the neutral circle. This means that the working impulses do not occur at the neutral circle but above it. Therefore, if these were the only impulses acting, the escapement would be highly torque-sensitive. As will be seen later there are other types of impulses present and the over-all torque sensitivity of the escapement depends upon the general effect of all.

Another and large impulse of momentum results from the fall impact of a tooth against a pallet. This follows the escape of another tooth from the opposite pallet. Unless the line of action of this fall impact passes through the center of rotation of the escape lever, it will affect the oscillation frequency. An analysis was made to determine the direction of action of the fall-impact force. This involved factors such as the coefficient of friction, the direction of motion of the lever, and the relative velocity of the teeth and pallets. Some of these factors are uncer-

[5] Numbers in parentheses refer to the Bibliography at the end of the paper.

[6] The phrase "base circle" is used here in the same sense as in gear-tooth design. It is the circle at which the generated tooth contour starts. In this case it intersects the points beyond which the tooth begins to escape beneath the pallet.

tain and the conclusions are only approximate, but it appeared that the most probable direction of the impact force is the vector I in Fig. 5. This is in the direction of motion of the escape-wheel tooth, at right angles to the radius of the wheel at the point of impact.

Fall impact on the left pallet occurs at a variable point, N, anywhere along the straight portion of the tooth depending upon the operating torque on the wheel. At the right pallet the fall occurs always at the same point, M, on the base circle, because the tooth is sufficiently undercut for the right-hand angular position. Fall impacts contain a great deal of momentum due to the large angular distance through which the escape wheel has accelerated before being stopped. They occur at a time when the escape lever is about farthest from its neutral position, and in the Mark 18 fuse exert a large and variable clockwise moment about the escape-lever center, hence are a major factor contributing to the torque sensitivity of the escapement.[7]

To summarize, the major impulses which drive the escape lever of the Mark 18 fuse are as follows:

1 The normal driving impulses, which are clockwise for the left pallet and counterclockwise for the right, supply momentum to the lever. These occur outside the neutral circle.

2 The fall impulses partly cancel each other because the one on the left side drives the lever while the right one retards it. They occur within the neutral circle. The left impulse originates from a variable point on the tooth, but the right one originates from a fixed point.

3 The absence of a true "dead-beat" action on the left pallet due to the forward slope of the straight portion of the tooth contributes two additional clockwise impulses to the left pallet There is no counterpart for the right pallet.

The torque sensitivity of this escapement is attributable to the fact that the net resultant of these several impulses varies in amount and direction with the driving torque, and does not in general average about the neutral position of the lever.

Mark 22 or U. S. Army Escapement

Fig. 6 is a layout of the Army escapement similar to Fig. 5. The normal driving impulses very nearly straddle the points of maximum velocity of the pallets. This is shown in Fig. 6 by the neutral circle intersecting the working face of the tooth near its mid-point. However, as in the Mark 18, there are the same off-neutral fall impulses, I. This escapement is an improvement over the Mark 18 in that both fall impulses occur on the base circle. There are no impulses due to imperfect dead-beat action. For this reason, it is probably a less erratic escapement. This fuse is also relatively torque-sensitive.

New Escapement

After the foregoing analysis to determine the possibility for improvement in existing escapements, a new design was undertaken. An analysis of the new escapement, similar to those in Figs. 5 and 6, is shown in Fig. 7 and the component parts are illustrated in detail in Figs. 10 and 11. The new escapement was designed according to the following principles:

1 Location of the wheel and level centers in the fuse plates and the center distance were not changed so that the remainder of the fuse would be unaffected by changes in the escapement.

2 The leading edge of the escape tooth was undercut sufficiently to cause the fall impact to occur at the point P on the base circle under all conditions.

[7] This explains the tendency of the Mark 18 escapement to lock on its right pallet under excess operating torque. The strong counterclockwise fall impulses throw the lever into deep engagement on its right side where a small amount of friction stops the motion completely.

3 The base circle of the wheel was located with respect to the centers of the wheel and lever so that the line of action of the fall impact I, taken in the direction of motion of the tooth, passes through the center of rotation of the lever. This prevents the fall impacts from producing driving torques and disturbing the frequency of oscillation.

4 An escape tooth form was derived as outlined in the next section. It delivers an efficient impulse over the major part of the curved portion of the tooth. It was made as broad as possible, consistent with the amount of space available, so as to obtain a maximum depth of engagement for reasons of safety.

5 The tips of the pallets were located so that the normal accelerating impulses occur symmetrically about each side of the neutral circle, that is, the neutral circle was made to intersect the curved portion of the tooth at the mid-point of the angle subtended by the radii OP and OR from the center of the lever to the ends of the curved portion of the tooth.

6 In designing the escape wheel, it was desirable to have as many teeth as possible and still allow free pallet action with adequate tolerances. These considerations permitted up to 24 teeth, but the number chosen was 20 to allow an easy change-over in the dynamic test equipment used with the former 30-tooth escapement.

7 In order for the new fuse with two thirds as many teeth to run as long as the Mark 18 (45 sec), it was necessary to reduce the oscillation frequency of the escapement proportionately. This was done by adding weights to the ends of the lever and keeping the same hairspring.

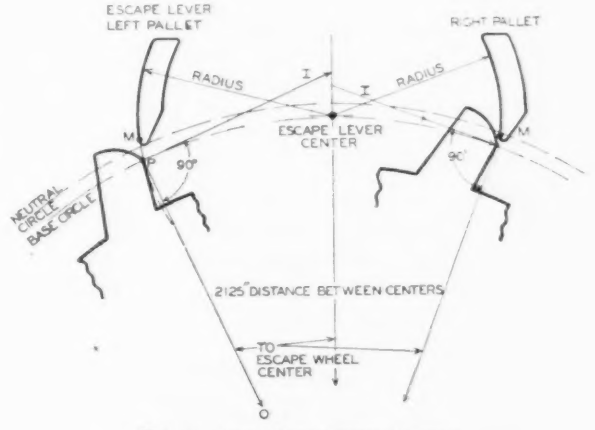

Fig. 6 Army Escapement Action
(The fall impulses I act above escape-lever center.)

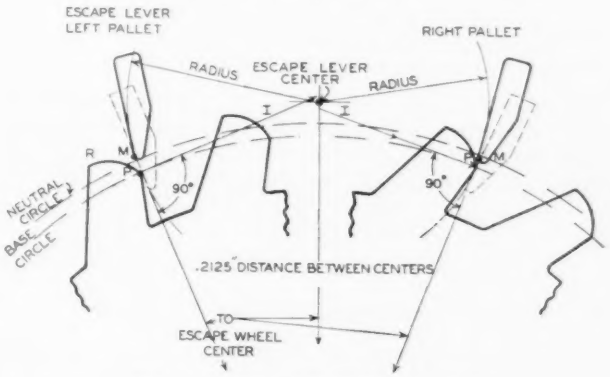

Fig. 7 Action of New Escapement
(The escapement is designed so that the fall impulses I come, on the average, at the escape-lever center.)

8 The manufacture of the new lever was simplified by making the pallets straight-sided instead of cylindrical and by swaging rather than grinding the angle of their back surfaces. (These are the surfaces which operate against the angles of the back sides of the escapement teeth during reverse running of the fuse when it is being wound.)

9 In adapting the new escapement to the Mark 18, a small amount of routing was necessitated in the No. 2 plate to clear the weights added to the lever.

10 Since the new escapement operates at 108.8 cycles per sec instead of 163.2, the dynamic test equipment was changed to accommodate the lower oscillation frequency. The same fuse standards and test tables were used, but the signal amplifier and the first stage of multivibrators driving the printer bar were tuned to 215 cycles per sec. Thus the dynamic test tapes obtained with the new fuse were identical in appearance and interpretation with those obtained for the Mark 18.

Derivation of Escape-Wheel Tooth Form

The tooth form was designed to transfer energy from the wheel to the lever efficiently and to produce the driving impulses, on the average, when the lever was passing through its neutral position. To transfer energy efficiently, the time of contact of the pallet with the tooth during the escape phase was made as long as possible by providing a broad tooth. To place the impulses properly it was not sufficient to use the geometrical layout as explained in item 5 previously. It was also desired to have a tooth form which would apply approximately a constant force to the escape lever during the entire time that the pallet and tooth are in contact.

The form for the escape surface is derived by assuming a wheel accelerating from rest under a uniform torque, a pallet traveling with uniform angular velocity, and by tracing the curve described by the pallet contact point M on the wheel. Assumption of a uniform angular velocity for the pallet is not strictly correct, but the approximation has not led to serious error as can be judged from the test results.

In order to simplify the discussion, losses in the oscillating lever will first be neglected. Following this treatment the derived tooth form will be corrected for these losses in a manner to be described.

In the derivation, reference is made to Fig. 8 and the following nomenclature is used:

- r = mean wheel radius at curved portion of tooth
- θ = angle turned by wheel from position where pallet tip M leaves point P on tooth, radians
- α = angular acceleration of wheel
- t = time, sec
- I = moment of inertia of escape wheel and driving gears
- v = maximum velocity of pallet
- T = driving torque accelerating wheel

Co-ordinates of the points M, x, and y are not rectangular. They are measured along arcs about C and O, centers of the wheel and lever, respectively. The constant acceleration of the escape wheel leads to an equation for the x-co-ordinate of the tooth

$$\alpha = T/I \quad [1]$$

$$x = r\theta = {}^1/_2\ \alpha t^2 r = {}^1/_2 T t^2 r/I \quad [2]$$

From the approximation of constant velocity of the pallet

$$y = vt \quad [3]$$

hence

$$x = {}^1/_2\ (rT/v^2 I) y^2 \quad [4]$$

The last equation shows the tooth form to be approximately parabolic (approximate because the co-ordinates are not exactly rectangular).

The tooth form is evaluated from Equation [4]. The displacement of the pallet is

$$y = A \sin 2\pi ft \quad [5]$$

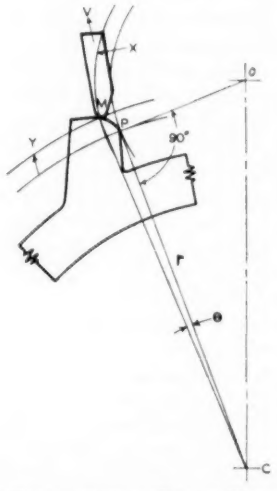

Fig. 8 Generation of Escape Tooth Form
(C is the center of the escape wheel; o is the center of the escape lever.)

where A is the amplitude of the pallet oscillation and f is its frequency, 108.8 cycles per sec. The average value of lever amplitude ϕ for the Mark 18 fuse, as manufactured, was ± 8 deg. The least value which would fully uncover the light exit slot used for dynamic regulation, was ±7 deg. The maximum amplitude allowed by stops was ±18 deg. Because higher amplitudes enhance the safety of a fuse, the minimum amplitude of oscillation of the new escapement was chosen as ± 8.5 deg. Using $R = 0.08$ in. for the radius of the point M on the pallet tip

$$A = R\phi \quad [6]$$

$$v = 2\pi fA = 8.1 \text{ in. per sec} \quad [7]$$

The moment of inertia of the Mark 18 escape wheel and pinion plus the inertias of the next two gears of the train multiplied by the squares of their speed ratios to that of the escape wheel was calculated very carefully. This value, 90 per cent of which was in the escape wheel and pinion, was

$$I = 7.2 \times 10^{-6} \text{ lb sq in} = 0.021 \text{ g sq cm} \quad [8]$$

The inertia of the remainder of the gear train was negligible. The foregoing value of inertia is that which must be accelerated by the fuse torque in the operation of the escapement. The same value of inertia in the new escapement wheel was obtained by making it 0.012 in. thick instead of 0.010 in. thick, it being slightly smaller in diameter than the original wheel.

The driving torque at the center shaft of the Mark 18 fuse, produced by the centrifugal sectors and starting springs, is 3000 gram-cm at the start of flight and 1100 gram-cm after 47 sec of flight.

Calculation of the torque efficiency of the gear train under actual flight conditions was made and was found to be 28 per cent. Multiplying the central-shaft torque values by this factor and by the gear-train ratio (1/275), the actual torques applied to the escapement shaft are 3.1 gram-cm maximum, and 1.1 gram-cm minimum. The minimum of these torques, together with other numerical constants previously given, were substituted in

Equation [4] and numerical values of x and y obtained. These are plotted in Fig. 9, curve A, on curved co-ordinates having radii of curvature originating at the wheel center C and lever center O.

The tooth form just calculated is based on the assumption of no frictional losses in the escapement. Actually, various losses cause the lever to lose momentum between impulses. In order to maintain the oscillation it is therefore necessary for the tooth to exert torque on the pallets during each driving impulse. This consumes part of the driving torque. The net torque accelerating the wheel equals the difference between the gear-train torque and that absorbed by the lever.

In order to maintain the same 8.5-deg minimum lever amplitude, it is necessary to correct the tooth form for frictional losses.

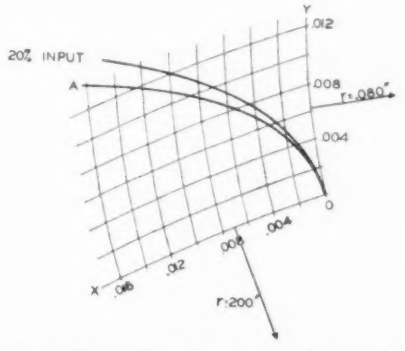

FIG. 9 CALCULATED TOOTH FORM PLOTTED ON CURVED CO-ORDINATES

Referring to Equation [4], if v is to remain unchanged, y must be varied inversely as the square root of T, since r and I are fixed.

Losses in the lever have been arbitrarily estimated to consume 20 per cent of the driving torque. All ordinates of the tooth form must therefore be increased by $1/\sqrt{0.8} = 1.1$. In Fig. 9 a corrected tooth-form curve marked "20 per cent input" has been drawn with all ordinates increased 10 per cent over their no-loss values.

In applying the 20 per cent input curve to the wheel, as shown in Fig. 10, the tooth form was approximated by a single circular arc of radius 0.020 in., terminating in a tangential line at 80 deg to the wheel radius. Due to manufacturing tolerances on so small a tooth, this approximation is adequate.

TEST RESULTS

Three pilot lots totaling about 400 escapements were produced with parts as shown in Figs. 10 and 11 and put into Mark 18 clock assemblies. These assemblies were given exhaustive laboratory and firing tests. While the laboratory results were excellent, the firing tests were at first disappointing as there were a number of duds and short-time firings. Trouble was traced to cap slippage and a mechanical interference with the W-74 safety-lever plate. Later, when this was corrected, the firing tests confirmed the engineering conclusions as to the timekeeping ability and reliability of the new escapement.

Characteristics, as revealed by tests on the pilot lots and by subsequent experience in production and use, are summarized as follows:

(*a*) *Timekeeping Ability.* The effect of driving torque on the rate of the escapement is less than one tenth that of the original Mark 18 escapement. When plotted on the graph, Fig. 4, the average production fuse with the new escapement gives a straight line for the timing-error versus running-time curve. If the initial timing rate is adjusted correctly, there is no appreciable accumulated timing error. Even when the engagement was purposely mismatched to test the effect of tolerance extremes on performance, the variation in rate after 45 sec of running, as determined by dynamic test, was never more than 0.08 per cent. The accumulated timing error was never more than 0.03 sec.

(*b*) *Reduction in Cost and Time of Manufacture.* In the pilot lots of escapements, one size of wheel and lever was manufactured and assembled without selection. Likewise, in production, only one size of wheel and lever was manufactured. No hand-matching was used or required. Skilled operators were eliminated in escapement assembly with consequent speed-up of the operation and reduction of cost.

In the final dynamic testing there were considerable savings due to increased rapidity of test and fewer retests. With the new escapement, the rate is inherently stable. The test operator was reasonably certain that if the initial rate were set correctly, the fuse would run well within tolerances. With the old escapement the rate was highly variable, and it was necessary for the operator to start the clock on the fast tolerance in order to fall within limits at the end of the run. There were 10 to 20 per cent of fuses which would not fall within the tolerance limits due to excessive change in rate. The borderline cases caused hesitancy and uncertainty and required retesting. The rejects had to be reassembled with other escapements.

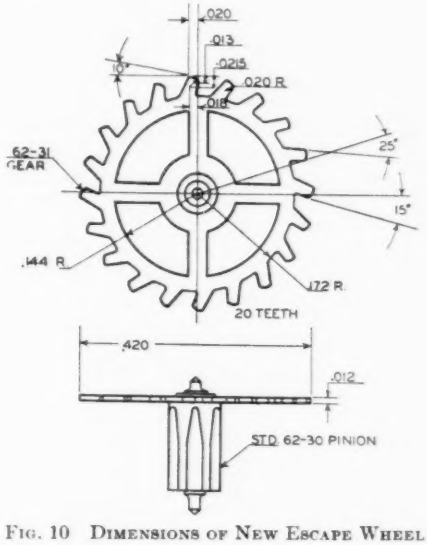

FIG. 10 DIMENSIONS OF NEW ESCAPE WHEEL

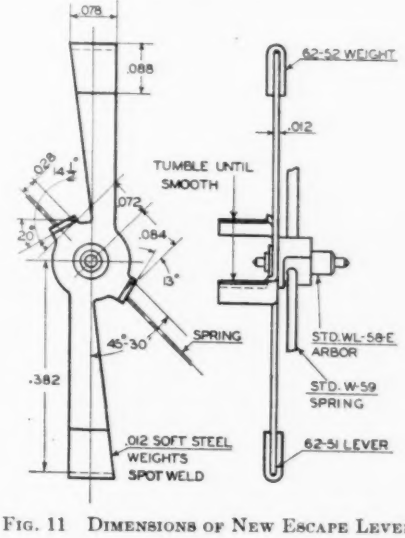

FIG. 11 DIMENSIONS OF NEW ESCAPE LEVER

The manufacture of the lever was simplified and expedited by swaging the back angles of the pallets, which formerly had been ground, reducing the number of grinding operations and amount of handling. The manufacture and stocking of the wheel was simplified by a reduction from ten sizes and ten part numbers to one size and one part number.

(*c*) *Tolerance in Engagement.* The following engineering test was made on the new design: In the escapement plates, saw cuts were made around the pivot holes for the escape wheel so that the center distance between wheel and lever could be adjusted by bending the resulting ribs. A series of tests were made with center distances varying from 0.2090 in. to 0.2160 in. (the correct center distance being 0.2125 in.). Over the entire range, the escapement would run and could be regulated to give good timing. This represented a range of engagement which would have required fourteen sizes of escape wheels had the experiment been attempted with the old escapement.

(*d*) *Low Operating Torque.* It was found that fuses with the new escapement would run full time with less than one half the normal operating torque. In the Mark 18 fuse, the available operating torque approaches the minimum running torque for the old escapement. If under actual service conditions, the gear-train friction becomes excessive, there is the likelihood that the old escapement would fail to run full time. With the new escapement this danger is lessened.

(*e*) *Self-Starting Characteristic.* The escapement was found to be self-starting for separations of the lever and wheel pivots ranging from 0.211 in. to the maximum that could be used. As soon as the normal torque is applied to the gear train, the majority of fuses with the new escapement would start to run. However, because of the wide range of escapement engagements encountered in production, the centrifugal starting device found in the Mark 18 is still necessary for that fraction of the fuses which requires a flick for starting. The easier starting of the new escapement contributes to the reliability of the fuse.

(*f*) *Firing Performance.* After several months of production experience with fuses using the new escapement, a comparison of firing results with figures for the old fuse showed a dispersion in firing time at long settings of about one half the value of the older escapement. Out of 35 lots of fuses tested at the proving grounds, there was not a single dud. Several factors other than the timing of the escapement contribute to the dispersion in firing time.

Acknowledgments

The development of this escapement was undertaken at the suggestion of Mr. K. G. Berggren, vice-president and manager of the Special Products Division of the authors' company. Certain theoretical work was contributed by Dr. J. Hornbostel. Trouble-shooting, assistance in firing-testing, and compilation of firing-test data were done by W. J. Meyers, Lieutenant U.S. N.R. Thanks are also due members of the Special Products Division, too numerous for individual mention, who aided in production and testing of the pilot lots of fuses.

Control and Prediction of Pulsation Frequency in a Duct System

By W. R. HEATH[1] and W. R. ELLIOT,[2] BUFFALO, N. Y.

The authors present the results of studies on compressor-duct systems which are characterized by unstable operation over some portion of the performance curves. The principles of the Helmholtz resonator are explained, and the prediction of pulsations in a duct system may be developed by considering that the system acts as a simple Helmholtz resonator. For certain cases electrical analogy is used to explain acoustical conditions in the duct. Methods of preventing pulsations are described.

CERTAIN compressor-duct systems exhibit unstable operating characteristics over a portion of the performance curve. Compressors are usually selected for such a capacity that stable operation will be maintained; however, it is sometimes necessary to reduce the volume delivered beyond the critical point on the performance curve, with the result that operation is unstable.

A typical performance curve for a single-stage centrifugal compressor is shown in Fig. 1. That this compressor may be unstable in operation at any point to the left of the peak pressure and stable at any point to the right may be demonstrated as follows (1).[3]

Consider the compressor to be operating at any point to the left of P, where an increase in static pressure is accompanied by an increase in capacity. If for any reason there is a slight rise in the static pressure against which the compressor is operating, the volume of air delivered will be increased. This increase in capacity results in a still further increase in static pressure creating even greater unbalance. Therefore the static pressure in the system is temporarily higher than that for the corresponding capacity on the compressor performance curve as, for example, at the point A. Conversely, if the static pressure is momentarily decreased, the resulting decrease in capacity causes a still further drop in static pressure, which is now less than the pressure corresponding to the capacity on the performance curve, as at B.

The actual operation of the compressor may be conceived to be not on the performance curve but around a loop close to the performance curve of the compressor. The minimum pressure which occurs during a cycle may be as low as the shutoff pressure, so that air flow through the compressor momentarily ceases. However, the pulsation, which occurs as the static pressure varies, may be of such high frequency or of such small magnitude that it is not detectable by the human ear.

If the compressor is operating at any point to the right of the peak pressure, operation may be shown to be stable by a similar method of reasoning, and pulsation does not occur.

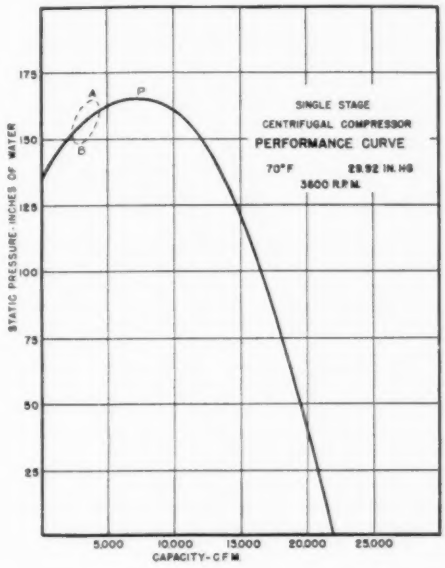

FIG. 1

HELMHOLTZ RESONATOR

When a compressor is operating on the unstable portion of its performance curve, the duct system to which it is connected acts as a Helmholtz resonator, and the frequency of the pulsation which occurs depends on the size and distribution of this system.

A simple Helmholtz resonator (2, 3) is shown in Fig. 2. This consists essentially of a relatively large volume V_0, connected to the outside through a neck of area S and length L. Such a resonator has practically uniform compressions and rarefactions in the main body, which is alternately compressed and expanded by movement of the air in the neck. The ratio of the area S to the length L of the neck is called the "conductivity" of the resonator. In the case of a circular orifice in the thin-walled chamber, the conductivity is equal to the diameter of the opening.

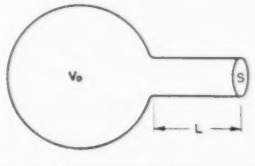

FIG. 2 HELMHOLTZ RESONATOR

The frequency of pulsation of a simple resonator with dry air at 70 F is

$$f = \frac{c}{2\pi}\sqrt{\frac{S}{LV_0}} = 178\sqrt{\frac{S}{LV_0}}$$

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

where

f = frequency of pulsation, cycles per sec
S = area of neck of resonator, sq ft
L = length of neck, ft
V_0 = volume of resonator, cu ft
c = velocity of sound in air, fps

From the form of the Helmholtz equation, it is apparent that the frequency of pulsation depends only on the three variables included in the equation and is independent of other quantities which may be variables in a duct system. It has been determined by both Lieberg (4) and Pochettino (5) that the shape of the orifice or neck has no effect except that a mouth with a large aspect ratio reduces the damping effect.

Prediction of Pulsation Frequency

The results of a series of tests conducted in the laboratory are given in Table 1. From this experimental work it has been found that the frequency of pulsation, if it occurs in a duct system, can be very closely approximated by considering that the system acts as a simple Helmholtz resonator. The following quantities may be substituted in the original Helmholz equation:

TABLE 1 LABORATORY PULSATION TEST RESULTS

TEST NO	VOLUME OF SYSTEM V_0	LENGTH OF NECK L	DIAMETER OF SMALL DUCT	CALCULATED FREQUENCY PULSATIONS PER MINUTE	OBSERVED FREQUENCY PULSATIONS PER MINUTE	DIAGRAM OF DUCT SYSTEMS
1	144	28 0	14"	174	173	
2	144	22 1	14"	196	186	
3	102 5	28 0	14"	206	210	
4	102 5	22 1	14"	234	229	
5	61	28 0	14"	267	285	
6	61	22 1	14"	302	296	
7	90	16 2	14"	290	270	
8	49	16 2	14"	392	400	
9	62 9	28 5	10"	225	240	
10	38 7	28 5	10"	255	280	

S = area of small duct, sq ft
D = impeller diameter, ft
L = $2\pi D$ plus length of transformation piece plus length of small duct, ft
V_0 = volume of ductwork plus transformation piece plus compressor, cu ft

The validity of the simple relationship established was subsequently verified in several wind tunnels. The computed and actual frequencies of same are tabulated in Table 2. It should be noted that it made no difference whether the volume V_0 was on the inlet or discharge side of the compressor or whether situated partly on both sides.

TABLE 2 WIND-TUNNEL TESTS

No.	Installation	S	L	V	—Frequency— Calculated	Observed
1	Blower	25	66	7250	77.4	77–80
2	Blower and exhauster (same unit as no. 1)	25	43	80500	28.7	27–28
3	Two compressors operating in parallel both exhausting from one chamber and blowing into another	27	100	99000	23	21–26

One interesting observation was that no pulsation was detectable until the static pressure was 8.9 in. of water or higher. At and close to this pressure point, pulsations could be started by causing a slightly higher static pressure temporarily, but they quickly died away. It is probable that below this static pressure any incipient pulsations are damped out and this may explain why pulsation is not a problem in most ventilating systems.

The one case for which the established relationship has not proved valid is when the compressor discharges into a long narrow duct with no "concentrated" volume. In this case, the frequency is invariably much higher than that predicted by the established empirical relationship. An explanation may be found in the analogous cases of electrical and acoustical phenomena. According to Weinbach (6), "the natural or resonant frequency of an electrical circuit with distributed capacitance, as they occur, for example, in a line, is 57 per cent greater than the resonant frequency of a circuit having an equal capacitance as the line but in a 'lumped' form."

Based on this electrical analogy, the constant in the Helmholtz equation should, for a long pipe of small diameter, be increased to 280 instead of 178.

Borderline cases in both electrical and acoustical phenomena cannot be predicted with too great accuracy. By a borderline case is meant one in which the volume of the duct is partly distributed and partly concentrated. For this case, the frequency will lie between that for a concentrated volume and that for an equal distributed volume.

Of some interest is the fact that in the electrical system, those factors which have no effect on the frequency of pulsation have no effect in the analogous acoustical system. These may be listed briefly as follows:

1 Variation in compressor speed or in the volume of air handled has no effect on the frequency.

2 Variation in static pressure has no effect on f, except in that the pressure developed may be low enough that damping prevents audible pulsation.

3 Introduction of a high resistance in either an electrical or a mechanical system is a method of preventing pulsation.

The pulsations produced by a compressor-duct system are of particular importance when the frequency of the pulsations is low. At low frequencies, high-amplitude beats result in increased noise level and in considerable pressure variations within the duct system. These pulsations may be detected as individual beats by the human ear up to a frequency of about 450 per min. Above 600 per min individual pulsations cannot be detected and are objectionable only in that the noise level possibly may be increased.

By predetermining whether or not pulsation is to be a problem, precautions may be taken to insure stable operation over the entire working range.

Prevention of Pulsation

When required operating conditions are such that the static pressure must be maintained but at a volume below the critical volume, pulsation may be prevented by by-passing a portion of the air delivered by the compressor (7).

For example, it may be necessary for the compressor to deliver a volume of air at the static pressure indicated by the point R, Fig. 3. In this case the volume at the point S may be delivered by the compressor at the required static pressure, the required volume admitted to the duct system and the excess volume, volume S minus volume R, by-passed to atmosphere. This allows the compressor to handle a volume greater than the critical volume and to operate on the stable portion of the performance curve. This system of bleeding the excess air delivered by the compressor is more wasteful of power than the other methods of control, as the power required remains constant for all volumes below the critical volume. It can, however, be applied to any

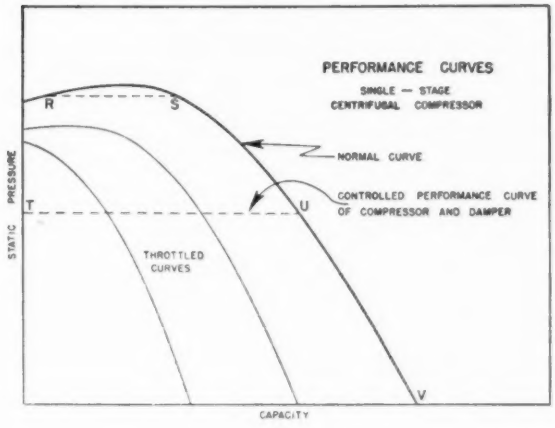

FIG. 3

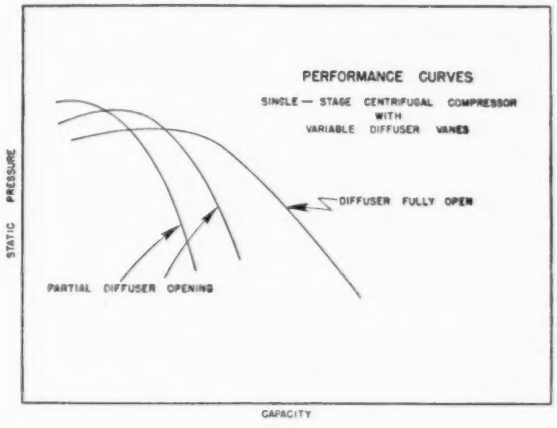

FIG. 4

centrifugal compressor and has the advantage that it allows a high static pressure to be maintained. The amount of air bled can be controlled by controlling the minimum velocity pressure at the inlet or discharge, or by controlling the horsepower input to the compressor.

A second method of pulsation control is to throttle close to the compressor and obtain a multiplicity of performance curves as indicated in Fig. 3. If control is to be obtained by throttling, the static pressure may be maintained constant over the major portion of the operating range, with the result that the controlled performance curve of the fan plus the damper can be represented by the line *TUV*, Fig. 3. Use of a throttle either before or after the compressor results in increased resistance in the system with consequent reduction in efficiency. However, as throttling reduces the horsepower required for a given volume, this method of control is less wasteful than bleeding. In the case of multistage compressors satisfactory control possibly may not be achieved solely by throttling because of the inherently large volume of the compressor, which itself may act as a resonator with a frequency low enough to be objectionable.

Prevention of pulsation by the use of variable diffuser vanes after the compressor is an efficient control method. This consists of providing movable vanes which may be adjusted automatically or manually. By use of diffuser vanes, the static pressure is maintained and regulation may be obtained nearly down to zero volume. Regulation by diffuser vanes results in a series of operating curves for various diffuser settings, as shown in Fig. 4. The envelope of these curves indicates the limit of stable operation for various settings of the diffuser. Diffuser vanes are applicable to both single-stage and multistage compressors. They require additional space and also have the disadvantage that they add to the initial cost of the compressor. They should be used only when conditions justify this additional cost.

Other methods of control are by varying the speed by use of turbine drive or variable-speed motor, and by use of a substage compressor ahead of the regular first stage (8). By this latter method when the volume required drops below the critical volume the excess air required to prevent pulsation is by-passed to the inlet of the substage fan. Part of the energy in the otherwise blowoff waste air is put back on the shaft through this substage fan acting as an air turbine.

The Theory of Curved Beams

BY G. C. BEST,[1] SAN DIEGO, CALIF.

In this paper, the theory of curved beams is developed by a somewhat different procedure from that customarily employed. Deflections at the centroid are first assumed and then loads and stresses resulting from these deflections are estimated. This process works out in a somewhat more orderly fashion than the conventional development. Throughout, all measurements are to the centroidal axis rather than to the neutral axis. Final results are presented in such a form that satisfactory accuracy may be obtained from slide-rule computations and approximate integration. Hence the procedure is applicable to any section, it being unnecessary first to develop a special formula for each different section. An illustrative example is given. The theory is extended to cover the case of unsymmetrical bending of curved beams. The effects of torsion, which will probably also occur in the generalized case, are not treated. These can be superimposed upon stresses due to bending.

Nomenclature

The following nomenclature is used in the paper:

A = area of cross section
R = distance from center of curvature to center of gravity (CG) of section
z = radial co-ordinate; positive outward, measured from CG of section
P = axial load at centroid, positive when producing tension at centroid
M_x = moment about x-axis (i.e., having x-arm), positive when producing tension on positive side of x-axis
M_z = moment about z-axis (i.e., having z-arm), positive when producing tension on positive side of z-axis.
M_{xx} = moment about x-axis = M_z
M_{zz} = moment about z-axis = M_x
ϵ = strain at centroidal axis, positive for extension
φ = rotation about x-axis (through CG of section), positive when producing extension for positive z
ψ = rotation about z-axis (through CG of section), positive when producing extension for positive x
E = Young's modulus
$\epsilon' = E\epsilon$
$\varphi' = E\varphi$
$\psi' = E\psi$

$$A' = \int \frac{dA}{1 + \frac{z}{R}}$$

$$Q_x' = \int \frac{zdA}{1 + \frac{z}{R}}$$

$$Q_z' = \int \frac{xdA}{1 + \frac{z}{R}}$$

$$I_x' = \int \frac{x^2dA}{1 + \frac{z}{R}} = I_{zz}' \text{ (i.e., subscripts are similar to moment subscripts)}$$

$$I_z' = \int \frac{z^2dA}{1 + \frac{z}{R}} = I_{xx}'$$

$$I_{xz}' = \int \frac{xzdA}{1 + \frac{z}{R}}$$

$a = A'$
$b = Q_x'$
$c = Q_z'$
$d = I_x'$
$e = I_z'$
$f = I_{xz}'$
D = determinant of system (refer to Equations [5])

$$J' = \frac{e}{1 + e/AR^2}$$

δ = distance from neutral axis to centroid of section, always positive

Introduction

In the following work the same assumptions are made as in the conventional development. In particular, radial plane sections remain plane, and stresses do not exceed the proportional limit. The centroidal axis of the beam considered lies in the (x, y) plane and the radius of curvature of this centroidal axis is R. Radial sections are all identical, i.e., the section is constant, though not

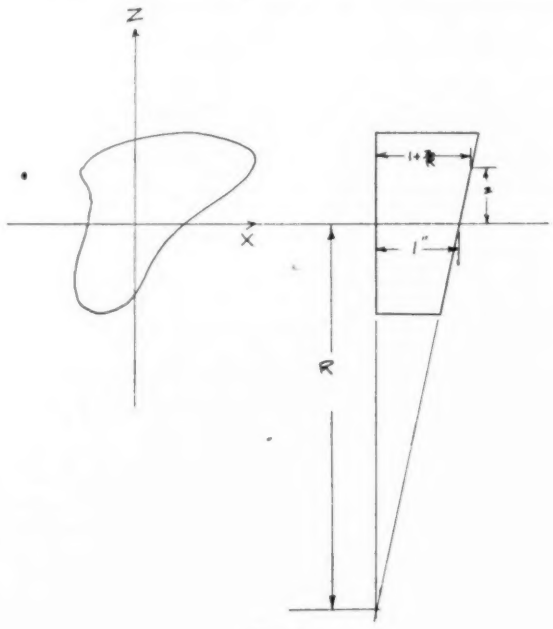

Fig. 1

[1] Stress Analyst.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., December 2–6, 1946, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1947, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

necessarily symmetrical about the z-axis. Radial planes are passed through the beam at two adjoining points 1 in. apart on the centroidal axis, isolating a portion of the beam as shown in Fig. 1. Inner and outer edges have been altered into straight lines for simplicity since the effect of this change is negligible; i.e., involves only second-degree infinitesimals.

Rotation About X-Axis. One face is then rotated relative to the other about the x-axis through an angle of φ radians. The stress at a point located a distance z from the x-axis is

$$\sigma = \frac{Ez\varphi}{1 + \frac{z}{R}}$$

The resulting loads at the center of gravity (CG) of the section are

$$\left.\begin{aligned} P_\varphi &= \int \sigma dA = \int E\frac{z\varphi}{1+\frac{z}{R}}dA = E\varphi\int\frac{zdA}{1+\frac{z}{R}} = E\varphi Q_x' \\ M_{x\varphi} &= \int \sigma x dA = \int \frac{Ez\varphi x}{1+\frac{z}{R}}dA = E\varphi\int\frac{zxdA}{1+\frac{z}{R}} = E\varphi I_{xz}' \\ M_{z\varphi} &= \int \sigma z dA = \int \frac{Ez^2\varphi}{1+\frac{z}{R}}dA = E\varphi\int\frac{z^2dA}{1+\frac{z}{R}} = E\varphi I_z' \end{aligned}\right\} \ldots [1]$$

Rotation About Z-Axis. Similarly, if one face rotates relative to the other about the z-axis through the angle of ψ radians, the stress σ at a point a distance x from the z-axis and z from the x-axis is

$$\sigma = \frac{E\psi x}{1 + \frac{z}{R}}$$

The resulting loads at the CG are

$$P_\psi = E\psi Q_z' \qquad M_{x\psi} = E\psi I_z' \qquad M_{z\psi} = E\psi I_{xz}' \ldots [2]$$

Uniform Extension. If one face is moved away from the other a distance ϵ without rotation, the stress at a point z from the x-axis is

$$\sigma = \frac{E\epsilon}{1 + \frac{z}{R}}$$

and resulting loads at the CG are

$$P_\epsilon = E\epsilon A' \qquad M_{x\epsilon} = E\epsilon Q_x' \qquad M_{z\epsilon} = E\epsilon Q_z' \ldots [3]$$

Relations Between Section Moments and Areas. It is possible to write

$$I_z' = \int\frac{z^2dA}{1+\frac{z}{R}} = R\int\frac{z^2dA}{R+z}$$
$$= R\int\frac{z(z+R-R)dA}{R+z} = R\int zdA - R^2\int\frac{zdA}{R+z}$$

The first integral = 0 since z is measured from the centroid; hence

$$I_z' = -R^2\int\frac{zdA}{R+z} = -R\int\frac{zdA}{1+\frac{z}{R}} = -RQ_x'$$

or in the simpler notation

$$e = -Rc$$

By similar manipulations all told there are the following relations

$$e = -Rc \qquad a = \frac{e}{R^2} + A \qquad f = -Rb \ldots [4]$$

General Formulas

Adding the loads at the centroid produced by deformations ϵ, ψ, φ gives

$$\left.\begin{aligned} P &= P_\epsilon + P_\psi + P_\varphi = a\epsilon' + b\psi' + c\varphi' \\ M_x &= M_{x\epsilon} + M_{x\psi} + M_{x\varphi} = b\epsilon' + d\psi' + f\varphi' \\ M_z &= M_{z\epsilon} + M_{z\psi} + M_{z\varphi} = c\epsilon' + f\psi' + e\varphi' \end{aligned}\right\} \ldots [5]$$

The determinant D of this system is symmetrical and reduces, in view of Relations [4], to

$$D = A(de - f^2) \ldots [6]$$

Adding stresses due to all three displacements gives

$$\sigma = \frac{1}{1+\frac{z}{R}}(\epsilon' + x\psi' + z\varphi') \ldots [7]$$

Solving Equations [5] for ϵ', ψ', φ' and making use of Relations [4] gives

$$\left.\begin{aligned} \epsilon' &= \frac{P}{A} + \frac{M_z}{AR} \\ \psi' &= \frac{Ae}{D}M_x - \frac{Af}{D}M_z \\ \varphi' &= \frac{P}{AR} - \frac{Af}{D}M_x + \left(\frac{1}{AR^2} + \frac{Ad}{D}\right)M_z \end{aligned}\right\} \ldots [8]$$

Inserting these values in Equation [7] and rearranging gives

$$\sigma = \frac{P}{A} + \frac{(ex-fz)}{(ed-f^2)} \times \frac{M_x}{1+\frac{z}{R}} + \left[\frac{1}{AR} - \frac{1}{\left(1+\frac{z}{R}\right)} \times \frac{(xf-dz)}{(de-f^2)}\right]M_z \ldots [9]$$

It can be seen that for an axial load alone the stress is constant, i.e., $\sigma = P/A$. For the case $R = \infty$ (i.e., a straight beam), Equation [9] simplifies into Swain's formula (1),[2] consideration being given to the difference in definitions in terms and sign conventions.

Symmetrical Sections

If the section is symmetrical about the z-axis and $M_z = 0$, Equation [9] simplifies considerably since $b = f = 0$. In this case, neglecting the term involving P, Equation [9] becomes

$$\sigma = M_x\left[\frac{1}{AR} + \frac{z}{\left(1+\frac{z}{R}\right)e}\right] \ldots [10]$$

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

This corresponds to the form in which this formula appears in reference (2).

Or the stress may be expressed in the following form, corresponding to reference (3)

$$\sigma = \frac{M_z(z + \delta)}{J'\left(1 + \frac{z}{R}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

where

$$J' = \frac{e}{1 + e/AR^2} = \frac{I_z'}{1 + I_z'/AR^2} \quad \ldots\ldots\ldots [11a]$$

and δ = distance from centroid to neutral axis; always considered positive

$$\delta = J'/AR \quad \ldots\ldots\ldots\ldots\ldots\ldots [11b]$$

The curved-beam factor K of reference (2) becomes

$$K = \frac{I(1 + \delta/z)}{J'(1 + z/R)} \quad \ldots\ldots\ldots\ldots\ldots [11c]$$

These relationships may be obtained by setting $\sigma = 0$ (neutral axis) in Equation [10], recalling that δ is always positive and making use of Relations [4].

Computation of Section Properties

In reference (2) the term Z is defined as "changing symbols to correspond with the notation used in this article"

$$Z = -\frac{1}{A}\int \frac{z}{R + z}\, dA$$

For large R this term will be very small, the co-ordinate z being measured to the CG of the section. Hence, if a slide rule is used and the integral evaluated by approximate methods, differences between slide-rule-computed values of nearly the same amount will occur and considerable loss in accuracy will result. To reduce this effect Z can be written

$$Z = e/AR^2$$

where

$$e = R\int \frac{z^2 dA}{R + z}$$

Here the only differences which occur are in the denominator in adding R to z when z is negative, since the numerators are always positive, being squares. The error in z will be the error in estimating the position of the centroid and $R + z$ will contain a larger percentage of error than z if $R + z < |z|$.

This effect, however, is much less serious than that encountered in the first-mentioned integral since, in the computation of e, the denominator term $R + z$ never approximately equals zero, and only a few terms of the sum are appreciably affected. It should be noted that, for sharp curvature, it is necessary to divide the area into more divisions near the center of curvature where $R + z$ will change rapidly than further from it.

Example Problem

In the following problem, the stress at the extreme inner fiber of the section, shown in Fig. 2, will be computed. The distance R

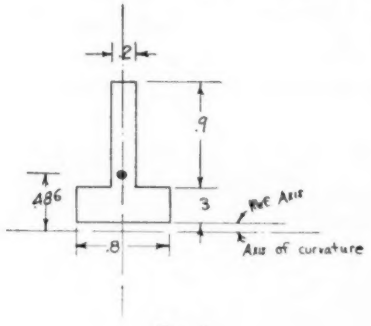

Fig. 2

from the centroidal axis to the axis of curvature is 0.486 in. The applied moment $M_z + = 3300$ in-lb. Since the section is one of those for which a curved-beam factor K has already been computed, see reference (2), this stress can be obtained from the formula

$$\sigma = \frac{MzK}{I}$$

In this case $K = 3.63$ since $R/c = \frac{0.486}{0.406} = 1.20$. From the following computations $z = -0.406$ and $I = 0.05069$; hence

$$\sigma = \frac{+3300(-0.406)(3.63)}{0.05069} = -96{,}000 \text{ psi}$$

All computations given in Table I are made upon the slide rule.

Σ	1.200		0.4200 = A	0.1709 = Q			0.05069 = I		0.15017 = I_z'/R

$$\bar{z} = \frac{Q}{A} = \frac{0.1709}{0.4200} = 0.406$$

$$I_z' = 0.15017 \times 0.486 = 0.073$$

$$J' = 0.073/[1 + 0.073/0.42 \times 0.486^2] = 0.073/1.735 = 0.0422$$

$$\delta = \frac{J'}{AR} = 0.0422/0.420 \times 0.486 = 0.206$$

Equation [11] gives $\sigma = \dfrac{+3300[-0.406 + 0.206]}{0.0422[1 - 0.406/0.486]} = \dfrac{3300 \times (-0.200)}{0.0422 \times 0.163} = -96{,}200$ psi

Discussion

A General Method for Calculating Critical Speeds of Flexible Rotors[1]

A. H. Ehlinger.[2] The author is to be congratulated for the valuable contribution he has made in the field of critical-speed studies. In regard to the application of gyroscopic effect of rotating disks, the writer wishes to point out a few simple relationships which might be helpful. For example, if the disk were set up on rectangular co-ordinates, Fig. 1 of this discussion, with the

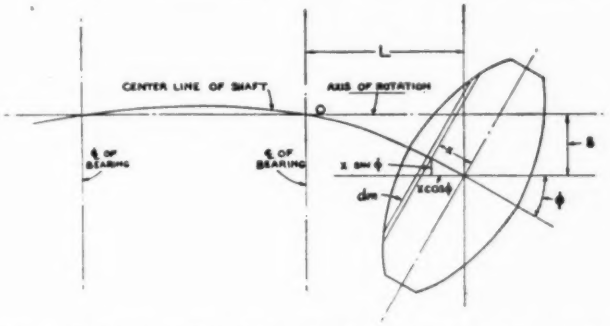

Fig. 1 Example of Disk Set Up on Rectangular Co-Ordinates

origin lying at the center of gravity of the disk and the X-axis coinciding with the center line of the shaft, then A and B may be defined as follows

$$A = \int Z^2dm + \int Y^2dm = 2\int Z^2dm$$
$$B = \int Z^2dm + \int X^2dm$$
$$A - B = \int Z^2dm - \int X^2dm$$

The last equation can also be derived by treating the disk as a series of thin disks. Den Hartog[3] shows that the moment exerted by the inertia forces on a thin rotating disk may be expressed as follows

$$M = \omega^2\phi \int Z^2dm$$

where

ω = speed of rotation, radians per sec
ϕ = angle of inclination between shaft center line and axis of rotation at location of disk, radians

The foregoing equation could also be used for a series of thin disks. However, one must not overlook the effect this would have on the bending moment due to transverse forces on the shaft. To illustrate, let us consider a disk of mass m overhung on a shaft at a distance L from point 0, the nearest support. Considering the disk as a point mass located at its center of gravity, the moment at point 0 due to transverse loading will be as follows

$$M_0 = m\omega^2\delta L$$

where

δ = deflection of center of gravity of disk

Now consider the disk divided into an infinite number of thin disks each having a mass dm. Assume all disks normal to the shaft and that angle ϕ remains constant. The increment of moment at point 0 due to any one of these elemental disks will be

$$dM_0 = \omega^2(\delta \pm X \sin\phi)(L \pm X\cos\phi)dm$$

Since ϕ is small, $\sin\phi = \phi$, and $\cos\phi = 1$.
Therefore

$$dM_0 = \omega^2(\delta \pm X\phi)(L \pm X)dm$$

The signs are positive when dm lies beyond the center of gravity of the whole mass and are negative when dm lies within the center of gravity.

Summing up moments within the center-of-gravity point

$$M_1 = \omega^2(\delta L\int dm - \phi L\int Xdm - \delta\int Xdm + \phi\int X^2dm)$$

Summing up moments beyond the center-of-gravity point

$$M_2 = \omega^2(\delta L\int dm + \phi L\int Xdm + \delta\int Xdm + \phi\int X^2dm)$$

By definition, $\int Xdm$ is of the same magnitude on either side of the center of gravity. Therefore in the addition of M_1 and M_2 the terms containing $\int xdm$ with opposite signs will cancel out, and the total moment at point 0 due to transverse loading is as follows

$$M_0 = M_1 + M_2 = m\omega^2\delta L + \omega^2\phi\int X^2dm$$

The total bending moment at point 0 due to the rotating disk becomes

$$M_B = M_0 - M$$
$$= m\omega^2\delta L + \omega^2\phi\int X^2dm - \omega^2\phi\int Z^2dm$$
$$= m\omega^2\delta L - \omega^2\phi(A - B)$$

The foregoing derivation is further proof that error is involved when the rotating disk is considered as a mass concentrated in a thin disk of thickness dX. It is also interesting to note that for a sphere $A = B$, and there would be no change in moment due to gyroscopic effect as applied to the rotating case.

A. M. G. Moody.[4] To be seen in perspective, the author's method should be compared with the many methods which have been developed in the past for calculating critical speeds. A work by Holba[5] presents more than a dozen methods, all about equally frightful to apply. To be sure, for lowest critical speeds of relatively simple shafts, present methods, as described in the standard works of Timoshenko and Den Hartog, are perfectly

FIG. 2 DEMONSTRATION OF AUTHOR'S METHOD OF CALCULATING CRITICAL SPEEDS

satisfactory. But the writer agrees with the author that no method based upon the Rayleigh approach that has to his knowledge been presented for higher critical speeds can compare with this as a practical working method.

A suggestion, however, is in order: The example given in the paper is very complicated. Admittedly, this is the type of problem which shows the new method to the best advantage. Nevertheless, it would be easier to master the procedure if a simple example, easily checked in the handbooks, were given. This would also tend to build confidence in the method since no one ever questions a handbook result.

The writer has therefore taken it upon himself to give a crude illustration of what he means. The example, Fig. 2 of this discussion, shows a two-bearing shaft, 2 in. diam, 16 in. between bearing centers, with two 100-lb loads each 4 in. from a bearing. The critical speed calculated from the formula given in Marks's handbook is 9680 rpm. Starting with this as an assumed speed and applying the author's method, we find, as would be expected, that we have no residual moment.

From Fig. 2

$$y_3 = (320.24 \times 10^{-7}V_0) + (30.87 \times 10^{-7}\theta_0) = 0$$

$$\theta_0 = -\frac{320.24}{30.87} \quad V_0 = -10.37V_0$$

$$M_3 = 30.94V_0 + 2.956\theta_0$$
$$= 30.94V_0 - 30.65V_0$$

H. PORITSKY.[6] We believe that the author's method is far superior to methods at present available and in common use This is particularly true when it comes to the calculation of the second and third critical speeds and also for rotors with multiple bearings and overhanging spans.

The methods commonly employed for critical-speed calculations are based upon Rayleigh's method and consist in assuming the shape of vibration, calculating the potential and kinetic energies, and computing the natural frequency from the ratio of these two. This procedure is justified by the fact that a first-order departure in the assumed shape of vibration from the true shape results only in a second-order error in the frequency. Moreover, the lowest critical is lower than any frequency which can be obtained by the foregoing method. In calculating the lowest frequency, it is customary to assume a deflection shape equal to the gravity deflection. This calculation may be improved by replacing the gravity weights by centrifugal loads derived from the gravity deflection and determining the resulting deflection; by similar further repetition the lowest critical can be accurately obtained.

When it comes to the higher critical, however or to rotors with several spans, it is clear that the gravity deflection is a very poor approximation, and various rather arbitrary schemes, all of them ill-founded, have been used for guessing the shape which will form the starting point of the calculations. With a poorly guessed shape the discrepancy between the computed vibration frequency and the true values of critical frequencies is likely to be considerable. Furthermore, for the second and higher critica s, an assumed shape may lead to a frequency which is either higher or lower than the true frequency, and it is impossible to tell which of two calculations is to be preferred.

Finally the foregoing method of iteration, which converges for the lowest critical, does not converge when applied to the higher critical speeds, unless the assumed shape satisfies a proper "orthogonality condition" relative to the shapes of the lower critical speeds. This condition is rather inconvenient to apply and only multiplies the uncertainties of the existing methods of computing critical speeds.

[6] Engineering General Division, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

As compared with the uncertainties mentioned, the method developed by the author is clear-cut and straightforward. It consists essentially in numerical integration of the differential equation of beam deflections for an assumed frequency. Since proper boundary conditions apply at either end of each span, two solutions have to be obtained over each span before all of the boundary conditions can be satisfied. Two or more frequencies have to be tried before the true critical frequency is determined by the vanishing of a proper residual moment.

The interpretation in terms of a finite number of thin disks on a massless shaft is illuminating and makes the method similar to Holzer's method for torsional vibrations. It will be noted that in the latter domain, Holzer's method has been universally adopted even though the Rayleigh method of assuming shapes is available here, too. It is the writer's opinion that a similar situation will soon obtain in the field of critical speeds of rotors, and the enthusiasm of several people who have tried the method in cases where long involved calculations hitherto have yielded relatively uncertain information only serves to corroborate it.

It may be pointed out in conclusion that the integration of the deflection may be carried out by means of the differential analyzer, though as many distinct solutions would still have to be obtained before the boundary conditions can be satisfied as outlined herein.

ERNEST L. ROBINSON.[7] This paper makes a very definite contribution to the technique of computation of the transverse critical speeds of rotating shafts, especially a shaft with several spans; it is bad enough to get the transverse critical speed of a single span by equating kinetic energy of rotation to the internal energy of bending for a variety of assumed deflection curves. This much-used technique works when one has a fairly good notion of the true shape. It is not necessary to be too precise but it is necessary to be pretty good. It is easily possible to be pretty bad. The likelihood of being pretty bad increases greatly when the arrangement of loadings and shaft diameters becomes complex and it gets almost hopeless with several spans. There is no doubt that skillful estimates are possible by existing methods, especially when the approximate answer is known from long experience. But when that is not the case, a straightforward way to proceed is most welcome indeed.

The writer recently sent the author the loadings and diameters for a complex four-bearing tandem-compound turbine generator set which had been the basis of analysis for several months. It must be admitted that these were wartime months and help was limited. However, using less than a week's time of one expert comptometer operator, the author produced the first critical speed, including its actual deflection curve and handed it to the writer at the meeting when he presented his paper. The calculations agreed closely with tests which had just been made on a dynamically similar model, both as regards frequency and shape of the deflection curve.

The paper, of course, still leaves to experienced engineering judgment the questions as to whether shaft speed should be restricted to values below the first critical or whether it is preferable to run through one or more critical speeds and operate at or between higher critical speeds.

STANLEY THOMPSON.[8] In his abstract, the author states that the Stodola process for finding critical speeds lacks generality in that critical speeds other than the fundamental cannot be determined definitely.

[7] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

[8] Design Development Engineer, Westinghouse Electric Corporation, Aviation Gas Turbine Division, Lester, Pa.

Den Hartog[9] gives a formula

$$a_n = \frac{\int_0^l \mu_1(x) y(x) y_n(x) dx}{\int^l \mu_1(x) y_n^2(x) dx}$$

by use of which the Stodola process is generalized to higher modes. By evaluating a_n the amount of any known mode present in an arbitrary curve can be determined and the mode removed. By the reasoning used by Den Hartog,[10] if the first mode, for instance, is removed, the Stodola process converges to the second mode.

The amount of work involved in the Stodola process is quite comparable to that in the present paper, since essentially the same operations are performed, but in different order. For the calculation of a first-mode critical, approximately the same number of trials would be needed to find the frequency by either method.

With the author's method it is possible to calculate any desired mode without determining lower modes which is not possible with the Stodola process.

AUTHOR'S CLOSURE

The author wishes to thank Messrs. Ehlinger, Moody, Poritsky, Robinson, and Thompson for their constructive comments.

Mr. Ehlinger has presented an alternative derivation for the "gyroscopic effect" due to the disk moment of inertia. This confirms the momentum analysis used in the paper. He points out that for a sphere the two moments of inertia A and B are equal and therefore the gyroscopic effect disappears. This condition also exists for the case of a thick disk, as may be seen by examining Equations [51] and [52] of the paper

$$A = B, \text{ when } \frac{h}{D} = \sqrt{\frac{3}{4}} = 0.866$$

where: h = axial thickness
D = diameter

The author is indebted to Mr. Moody for a sample calculation dealing with a very simple rotor. This makes a valuable addition to the paper.

Dr. Portisky has presented an excellent comparison of various critical-speed calculation methods with which the author is in complete accord.

Mr. Robinson has indicated the difficulties which arise in applying Rayleigh's method. It should be pointed out that this method usually gives good results for the first critical speed of single-span rotors if the assumed deflection curve is taken equal to the static deflection curve. The first critical speed of two-span rotors and some three-span rotors can often be calculated with sufficient accuracy if a static deflection curve is used where the direction of the gravity loading is reversed in going from one span to the next. For the calculation of the first critical speed of complicated multispan rotors Rayleigh's method does not provide a satisfactory line of attack; and for the calculation of higher critical speeds the basic principle of the method is not applicable. Incidentally, the second as well as the first critical speed was calculated by the author for the four-bearing turbine generator set mentioned by Mr. Robinson.

Mr. Thompson has taken exception to the following statement in the abstract of the paper ". . . the methods for which the computations are comparatively simple, such as the familiar methods of Rayleigh and Stodola, lack generality in that critical speeds other than the fundamental cannot be definitely determined." The Stodola method to which reference is made is the simple itera-

[9] Reference 3 of Ehlinger discussion, "Mechanical Vibrations," p. 193.

[10] Ibid., pp. 194–196.

tion procedure described in detail by Den Hartog[11] which converges only for the fundamental mode of vibration. This method can be modified or generalized as pointed out by both Mr. Thompson and Dr. Poritsky, so that higher critical speeds can be evaluated, but when this method is thus generalized it does not appear to the author that the calculation procedure will be as practical or straightforward as that given in the author's paper.

Messrs. N. A. Boukidis and R. J. Ruggiero in a recently published paper[12] give a working procedure for calculating natural-frequencies which is based on this generalization of the Stodola process. One disadvantage of their procedure is the large number of significant figures which must be carried in the computations in order to get definite values for the higher criticals, and these authors make the following recommendation ". . . the safest procedure is to retain as many significant digits as the calculating machine to be used will handle."

The Effect of Triaxiality on the Technical Cohesive Strength of Steels[1]

L. R. Jackson.[2] Through the use of some exceptionally carefully obtained data on the strength of notched steel bars, the authors have made a distinct contribution to the difficult problem of fracture under combined stresses.

Their interpretation of their results depends to a large extent upon the premise that, after a small amount of plastic flow has relieved stress concentration, both the longitudinal and radial stresses are substantially uniformly distributed over the base of the notch.

This premise and its consequences deserve some further comment.

Assuming that the premise is true, one of the methods they have used to compute the radial and circumferential stresses is through the use of Equation [5], which involves the measurement of stress at maximum load for both notched and unnotched bars.

There is some recent information, not cited by Sachs and Lubahn, which provides further support for this method of computation.

As they point out, this computation depends upon three assumptions (in addition to the assumption of uniform stress distribution):

1 That the metal flow obeys either the "maximum shear condition" or the "energy of distortion condition."

2 That the maximum load is reached after the same amount of flow in both the notched and unnotched bars.

3 That a given amount of flow results in the same state (hardness) of the metal regardless of stress system under which that amount of flow was obtained.

The first of these assumptions has a rather extensive experimental background, and while the last two assumptions would appear in any case to be good approximations there is some additional evidence supporting them.

Regarding assumption 2, Gensamer[3] has shown that in a simple tension test the maximum load is reached when

$$\frac{dS_0}{d\delta} = S_0 \qquad [1]$$

where S_0 is the tensile stress and δ is the true strain.

Or that

$$\delta = \int_{S_{0y}}^{S_{0m}} \frac{dS_0}{S_0} = \ln \frac{S_{0m}}{S_{0y}} \qquad [2]$$

where S_{0m} is the stress when maximum load is reached and S_{0y} is the stress when plastic flow begins.

Assuming with the authors that enough plastic flow has occurred to eliminate stress concentration, and make Equation [5] of the paper

$$\frac{S_T}{S_L} = 1 - \frac{S_0}{S_L} = k \text{ (a constant)} \qquad [3]$$

The load L at any time during plastic flow as measured on a tensile machine is

$$L = S_L A \qquad [4]$$

where A is the instantaneous area and can be computed from the relation

$$\delta = \ln \frac{A_0}{A}$$

$$A = A_0 e^{-\delta} \qquad [5]$$

from Equation [3]

$$S_L = \frac{S_0}{1 - k}$$

and

$$L = \frac{S_0}{1 - k} A_0 e^{-\delta} \qquad [6]$$

At maximum load, $dL = 0$ or

$$dL = \frac{A_0}{1 - k} e^{-\delta} dS_0 - \frac{A_0}{1 - k} e^{-\delta} S_0 d\delta = 0 \qquad [7]$$

from which

$$\frac{dS_0}{d\delta} = S_0 \qquad [8]$$

This is identical with Equation [1] of this discussion, obtained for simple tension, and indicates that except for the small amount of flow required to eliminate stress concentrations and establish $\frac{S_T}{S_L} = k$, the true strain is the same at maximum load for both notched and unnotched bars.

With respect to the third assumption, Bridgman[4] has recently obtained some data indicating that if a steel is plastically deformed by a combination of hydrostatic pressure and tension and subsequently tested in simple tension, the true stress - true strain curve so obtained is a prolongation of the one obtained in simple tension, and starts at the point which would be predicted from the amount of strain it had previously received under combined stresses. That is, at least for combinations involving hydrostatic pressure and tension, it appears that strain-hardening does not depend to a large extent upon the stress system producing that hardening.

[4] "Effects of High Hydrostatic Pressure on the Plastic Properties of Metals," by P. W. Bridgman, *Reviews of Modern Physics*, vol. 17, 1945, pp. 3–14.

While the foregoing arguments support the method used by the authors to compute the triaxiality of the stress system, the validity of the method still rests on the premise that the stress distribution is substantially uniform. The authors present indirect evidence that this is correct; however, it might be possible to produce an experimental proof which should be quite convincing along the following lines:

As the authors have pointed out, it is difficult experimentally to produce a known hydrostatic tension; however, it is relatively easy to produce known hydrostatic compression. If notched bars similar to those used by Sachs and Lubahn were pulled under hydrostatic pressure, it should be possible to use a value of pressure which would just cancel the hydrostatic tension as computed by their methods. If their initial premise is correct and the hydrostatic tension provided by the notch is substantially constant, then the bars should break as though the stress applied were simple tension.

D. J. McAdam, Jr.[5] The comment made in the paper concerning the investigation of technical cohesive strength by the writer and associates may give an incorrect impression to those who have not read our papers. The first of these comments is "...only a limited amount of information of a rather speculative nature is available regarding the effect of triaxiality on the cohesive strength (17, 18)."[6] The amount of information obtained in our investigation, however, is not limited to the two papers (17, 18), but has been presented in six papers. Three of these are more recent than the two papers mentioned and two of the three have been in print for $1^1/_4$ and $2^1/_4$ years, respectively. A list of six papers (*a* to *f*), together with three additional papers (*g*, *h*, *i*), which are now preprinted, appears at the end of this discussion. Far from being merely "speculative," these papers present the results of extensive experiments on a great variety of ferrous and nonferrous metals, in various conditions as regards heat-treatment and work hardening. The temperatures range between room temperature and —188 C. The notched tensile specimens used varied widely in notch depth, notch angle, and root radius.

The derived curves of variation of strength and ductility with notch angle and with notch depth made it possible to distinguish the influences of the transverse radial stress and the stress concentration, and to reveal the influence of the radial-stress ratio (ratio of mean transverse radial stress to mean longitudinal stress) on the breaking stress. Each of the papers (*a* to *i*) shows that the "technical cohesion limit" tends to increase with increase in the radial-stress ratio and does so increase unless the influence of the radial-stress ratio is masked by associated variations of the stress concentration and ductility. It was also stated that the "technical cohesive strength" (a property of the metal) of a brittle metal may be represented by a curved surface in a diagram with the three principal stresses as co-ordinates, and that the "initial" technical cohesive strength of a ductile metal may be pictured approximately by a similar surface outside the surface representing yield but inside the generally more complex surface representing fracture, after the varying plastic deformation due to the varying ductility. Any point on such a surface represents a technical cohesion limit.

It was also reported that plastic deformation increases the technical cohesive strength continuously, at a decreasing rate, and only slightly less rapidly than it increases the flow stress. It was shown in numerous diagrams that this small differential effect of plastic deformation accounts for the wide variations of ductility with the radial-stress ratio and with other factors that have even slight differential effect on flow stress and cohesion limit.

In a previous paper by the authors (9) is the following statement: "The cohesive strength of a heat-treated steel increases with increasing triaxiality, only slightly less rapidly than the flow stress (shear stress), confirming McAdam's conceptions. The closeness of these two relations accounts for the rapid changes from a ductile to a brittle condition, which may be caused by rather small changes in metal structure or type of load application." A less complete statement of the same ideas is given by the authors in the third conclusion of their present paper.

The evidence for the first conclusion stated at the end of the paper now under discussion does not appear convincing. Moreover, even if the ratio between the mean radial and longitudinal stresses does remain constant throughout the first 5 per cent of strain, there is much redistribution of both stresses, and the ratio between the radial and longitudinal stresses at the origin of fracture probably differs considerably from the initial ratio of mean values. The values for radial-stress ratio used in the writer's diagrams were obtained by an empirical method, and the diagrams represent qualitatively the variations of strength and ductility with the radial-stress ratio. The authors' implication that our empirical derivation is similar to theirs is incorrect (*c*, *d*).

Results of our experiments (*c*, *d*, *e*, *f*, *g*) indicate that the second conclusion presented by the authors is not generally correct. Many of our curves of variation of strength and ductility with the notch angle show clearly that plastic deformation of only 2 per cent leaves an objectionable amount of stress concentration, in some metals at least, when the initial stress concentration is high. The amount of plastic deformation required for satisfactory reduction of the stress concentration varies with the metal, with the notch characteristics, and with the temperature. This amount of plastic deformation sometimes is as high as 30 per cent, and stress concentration may affect the entire flow-stress curve to the point of fracture. The explanation for the slow relief of initially high stress concentration probably is that plastic deformation causes first a quick partial relief of the concentration but that the relief of stress concentration is associated with the development of a deformation gradient and a resultant hardness gradient. Because of this hardness gradient, further diminution of stress concentration is relatively slow. Moreover, the evidence presented by the authors for their second conclusion is not convincing, but may be interpreted in different ways which cannot now be discussed.

The linear variations of cohesion with plastic strain, represented in Fig. 19 of the paper, is not in accordance with the evidence obtained in our experiments with metals that had been cold-worked various amounts. Moreover, as the increase of cohesive strength with plastic deformation is the result of work-hardening, it would be expected that the increase would be at a decreasing rate, qualitatively similar to the increase of the flow stress. As the rate of work-hardening of heat-treated steels, such as those used by the authors, is relatively slow, the curvilinear variation of the cohesive strength would be less prominent than if they had used metals that harden rapidly with plastic deformation.

The fourth conclusion by the authors is of some value as an empirical criterion. In a paper (*i*) now preprinted, the writer discusses the complete three-dimensional diagram representing fracture, and concludes that fracture is determined by a limiting value of some shearing stress, either the maximum shearing stress or the octahedral shearing stress. This critical shearing stress, however, is not constant, but decreases with increase in the volume stress and becomes zero when the stress is polar-symmetric ($S_1 = S_2 = S_3$).

CLARENCE ZENER[7] AND J. H. HOLLOMON.[8] On their first reading of this paper the writers were skeptical of the conclusions contained therein that the technical cohesive strength increases with increasing triaxiality. They therefore examined the original data contained in the authors' previous paper (9) in an attempt to see if the influence of strain could be more completely eliminated. This paper contains the data for five tests of the S.A.E. steel heat-treated to the 220,000-psi strength level in which the strain at fracture lay within the narrow range from 0.026 to 0.028. These data are presented as Fig. 1 of this discussion. The conclusions reached by the authors are apparently incontrovertible.

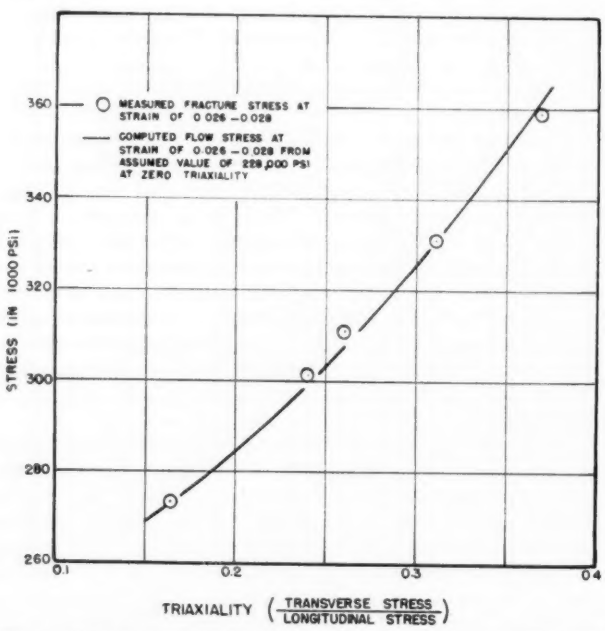

FIG. 1 DEPENDENCE OF FRACTURE STRESS UPON BIAXIAL TENSION

At fracture the flow stress intersects the virtual cohesive stress. The measured fracture stresses in the strain range 0.026 to 0.028 should therefore also be the flow stresses at the same value of the triaxiality. In order to test this viewpoint a flow stress curve was computed as a function of the triaxiality and this curve is also shown in Fig. 1. Complete agreement is obtained.

AUTHORS' CLOSURE

Mr. Jackson offers proof for the validity of our assumption that the ultimate strength values for notched and unnotched specimens, respectively, can be taken as the stresses the ratios of which depend primarily on the magnitude of the (average) transverse stress relative to the (average) longitudinal stress. It should be pointed out, however, that whereas the theoretical analysis of the maximum load strains referred to by Mr. Jackson should apply correctly for conditions where the stress and strain are uniformly distributed over the cross section, the stress and strain gradients present in notched specimens may be such that the necking strain for the notched specimen might be considerably different from that of the unnotched specimen. The stress-concentration factor is reduced practically to unity after a small plastic strain has occurred, i.e., it is reduced to a value which has a negligible amount of effect on the stress at fracture. However, the small stress-concentration factor which remains after a small plastic strain has occurred and the changes of this quantity with further plastic flow may be sufficiently large to affect the shape of the stress-strain curve, and thus also the maximum load strain, or "necking strain." Furthermore, the triaxiality may depend slightly on the amount of strain (because of changes in notch contour, for example) and this also would affect the shape of the stress-strain curve and the necking strain for the notched specimen. The magnitude of the effects which small changes in the triaxiality and stress-concentration factor may have on the necking strain is indicated by data on heat-treated steels presented in a previous publication.[9] According to these results, the necking strain may be higher for a notched specimen than for an unnotched specimen, and apparently increases with increasing notch depth. For other materials, however, particularly those possessing large strain-hardening rates, the necking strain of a notched specimen may be considerably less than that of an unnotched specimen of the same materials, as follows:

CONVENTIONAL LONGITUDINAL NECKING STRAIN

Type of specimen	Copper	Mild steel
Unnotched, per cent	53	31
Notched, per cent	43	22

Regarding Mr. McAdam's comments, we feel that the value of his work is generally recognized, particularly regarding the wide range of variables he has investigated, and we have expressed this in our paper. On the other hand, it appears that many others feel, with us, that a complete understanding of the notched tensile test cannot be reached without an extensive fundamental investigation under conditions which reduce the number of variables to a minimum. According to the most basic laws of research, definite and generally recognized conclusions can be drawn only from series of tests in each of which all the variables have been eliminated except one and which therefore require a long and tedious procedure if the validity of any general conception is to be proved conclusively. Our efforts have been primarily in this

[9] "Notched-Bar Tensile Tests on Heat-Treated Low-Alloy Steels," by G. Sachs and J. D. Lubahn, Trans. American Society for Metals, vol. 32, 1943, pp. 125–158, Fig. 7.

direction, and consequently the experimentation has been aimed at a study of the effect of one variable at a time. Certainly, the last word regarding the dependence of the conditions at fracture upon the state of stress has not yet been spoken. Many extensive additional investigations will be required to establish the basic function which has so far been found to be particularly elusive.

There is one factor regarding notched tensile tests which perhaps should be clarified at this time. This is the dependence of the triaxiality upon progressive plastic strain. It has been mentioned in the paper that nearly the same triaxiality value was obtained by measurements in the elastic region and after a rather small amount of plastic strain, say, five per cent. For very large plastic strains it is recognized that appreciable variations in triaxiality might occur, especially because of changes in the notch contour, and possibly also because of small changes in stress-concentration factor and deformation gradient.

VARIATIONS IN TRIAXIALITY WITH PLASTIC STRAIN

	Plastic strain per cent	Triaxiality
Copper	2	0.32
	50	0.17
Heat-treated low-alloy steel	2	0.33
	13	0.29

It should be observed that the larger the plastic strain involved, the larger is the variation in triaxiality. Certainly, over the range of strains investigated in the paper, it may be concluded that variations in triaxiality may be neglected.

We are particularly indebted to Messrs. Zener and Holloman, who obtained quantitative agreement with our analysis by a different approach, and who have thereby contributed significantly to a more basic understanding of the notched tensile test.

Stresses in a Cylindrical Shell Due to Nozzle or Pipe Connection[1]

WALTER SAMANS.[2] The work done in these tests confirms what has always been the supposed type of deformation in the shell of a drum subject to internal pressure at a point where piping was attached. As the authors point out, it is not complete and needs to be supplemented by a whole series of tests to become of use to the designer.

It is not possible to have codes for boilers or pressure vessels show methods of computation for all types of loadings on the vessel causing secondary stresses, although there is a tendency to keep adding that type of information in appendixes. The general acceptance of that practice would depend on whether or not it is agreed that codes shall become a handbook of engineering information. It would seem better that such data be collected and published separately, letting the codes be the guide on the selection of materials and working stresses as applied to the membranes of vessels.

The test was made on a type of shell having two different thicknesses and, as the authors acknowledge, too short to avoid the effect of the end restraint. There was no opportunity to apply internal pressure to the shell, and this would indicate that the outward deformation, where the maximum tensile stress existed axially in the attached pipe, would not be decreased or increased by internal pressure, while the compressive forces on the opposite side would be reduced.

For every combination of shell diameter and thickness, with diameter and thickness of attached pipe, there would be an internal pressure at which the deformation would be substantially the maximum. In the test, the pipe attached to the thin shell had better be reinforced as would be required by code rules, to get a true comparison with practice. As the pipe becomes larger it may be found that the reinforcement should continue around the connected pipe as a ring; although it is recognized that the authors have confined this particular paper to ordinary sizes of pipe connections on boiler drums.

In the particular assembly, there may have been some condition of restraint imposed by the half of the vessel of greater thickness on the thinner wall, and likewise proportionately less restraint by the half of the vessel having the thin wall on the deformation due to the loading of the pipe inserted in the thick wall.

For the application of this principle to large drums at high temperatures, as used in the oil-refining industry and in which sizes of connected piping may be as much as 30 in., the effort in design is to minimize the travel of the pipe near the drum by proper expansion joints and support independent of the vessel. Therefore, the amount of deflection in the pipe should be segregated between that due to the flexure in the pipe itself and that due to distortion in the vessel wall around the connection. For that segregation, it is necessary or at least seems desirable to reproduce the pressure in the vessel. In this connection there is no indication that the experiment reported in this paper could include the out-of-roundness in diameter produced by the loads on the piping. With two-way stresses existing in the shell, the deformations are not strictly a measure of stress, and in fact the stress may be higher than the deformation indicates due to Poisson's ratio.[3]

On the whole, however, this experiment indicates the need for further work of the same kind, but carried out more extensively. For instance, there might be two models each longer than used here, in which various sizes of pipe are attached in a row in sufficient distance from each other. These pipes could be of different lengths, the larger pipe being at the top and the longest, and so on down. This might permit simultaneous loadings or loadings applied on each pipe in turn without much effort in changing the attachment. In order to obtain the full value of such tests and retain the value of balanced loading, a symmetrical arrangement of piping on both sides similar to the original tests could be used. There should be two separate cylinders of different thicknesses and then the connection of the pipe to the cylinder could be made in a different manner on opposite sides, particularly as to the type of ring reinforcement around the pipe to maintain the circular shape. This should produce less distortion in the shell.

The tests could also be amplified to take care of torsional moments on the pipe.

Altogether the authors have opened up by direct action a new field of investigation in connection with the safe use of pressure vessels which has been too long deferred.

AUTHORS' CLOSURE

Mr. Samans' comments are well applied to this paper and are very much appreciated by the authors. He brings in the question of whether or not methods of computation for loadings causing secondary stresses should be included in codes for boilers or pressure vessels. The authors agree with him that the subject has not reached the stage where this could intelligently and simply be accomplished.

As pointed out by Mr. Samans, it is true that many other arrangements could be adapted, including adding of reinforcing pads around the connections to the shell which would provide additional data and which certainly should be given full considera-

[3] Unless a correction was made to allow for this.

tion if additional tests are contemplated by any of our readers.

Regarding the question of deformations not strictly a measure of stress, it may be pointed out that the stresses reported in the paper were the results of two-dimensional strain-gage readings that were corrected for deformation due to Poisson's ratio and therefore in so far as the authors know are correct and true stresses. In points where the direction of the principal stresses was not known, strain-gage rosettes were used to determine both direction and magnitude. By Mr. Samans' footnote comment,[3] he appreciates that possibly this correction was made.

As pointed out in the paper, the authors realize that this is just the beginning of the accumulation of actual data on a construction that is commonly used today and in which the value of secondary stresses becomes more important as higher design membrane stresses are allowed and the vessel walls become correspondingly thinner and have less margin of working stress available to absorb these secondary bending stresses.

We hope that this paper will help to stimulate thinking along the proper lines and will lead to additional strain-gage investigations and mathematical analyses.

Experimental Investigation of Turbulence Diffusion—A Factor in Transportation of Sediment in Open-Channel Flow[1]

A. A. KALINSKE.[2] The writer has been carrying on experimental investigations on the subject of the author's paper for several years and he is gratified to note that the author's final conclusions are, in general, in agreement with his. Several years ago, in conversation with the writer, the author expressed the opinion that the curve relating the mean-square deviation of the globules to the downstream distance did not approach a straight line. The writer strongly disagreed, as his own data indicated otherwise, and also he stated that if a straight line were not approached this would indicate an infinite scale for the turbulence which, of course, is physically impossible in a finite channel. The writer is pleased to note that the author now comes to a similar conclusion.

The mere fact that a power law fits the experimental data does not indicate that such a law is physically correct. Power laws can be made to fit data; however, the derivatives or integrals obtained from such power laws may give results physically impossible. If such is the case, there is no particular significance in considering such a law.

The writer, in the past, has used the globule-injection and photographic method for obtaining eddy-diffusion data; however, the use of another method, described in a recent paper[3] by the writer, has given much better results and was much less laborious; this method consisted of injecting into the flowing water a mixture of hydrochloric acid and alcohol, the proportions adjusted to the density of the water, and then taking samples of the water at various points downstream. If samples are taken for 1 min or longer, the sample has a true average concentration of the injected mixture. The sample is then analyzed for chloride concentration, which is a fairly simple procedure.

Others, including the writer, have made investigations relating to turbulence diffusion and have published their results; however, the author appears to have overlooked these references.[4] The writer believes they should be included in author's bibliography.

H. W. LIEPMANN.[5] The author's method of measuring some characteristics of turbulent motior is a welcome addition to the experimental technique used in the study of turbulent flows.

The evaluation of these measurements using the exponential correlation law is very interesting. The exponential law has been found, in numerous investigations of isotropic turbulence in air, to approximate the actual correlation curve very closely except near the origin. Hence the writer agrees with the author that it is more reasonable to fit the measurements to the exponential curve than to a power law. The results obtained by the author for the magnitude of the fluctuation level $\frac{\sqrt{\overline{v^2}}}{U}$ can be compared roughly with measurement of the same quantity in the turbulent boundary layer near a flat plate carried out in a wind tunnel at the California Institute of Technology, with the use of hot-wire anemometers. Fig. 1 of this discussion gives a comparison between the author's results for $\frac{\sqrt{\overline{v^2}}}{U}$ as a function of the wall distance y (curve I) and the direct hot-wire measurements in the boundary layer (curve II).

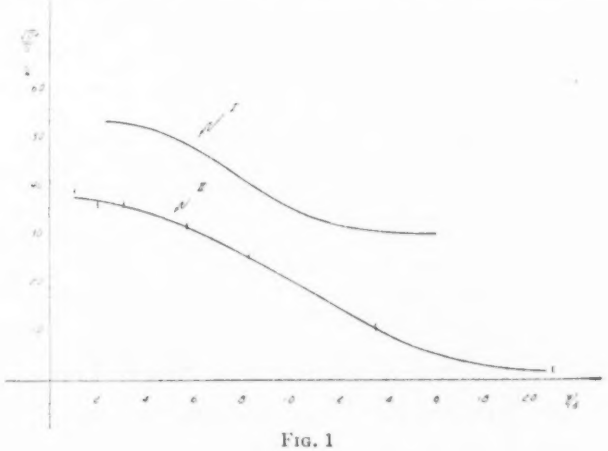

FIG. 1

The boundary-layer thickness δ for the water-channel measurements was taken as 4.8 in., corresponding roughly to the distance from the wall in which the mean velocity U varies. It is seen that for $\frac{y}{\delta} < 1$, the behavior of $\frac{\sqrt{\overline{v^2}}}{U}$ is quite similar in the two cases. The absolute magnitude of $\frac{\sqrt{\overline{v^2}}}{U}$ is somewhat larger in the water channel as compared with the boundary-layer measurements. For $\frac{y}{\delta} > 1$, curves I and II are evidently quite different. This latter fact is due to the difference in the turbulence levels of the uniform streams. The level is much lower in the wind tunnel than in the water channel.

It should also be mentioned that correlation curves which do not approach zero rapidly enough to insure a finite value of the scale integral are sometimes encountered in wind-tunnel measurements. This is often due to pulsations in the stream, i.e., velocity fluctuations other than true turbulent fluctuations.

The writer does not believe that the periodic wandering of the globules, as shown in Fig. 5 of the paper, indicates the existence of a "regular turbulence" pattern. In studying records of random fluctuations one may often tend to see pseudoperiodicities. If, however, periodicities of this type have been observed consistently, the writer would be inclined to attribute them to periodic pulsations in the stream rather than to a turbulence pattern. In this connection the wake of the injection tube should be considered. The Reynolds number based on the diameter of the tube used in the author's measurements is of the order of a few hundred. Hence a von Kármán vortex street will exist in the wake of the tube, and consequently a certain amount of regular fluctuation must be expected. The distance between the vortexes is of the order of 5 times the diameter of the cylinder or about 0.1 in. in the presented measurements; this is of the same order of magnitude as the length l_1 which was determined to be about 0.2 to 0.4 in. The influence of the vortex street will, of course, diminish rapidly downstream; however, the influence of these regular fluctuations, e.g., upon the initial motion of the globules, should not be overlooked.

It is to be hoped that the experiments will be continued. The investigations of true isotropic turbulence in water flow behind a grid using the method of the author appears to be of great interest.

J. M. Robertson.[6] Knowledge of the eddy diffusivity, its magnitude and manner of variation in the channel, allows prediction of the manner of distribution of suspended material in a flowing stream. Experimentally the diffusion coefficient can best be determined by direct measurement of the diffusion of some foreign material, of heat, of salinity, or other quality or content of the fluid. In air the diffusion of heat was used by Schubauer[7] to measure the magnitude of the turbulent velocity fluctuations; the diffusion of smoke from chimneys was used by Taylor[8] as an indication of the nature of the diffusion process; and the diffusion of carbon dioxide and hydrogen was used by Towle and Sherwood[9] to determine the diffusion coefficient. In a water stream, Richardson[10] used the diffusion of dye to measure the diffusivity.

At the University of Iowa the determination of the diffusion coefficient by means of the measurement of the spread of oil droplets has been accomplished with seemingly good results.[11,12,13,14] As this method is extremely tedious and cannot be used in the presence of appreciable amounts of suspended sediment, another method was developed by Kalinske and Pien.[14] In this method the diffusion of chlorides in the water at various distances from the point of injection was obtained chemically on samples taken at the desired locations; a relatively easy process. At present this seems to be the best method developed for measuring the diffusion.

As noted by the author, the diffusion coefficient D defined by Equation [9] of the paper, can be expressed either in terms of the correlation coefficient or the rate of spread of particles, thus

$$D = \sqrt{\overline{v^2}}\, l_1 = \overline{v^2} \int_0^{T_1} R_\xi d\xi = \frac{1}{2}\left(\frac{d\overline{Y^2}}{dt}\right)_{\max}$$

The correlation coefficient R_ξ is at present little more than a concept used in arriving at more useful relations; it is obviously difficult to follow a particle as it moves in a fluid stream and to measure its velocity from time to time. Therefore knowledge about diffusion must come from direct measurement, i.e., from a study of the variation in $\overline{Y^2}$. The fundamental relation for the variation of $\overline{Y^2}$ is presented in Equation [12] of the paper, which may be written

$$\frac{d\overline{Y^2}}{dx} = \frac{2\overline{v^2}}{U} \int_0^{\xi} R_\xi d\xi$$

using the relation $U = dx/dt$. As noted by the author for values of time greater than some time T_1

$$\int_0^{\xi \geq T_1} R_\xi d\xi = \text{const}$$

Thus, for such times, integration gives

$$\overline{Y^2} = \frac{2\overline{v^2} X_0}{U^2}(X - X_0) = \frac{2D}{U}(X - X_0)$$

where X_0 is a constant distance related to T_1 and the velocity U. The linear relation indicated by this relation for distances considerably larger than X_0 is quite apparent in the data previously presented.[12,13] Measurements made for distances up to 4 times X_0, indicated that the linear relation applied for values greater than 2 times X_0.[13] This constant was found to vary between 0.18 and 0.61 ft for different channels (0.94 ft and 2.5 ft widths, smooth and rough bottoms), depths (0.5 to 1.25 ft), velocities of flow (0.4 to 1.5 fps), and locations in the channel. For distances less than $2X_0$ the variation in $\overline{Y^2}$ was the same for the various cases when the data were presented in the dimensionless form

$$\frac{\overline{Y^2}U}{2DX_0} = \text{function}\left(\frac{X}{X_0}\right)$$

If a very accurate picture of the variation in the left side of this relation with values of X/X_0 between zero and 2 could be obtained, it would be possible to obtain R_ξ by differentiation. As it is quite difficult to obtain very accurate measurements of $\overline{Y^2}$ at small distances with the usual proportions of the measuring apparatus used, conclusions as to the nature of this correlation coefficient based upon such measurements appear to be quite uncertain.

In most discussions of the relation of turbulence diffusion to the transportation of suspended material it is assumed that the diffusion coefficient D is equal to the momentum transfer coefficient ϵ, defined by the well-known shear relation

$$\tau = \epsilon \frac{d\rho U}{dy}$$

As the density ρ of water, or water and sediment, varies but little, one need only know the vertical velocity distribution and the

shear to compute ϵ. This was done by Kalinske and the writer,[13] and the values of ϵ were found to agree reasonably well with the measured values of D both in magnitude and mode of variation, an indication that the assumed equivalence of these two factors is reasonably accurate. More important than this, however, was the close agreement found by Kalinske and Pien[14] between measured suspended sediment distributions and those computed on the basis of measured values of D. This is a check of the usual sediment-suspension theory and an indication of the reliability of the method used in obtaining the diffusion coefficient.

The measurements of D referred to[13,14] indicate that in the center of a channel it is probably zero at the bottom (as theory indicates), increases with distance from the bottom to a maximum value at about mid-depth, and then decreases as the free surface is approached, but does not necessarily become zero at the surface. Closed-channel studies by Towle and Sherwood,[9] and Sherwood and Woertz[15] indicate that in the turbulent range, D increases approximately linearly with increasing Reynolds numbers. For flows below the critical (laminar flow), the diffusion would be that predicted by the molecular theory such as presented by the author's Equation [5]. The order of magnitude of such diffusion may be 0.01 to 0.0001 that of turbulent diffusion.

Author's Closure

With regard to Professor Kalinske's discussion it is evident that he is under certain misconceptions. It should be appreciated by him that the data on diffusion were collected in 1940. As stated in the paper these data in spite of the large number of observations taken did not prove to be of sufficient accuracy to warrant definite conclusions as to the exact shape of the mean-square deviation and resulting correlation curves. In the author's conversation with Professor Kalinske the fact that the desired limiting straight line could not easily be located was indicated. This point was stressed rather than that the data did not approach a straight line. The use of the exponential correlation law was suggested by Dr. H. L. Dryden who reviewed the test data.

With reference to a bibliography, it was out of place to include one of an exhaustive nature and therefore the paper included only those references which would provide the reader with sufficient background to analyze the data. Since the paper was prepared for publication prior to Professor Kalinske's publications of 1943 and 1944, obviously these particular references could not be included. The author is, however, very happy to learn of the less laborious injection and sampling method recently used at the University of Iowa.

The author sincerely appreciates the encouraging comments by Dr. Liepmann. The data presented in Fig. 1 of his discussion are very interesting. The divergence of the two curves is undoubtedly due to the side-wall effect of the water channel. The disturbance of the flow by the insertion of the injection tube is certainly a major objection to the use of such instruments in making measurements near the origin. In addition to the generation of Kármán vortexes, there are two other sources of error, namely, the vibration of the tube and the inertial effect of the globules at the point of introduction. The vibration of the tube can be practically eliminated. Although the length l_1 was found to be of the same order of magnitude as the distance between the vortices of the Kármán vortex street, it should not be concluded that the magnitude of l_1 is due to the vortex street, which as Dr. Liepmann points out, will diminish rapidly downstream. The order of magnitude in this case is purely coincidental.

The remarks of Professor Robertson are appreciated.

[15] "Mass Transfer Between Phases—Rule of Eddy Diffusion," by T. K. Sherwood and B. B. Woertz, *Industrial and Engineering Chemistry*, vol. 31, 1939, p. 1034.

Dynamics of an Elastic Bar[1]

K. J. DeJuhasz.[2] The present paper is a valuable addition to the existing literature on the dynamics of elastic bars in general, and of long trains in particular, to which important field the author has previously made several basic contributions. The value of these papers resides not only in the solution of definite problems, but also in the precise definitions of characteristics and concepts peculiar to train dynamics, such as "speed of progressive force application," "propagation ratio," "passing point," and others. The results of the author's analysis appear to be transferable, with suitable adaptations to other elastic phenomena such as surges in springs, in hydraulic piping, behavior of chains, and others.

The paper is, however, somewhat difficult to read and understand which detracts somewhat from its general usefulness. This is due partly to its extreme conciseness, omission of derivations, and insufficient explanations, which was no doubt imposed on the author by limitation of space. But the difficulty of understanding is partly inherent in the method of treatment which is preponderantly mathematical and makes insufficient use of graphic illustrations.

In recent years increasing use has been made of the graphical method of analysis in treating problems involving elastic columns. For the explanation of this method reference is directed to previous literature.[3] The present discussion will be restricted only to the illustration of the graphical method on two of the cases treated by the author.

Case 1. A Constant Force Acts at the End of a Solid Elastic Bar. This phenomenon is illustrated in Fig. 1 of this discussion. Fig. 1(*a*) represents the t-x diagram, in which a point denotes a certain cross section x, and a certain instant of time t. In this diagram the progress of a disturbance along the bar is represented by straight lines having the slope

$$\tan(\pm\varphi) = \pm V = \Delta x/\Delta t = \sqrt{k/m}$$

Fig. 1*b* represents the V-P diagram in which a point denotes the velocity V and force P, existing in a certain cross section x of the bar, at a certain time t. Any change of force involves a proportional change of velocity and vice versa, for which $\Delta P/\Delta V = \tan(\pm\alpha) = \sqrt{mk}$.

It is assumed that the bar is initially at rest, $V = 0$, and there is no force, $P = 0$; this condition is represented in the V-P diagram by point 1. At $t = 0$ instant (t-x diagram) a force P_1 is applied at the end A. The problem is to find the velocity and force in all cross sections of the bar at subsequent instants of time.

The changing of the loading at the end A from zero to P_1 constitutes a disturbance, as a result of which the velocity is changed from zero to V_2, the new state of the end A being defined by point 2, situated on the tan α line drawn from point 1 at its intersection with the $P = P_1$ line. This disturbance travels toward the end B of the bar. On its arrival there, after the elapse of L/V time,

Discussion by K. J. DeJuhasz of paper: "Calculation of Load and Stroke in Oil-Well Pump Rods," by B. F. Langer and F. H. Lamberger, Journal of Applied Mechanics, Trans. A.S.M.E., vol. 65, 1943, p. A-178.

the bar tension is relieved, $P = 0$, and the new state of the bar will be represented by point 3 in the V-P diagram, which is at the intersection of the tan $(-\alpha)$ line drawn from point 2 with the $P = 0$ line. This is a new disturbance which travels from end B to end A, as shown in the t-x diagram by the line tan $(-\varphi)$ drawn from the point 1, representing the $t = L/V$ instant of time. This procedure is continued in the manner shown; a t-x diagram is obtained showing the triangular zones 1,2,3,4,5,6, ... ; each of which zones is characterized by a V-P condition as given in the V-P diagram by similarly marked points 1,2,3, 4,5,6, ...

Erecting the V and P co-ordinates, as ordinates, over the plane t, x as a base, the stereogram of force, Fig. 1(*c*), and the stereogram of velocity, Fig. 1(*d*) are obtained. Any cross section of these at a given x value will give the history of force, respectively, of velocity at that point in the bar. Forming the integral $v\,dt = S$ and erecting these values over the t,x plane as a base gives the stereogram of travel, Fig. 1(*e*).

It is seen that the force and velocity existing at a given instant are different at the different cross sections X of the bar, except at the instants L/V, $2L/V$, $3L/V$, ... and so on.

Case 2. A Constant Force Acts on a Body Connected to a Solid Elastic Bar. This phenomenon is illustrated in Fig. 2 of this discussion, with the approximation that the "body" is treated as a short thick bar of L_1 length, having a wave resistance $\sqrt{m_1 k_1} = \tan \gamma$, and the bar itself as having a greater length $L_2 = 4\,L_1$ and a smaller wave resistance $\sqrt{m_2 k_2} = \tan \alpha$. The speed of propagation

$$\sqrt{k_1/m_1} = \sqrt{k_2/m_2} = \tan \varphi$$

is assumed to be the same for both bars.

The t-x diagram is shown in Fig. 2(*a*), and the V-P diagram in Fig. 2(*b*). This latter shows the points 2,4,6,8, ... characterizing the state of velocity and force for the point A, the points 3,5,7,9, ... for point B, and points 4′,6′,8′,10′ . . . . . for point C. From the t-x and v-p diagrams, stereograms of force, velocity, and travel could be obtained in a manner similar to that shown for Case 1. Instead of that, only the history diagrams of velocity and force are given in Fig. 2(*c*), for the three points A,B, and C in the bar.

Other cases dealt with in the paper could be treated by the method of graphical analysis, but even these two examples show the clarity, easy applicability, and flexibility of the graphical method, which is able to yield an insight into the fine details of the phenomena, which is not possible to attain by mathematical methods, or only at prohibitive labor and complication.

The mathematical and graphical methods complement each other; broadly it can be stated that the mathematical method has the advantage in the solution of steady states, while the graphical method has the advantage in the solution of transient phenomena.

Author's Closure

The method of graphical analysis, developed by Mr. DeJuhasz, and applied by him to two elastic-bar problems, is very interesting and should be useful in the solving of and the checking of the solution of other problems of that nature.

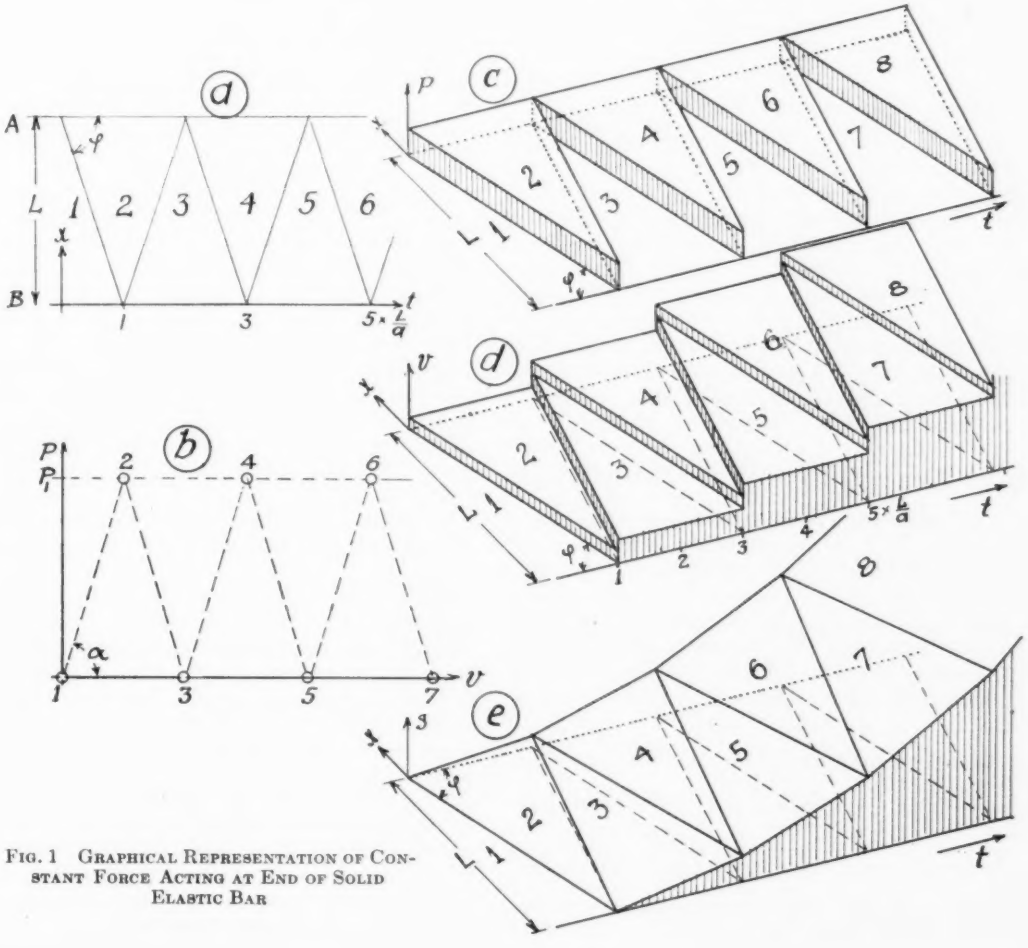

Fig. 1 Graphical Representation of Constant Force Acting at End of Solid Elastic Bar

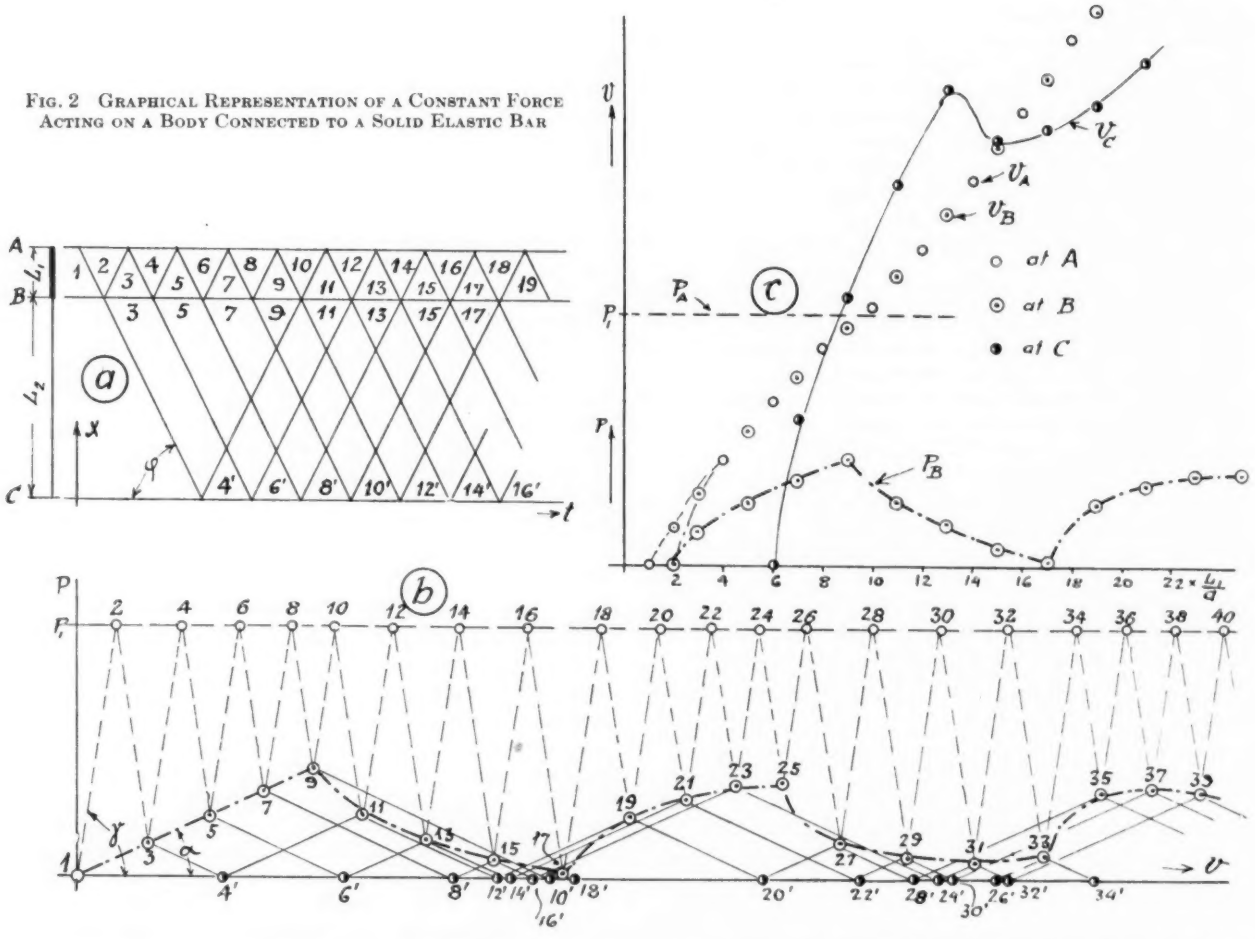

FIG. 2 GRAPHICAL REPRESENTATION OF A CONSTANT FORCE ACTING ON A BODY CONNECTED TO A SOLID ELASTIC BAR

The analytical method used in the paper is largely based on a graphical analysis of the mechanics of an elastic bar, published in an earlier paper.[4] For this reason as well as due to space limitation, derivations and explanations were kept to a minimum.

In a companion paper,[5] treating the application of elastic bar mechanics to railroad trains, a more generous use has been made of graphic illustrations so as to make up for the deficiency to which Mr. DeJuhasz refers.

Design of Crankpins for Locomotives[1]

KENNETH CARTWRIGHT.[2] The failure of a main crankpin on a modern high-speed locomotive usually results in serious consequences. For this reason, most roads limit the life of main crankpins to that which experience has shown to be acceptable without service failures, and the pins are arbitrarily renewed on this basis. This results in considerable recurring maintenance expense. An increase in the fatigue life of main crankpins will both minimize possibility of service failures and also reduce maintenance expense.

Unfortunately, on modern steam locomotives in so far as the actual design of the crankpin is concerned, there is not much that can be done. The diameter of the wheel-fit portion of the pin is limited by the diameter of the driving axle, the stroke, and the necessity of leaving a sufficient bridge of metal in the wheel center between the axle and crankpin fits. On modern locomotives with high piston thrust, the diameter of the wheel-fit portion of the crankpin under the foregoing limitations necessarily results in high unit stresses. The diameter of the side-rod journal of the pin is usually the same diameter as the wheel-fit portion of the pin, being necessitated by limitations of bearing pressure in the middle connection bushings, and this combination of equal diameters of the side-rod journal portion and wheel-fit portion of the pin results in the least favorable design from the standpoint of fatigue life.

Inasmuch as these limitations preclude designing the pin so as to reduce the unit stresses, it is necessary, in order to increase the fatigue life, to develop some means of increasing the resistance of the pin to breaking under high unit stresses. This might be done by changing the material. Results of a questionnaire sent to the locomotive voting members of the Association of American Railroads (A.A.R.), however, showed that the great majority of main crankpin failures occurred with pins made of plain-carbon steel, and also that the great majority of main crankpins removed by reason of having reached a mileage limitation, or having reached a wear limit, or found cracked on inspection were plain-carbon-steel pins. It was therefore decided that if some means could be found to increase the fatigue life of the plain-carbon-steel pin, immediate benefit would result.

[2] Chief Mechanical Engineer, New York, New Haven, and Hartford Railroad, New Haven, Conn. Mem. A.S.M.E.

The paper clearly outlines the work that has been done along these lines and shows that by various methods of treating the surface of the wheel fit of the crankpin, increases in fatigue life up to double that of the conventional plain-carbon-steel crankpin can be obtained. The work is by no means complete and additional tests now in progress and those contemplated will undoubtedly afford other and perhaps better means of accomplishing the desired results.

Results to date, however, do afford those railroads having difficulties with plain-carbon main crankpins with means of improving the performance. The various methods, as outlined in the paper, are simple and reliable and capable of being readily integrated with existing shop practice.

MORRIS P. TAYLOR.[3] As described, the method of fatigue-testing on parts of actual size is accurate and eliminates all possible scale effects, as well as the effect of size on strength of the forged steel used. However, as the paper is somewhat in the nature of a preliminary report, as stated by the authors, it may be pertinent to discuss several factors that should be investigated in the succeeding work, as follows:

1 Many locomotive crankpins do not have a uniform diameter of hub fit and side-rod journal portion, as did the parts tested. Probably, in a majority of cases the hub fit is from 1/4 to 3/8 in. larger than the side-rod journal when new; and as the side-rod journal is re-turned at general shoppings the difference may be as much as 3/4 in. before the pin is removed. The connecting radius is usually 1/4 or 3/8 in., the pin having about the form as shown in the left-hand illustration in Table 6 of the paper. It would be interesting to determine by test whether this enlargement of the hub fit is advantageous and to what extent. It is also important to know the best dimension for the connecting radius of fillet, within the limits as allowed by the side-rod bearing.

It is also evident that with rolled pins, type 3, the technique would have to be altered owing to the connecting fillet, and also the fillet would have to be rerolled when the pin is quartered and turned without removing it from the wheel. Possibly the best method would be to shot-blast the fillet.

2 In all the tests described, the pins were apparently pressed in from the outside of the wheel hub, and part of the loss of fit, as shown in Fig. 23 of the paper, may have been due to the scruffing effect as the pins were pressed in. There are several good arguments for reversing this process, and pressing the pins into the wheels from the inside,[4] so the surface of the bore next to the outer face (on a locomotive) is not scruffed by the entire length of the pin fit being pressed past it. Of course such a method could not be used with the type 2 fit, as the taper is at the wrong end; but it might be possible to bore the hub with a slight taper, smaller on the outside by 0.003 in. or so, and obtain an excellent fit with uniform distribution of pressure between hub and pin.

3 It is shown that flame-hardening is of advantage but is a questionable practice due to possible thermal cracks. Possibly the process of induction-hardening, because of the exact control, would give better results, especially as the hardness could be held to various limits as were indicated by test results.

4 It would be well to try the effect of prestressing the bore of the hub, by pressing through a slightly oversized tapered plug, or some such method, to get an autofrettage effect. This might eliminate the fretting corrosion.

5 Several designs of stress-relieving grooves may be worth trying. One possible method would be to put a rolled groove in the pin, next to the hub. It would also be possible to put an inverted fillet in the hub to relieve the stress concentration at the face of the wheel.

The research carried out thus far, as outlined in the paper, is of great value to locomotive designers. The foregoing discussion is not in any way meant as a criticism, but entirely as a series of suggested topics that are worth considering for future research, The only possible criticism is that the Association of American Railroads should have started work along these lines some years ago, as crankpin overstressing has been a serious problem on large locomotives for many years.

[3] Engineer, Joshua Hendy Iron Works, Sunnyvale, Calif. Mem. A.S.M.E.

[4] The terms "inside" and "outside" have been used as applying to an actual locomotive; thus in Fig. 11 of the paper, the outside would be the side of the wheel on which the force is applied.

AUTHORS' CLOSURE

The discussion of both Cartwright and Taylor indicates a keen realization of the many controversial factors involved in crankpin design practice. Many of the influences mentioned by Taylor have been under investigation. Application of some of these ideas indicate that much benefit will be derived but this will be the subject for a later progress report.

A Uniform Method for Determining Angular Accelerations in Mechanisms[1]

A. E. R. DE JONGE.[2] Before commenting on the author's paper proper, the writer deems it necessary to say first a few words about the science of mechanisms and particularly about its subsidiary science, kinematics, with which the paper is concerned.

During more than a decade previous to the publication of the writer's first paper on kinematics and mechanisms,[3] only a few papers had been published in this country on these subjects, and although they professed to present something new, they scarcely did so in reality. After the presentation before the A.S.M.E. in 1941 of his second paper,[4] by which the writer had tried to stir up a more active interest in the science of mechanisms and its subsidiary sciences,[5] he had the satisfaction of seeing that a few papers on mechanisms and particularly on accelerations in complex linkages appeared, among which there were of especial interest two by Messrs. Hall and Ault.[6,7] After the writer's third paper[8] had been presented before the A.S.M.E. in December, 1943, some further papers appeared, from which there may be selected for special mention one by L. Beskin.[9] All these papers, which are the most significant ones on plane kinematics published in this country, deal with but one particular phase of this science, namely, with accelerations. Now, a further paper on this same subject has been presented by Professor Koenig.[1]

One cannot escape the temptation of making some comparisons

between the papers cited. In the first paper by Messrs. Hall and Ault,[6] these authors considered it necessary to use complex quantities in order to attain their end. This was entirely unnecessary, as the result could have been obtained with quite elementary means. In their second paper[7] the same authors returned to simple vector equations, which, undoubtedly, is a most commendable step, although they still used an analytical approach. Mr. Beskin, on the other hand, showed[9] how the same result could have been obtained by means of the inflection circle and inflection "pole," to which the writer had drawn attention in his third paper.[8] Mr. Beskin, incidentally, caught an error by Messrs. Hall and Ault in the designation of a "floating link" in their second paper. Mr. Beskin's much simpler method led him to the same result which the two authors had obtained by more complex analytical methods. Mr. Beskin's approach is therefore a step in the right direction, keeping Lord Kelvin's well-known statement in mind, to which the writer has referred several times on previous occasions, namely, that a problem is never solved until it has been reduced to its simplest terms. The only fault that can be found with Mr. Beskin's paper is that he, too, has used algebraical formulas to determine simple vector quantities while using otherwise a geometrical method, but it is due to the latter that he arrived at a considerable simplification of the problem. Actually, he could have used the geometrical method all the way through with still greater simplification in obtaining his final result.

Let us now consider Professor Koenig's paper. He, too, deals with the limited subject of accelerations, indicating thereby that this subject is yet uppermost in the minds of American engineers. The writer still hopes that his third paper,[8] "A Brief Account of Modern Kinematics," may ultimately prove an incentive for American engineers to attack the far more difficult problems of kinematic synthesis of mechanisms. A slight attempt in this direction has been made by two young students of the City College of New York, who presented a paper entitled "A System of Kinematic Analysis" before the student branch of the A.S.M.E. at that college. Although they dealt with a system of "analysis" of mechanisms, this system has a distinct bearing on the kinematic synthesis of mechanisms. The system they presented is Assur's system of the composition of link mechanisms.[10]

Professor Koenig starts from the two different expressions for the pole velocity of two plane systems rotating about fixed centers in a third and fixed system, the "frame." By expressing this pole velocity by the respective angular velocities and the "radii of the instantaneous rolling circles," which, in fact, are nothing but the pole distances, he obtains a basic equation which he subjects to differentiation with respect to time. Then he substitutes in the various terms of this differential equation the meaning of the differential quotients as well as the original equation from which he started, and obtains thereby, in a straightforward manner, a relation which contains only the known angular velocities, the acceleration of a member of known motion, and the velocities of change of length of the pole distances as known quantities.

This is indeed a simple solution, and to the best of the writer's knowledge, this solution is new. For this reason he recommended the paper for presentation before the A.S.M.E. when requested for his opinion about it. As this is a completely new approach, Professor Koenig deserves commendation for having added this interesting solution to our knowledge of the theory of accelerations.

Although the writer has no fault to find with the method as such, there are a few pitfalls which he believes should be pointed out here. One of these Professor Koenig has mentioned himself, namely, the great importance of determining the proper signs for the various terms of his final equation. This is absolutely essential if correct results are to be obtained. A second pitfall is the scaling of the various quantities from the diagrams with the appropriate scales, before the terms can be calculated. In this process errors in scaling may easily be committed due to the different scales that have to be used. The third, and by far the most important pitfall, however, is that the "rotopoles" which are required to be found, do not always fall within the limits of the paper on which the diagrams are drawn. In that case a different approach will have to be used which Professor Koenig has neither explained nor even indicated.

It is a great pity that this method of solution does not lead to a completely graphical determination of the final result, that is, of the desired angular acceleration. Nevertheless, the calculations are simple, and once the various terms are calculated from the scaled quantities of the diagrams, the calculation of the angular acceleration consists only of additions and subtractions.

Professor Koenig then shows the application of this method to a crank-lever mechanism, that is, to a four-link chain, one link of which is fixed. He determines first the angular acceleration of the lever from the known velocity and angular acceleration (the latter assumed to be zero) of the crank. No fault can be found with this application, the most interesting part being the way in which he obtains graphically the velocities of change of the pole distances.

Secondly, he determines for the same mechanism the angular acceleration of the connecting rod, using the same method but applying the principle of inversion. Although this application of the new method is quite correct, in practice, where time is the most essential factor, he would not have had to go to all this trouble as he could have obtained it by applying some known theorems from the theory of accelerations. For this angular acceleration of the connecting rod can be obtained far more simply from the known total accelerations of its two end points. That of the crankpin can be determined geometrically with ease since only a normal acceleration is present (the angular acceleration of the crank, and thus the tangential acceleration of the crankpin, being assumed to be zero). The other for the lever-connecting pin can also be obtained easily once the angular acceleration of the lever has been found; for instance, by Professor Koenig's method as used in the first part of the example. This angular acceleration determines the tangential component of the lever-pin acceleration, and its normal acceleration is derived readily, in a graphical way, from its velocity and the length of the lever. By combining both, the total acceleration results, and consequently also the distribution of the total accelerations along the whole length of the connecting rod. The end points of the components of these accelerations normal to the connecting rod lie on a straight line which makes with the center line of the connecting rod an angle that measures the angular acceleration of the connecting rod. However, it was Professor Koenig's intention to illustrate, by this second part, the application of his method to the case of a generally moving link and at the same time, the usefulness of the principle of inversion.

The writer has to find one important fault with Professor Koenig's paper. This fault is not attributable to him, however, but rather to the Applied Mechanics Division who prepared it for publication. When the paper was first presented to the writer for his opinion of it, the paper contained a number of further examples of application, among which the last, which referred to a complex mechanism, was by far the most interesting. In that case the method proves particularly valuable because it still remains relatively simple while other methods become far more involved. That these examples were eliminated from the paper is definitely to its detriment, and must be regretted very much by the profession. It is the writer's considered opinion that the

[10] The paper exists only in manuscript form.

author should be permitted to publish the missing part of his paper, perhaps in his "author's closure" to the discussion, in which case, however, further opportunity should be made available to discuss this missing part.

A few remarks must be made, however, regarding some of the details and terminology of the paper, for there are a number of items which the writer appreciates, and others which he does not like. Among the former is the courage of the author to break away from the antiquated and cumbersome terminology, and to use instead some of the new terms proposed by the writer, especially the term "rotopole." However, the author did not follow through, for he speaks of "instantaneously fixed lines k" of rotopoles, instead of calling these simply "pole lines k." He also has the courage of calling the three-pole theorem the "Aronhold" theorem instead of "Kennedy's" theorem, as recommended by the writer. This is appreciated for the reason of historical truth. On the other hand, he has not followed the advice of the writer of using for the line connecting the end points of the velocities of a link the accepted term "theta line,"[8] but calls this line instead the "proportioning line" and has designated it by ϑ in the text and by v in the figures. This introduces only further confusion, and the writer hopes that the author will change his mind and use in the future the now firmly established terms "theta line" and "theta angle."[8]

The greatest fault to be found with the author's paper concerns his extremely cumbersome system of notations which unnecessarily complicates the reading of the paper. Had he adopted the European system of notations, the paper would be far simpler and more pleasant to read. Thus he speaks of "point systems," meaning, however, "plane systems" of points, lines, curves, angles, etc. Had he designated the systems by $S_1, S_2, S_3, \ldots$, or simply by 1, 2, 3, ..., points by capital Roman letters and line segments by lower-case Roman letters, he would not have found it necessary to use for a line segment such cumbersome combinations as (*ab*—*af*) for example. Had he even designated the rotopoles of systems 1 and 2 by P_{12}, of systems 2 and 3 by P_{23}, and of systems 1 and 3 by P_{13}, he could have written the line segments between rotopoles as $P_{12}P_{23}$, $P_{13}P_{23}$, $P_{12}P_{13}$, or simply by lower case Roman letters, as he finally has done, and so forth. Velocities are usually designated by a lower case v with subscript, while turned velocities in the velocity diagrams (that is, velocities turned by 90 deg in the direction of the acting angular velocity) are frequently designated by a capital V with subscript. Pole lines are usually designated by a lower case p with subscript, pole velocities by a lower case u, and, if necessary, with a suitable subscript, the circles of curvature of the polodes (not the "instantaneous rolling circles") by a π with appropriate subscripts, while ϕ is reserved for variable angles. There is no reason why the "frame" should be designated by a capital Roman **F**, as it is simply a link (or system) of a kinematic chain, which latter, by fixing this link to the surrounding space, becomes a definite mechanism. Use of superscripts is to be avoided and is generally unnecessary, as they may lead to errors in being taken for powers. Only primes are permissible.

In addition, the author speaks of "kinematic layouts" and "vector layouts" instead of using the accepted terms of "kinematic skeleton diagrams," or simply "skeleton diagrams," and "vector diagrams" or "vector polygons."[8] An almost unpardonable sin, however, is the changing of notations in examples relating to mechanisms obtained from the same kinematic chain, by fixing only a different link in the different examples. These are some of the more outstanding defects.

Nevertheless, these defects should not detract from the real value of the paper, for Professor Koenig has produced a very creditable piece of work on which he should be complimented highly and which, no doubt, will prove useful to the profession. As stated, it forms a valuable addition to our knowledge of the theory of accelerations.

Author's Closure

The author appreciates Mr. de Jonge's thorough understanding of the subject, his constructive criticism, and his efforts to encourage a more active interest in the sciences of mechanisms and kinematics.

He is in agreement with Mr. de Jonge's position that the subject of kinematic synthesis of mechanisms deserves more attention, and is of the opinion that an important key will be found in that field when there is discovered a thoroughly sound criterion for kinematic constraint in mechanisms. He hopes in the future to perfect one that in its present formative stage is too complex. Meanwhile, his paper was directed particularly toward the simplification of acceleration problems in mechanisms because in his experience, these, by the usual methods, became so involved in cases of complex machines as to invite the use of empirical methods.

Mr. de Jonge's analyses of the author's basic procedure and applications are correct. Regarding pitfalls, any prospective user of the new method has, between Mr. de Jonge and the author, been sufficiently warned. Fortunately, the requirements for maintaining proper signs and scales systematically are within expected engineering skill.

The matter of rotopoles falling off the paper constitutes a more serious problem. When it occurs it may be offset, to some extent, by such means as are used in velocity analyses requiring rotopoles; for example, (1) by reducing scale in positions involving remote rotopoles not at infinity, in so far as is possible before accuracy is unduly sacrificed; (2) by using the so-called connecting-link and orthogonal-component method of velocity transfers; and (3) trigonometrically calculating distances to inaccessible rotopoles. It may be pointed out that rotopoles at infinity often give less trouble than distant finite points, because the resulting constructions frequently become degenerate in such a way that answers become obvious. Thus for example, in Equation [13] of the paper, when r_B becomes infinite, α_B becomes 0. While, from the viewpoint of the labor involved, the three procedures mentioned are not ideal, many mechanisms occur wherein such procedures are not required. The following is an example to the point (Fig. 1 of this closure), in which the terminology of the author's original paper has been retained.

The author would at this point prefer to adopt a larger number of Mr. de Jonge's suggested system of notation (some have been adopted in the following), except that a substantial consistency between this communication and the author's original paper is believed to be imperative.

Fig. 1 shows a quick-return mechanism A, B, C, F in which the driving crank A is 2 in. long to full scale. The other dimensions are in proportion. Let $\omega_A = 3$ radians per sec, and $\alpha_A = 0$. Required is the angular acceleration α_B of the lever B in the position shown. The frame of reference is F.

Determine the rotopoles *bf*, *af*, and *ab*, establishing pole line k, as shown; also *ac* and *cb*. To full scale $r_A = 1.66$, and $r_B = 5.16$. To a convenient scale draw $V_{ac} = \omega_A(ac——af) = 3 \times 2 = 6$ in. per sec.

Vector V_{ac} has two components, V^1_{ac} representing the instantaneous translation of line (*ac*——*cb*) parallel to itself along line (*ac*——*bf*); and V^2_{ac} representing the tangential velocity of point *ac* on line (*ac*——*cb*). Note that the line (*ac*——*cb*) also has absolute rotation around center *bf* as it swings with (*ac*——*bf*), to which it remains perpendicular. Vector V^1_{ac} is transferred to point *ab* as V^1_{ab}. This represents the component of translating movement of line (*ac*——*cb*) parallel to itself. This movement affects the position of point *ab*.

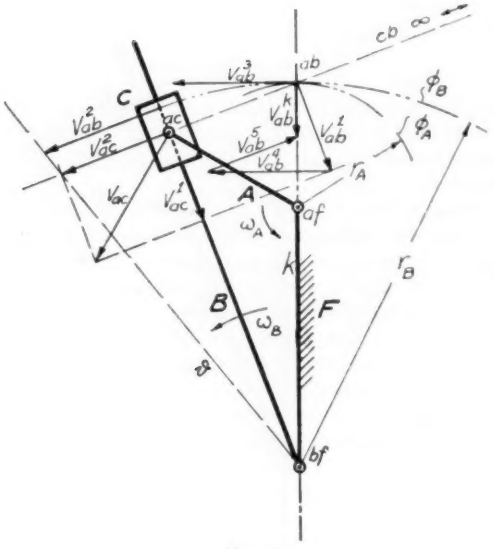

FIG. 1

Returning to V^2_{ac}, the theta line ϑ from point bf proportions V^2_{ab}, which is placed at r_B from bf. Swing V^2_{ab} into ab and draw V^3_{ab} which represents the velocity effect on point ab had by the rotary component of movement of line (ac——cb) around center bf. Add V^3_{ab} to V^1_{ab} by transferring V^3_{ab} to V^4_{ab}. Vector V^5_{ab} drawn from the end of V^4_{ab} and parallel to (ac——cb) and reaching to pole line k determines $V^k_{ab} = \frac{dr_A}{dt} = \frac{dr_B}{dt}$. Velocity V^k_{ab} represents (—2.19) in. per sec to the same scale that V_{ac} = 6 in. per sec. The negative sign indicates that r_A and r_B are decreasing, and hence that $\frac{dr_A}{dt}$ and $\frac{dr_B}{dt}$ are decreasing. Substituting in Equation [13] of the original paper, we obtain

$$\alpha_B = \frac{1}{5.16}\left[\left(3 \times (-2.19)\right) - \left(\frac{3 \times 1.66}{5.16} \times (-2.19)\right) + 0\right] = -0.863$$

radians per sec per sec, deceleration of B.

It will be noted that in at least the usual proportions of this mechanism, no required rotopole becomes inherently inaccessible, regardless of the position of the mechanism, and on the foregoing basis an entire history of its acceleration throughout a cycle can be conveniently determined. It should be noted that only the direction of cb is required.

This example is one of those which were in the author's original manuscript before condensation for publication. The remaining two examples, which Mr. de Jonge believes should also appear, are shown in Figs. 2 and 3 of this closure. The example of Fig. 2 shows how pole-velocity operations may be performed on the pole line k without an inversion and by vector subtraction. The example in Fig. 3, as mentioned by Mr. de Jonge, is of interest in showing the relative simplicity of the method when applied to a complex mechanism.

Fig. 2 shows a slider-crank mechanism A, B, C, F, in which the crank A is 2 in. long, actual size. The other links are in proportion. Let ω_A = 10 radians per sec, and α_A = 10 radians per sec per sec. The dependent angular acceleration of link B is required.

Lay out the linkage to scale in the proper position and determine the necessary rotopoles as shown, particularly af, ab, and bf, determining pole line k. Since the crank length (af——ab) is constant it may be seen that $\frac{dr_A}{dt} = 0$. However, r_B is changing in time, this being due to the change in time along moving pole line k of the intersection at bf. The movement of this intersection bf on the pole line is determined by the relative movements of the lines (bc——cf) and (af——ab) extended. Lay out V_{ab} perpendicular to line (af——ab) and by the theta line ϑ^1 find the parallel vector V^1_{bf}, which is the movement of a point coincident with bf but on line (af——ab) extended. Note that line (af——ab) swings on point af. Point bf may also be considered to have a coincident point on line (bc——cf) which is translating parallel to itself and with the slider C. This translation is found by swinging V_{ab} into (bc——cf) and drawing V^1_{ab}. Then drawing the theta line ϑ^2 determines V_{bc} which, reproduced as V^2_{bf}, is the motion of a point coincident with bf on line (bc——cf). Vectorially subtract V^1_{bf} from V^2_{bf} as indicated, thus obtaining vector ($V^2_{bf} - V^1_{bf}$) shown. This represents the translation at bf of line (bc——cf) relatively to line (af——bf). A component vector V^3_{bf} drawn through the end of this vector parallel to (bc——cf) represents the relative motion of bf along line (bc——cf) and determines $V^k_{bf} = \frac{dr_B}{dt}$.

Now $V_{ab} = \omega_A(af$——$ab) = 10 \times 2 = 20$ in. per sec, and to

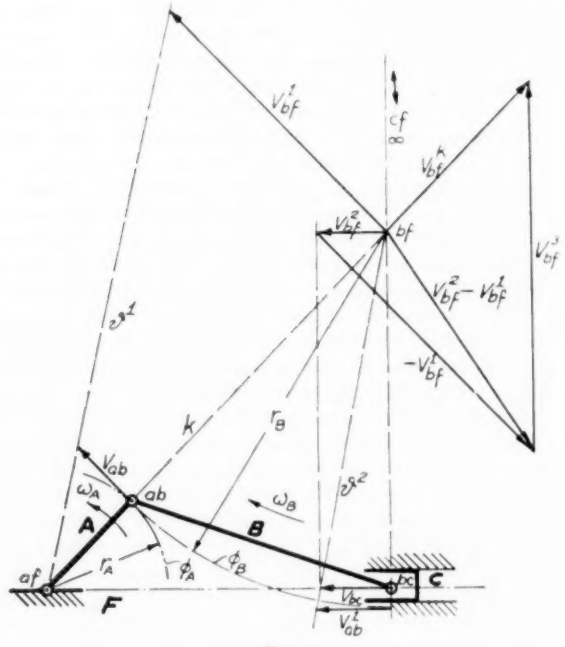

FIG. 2

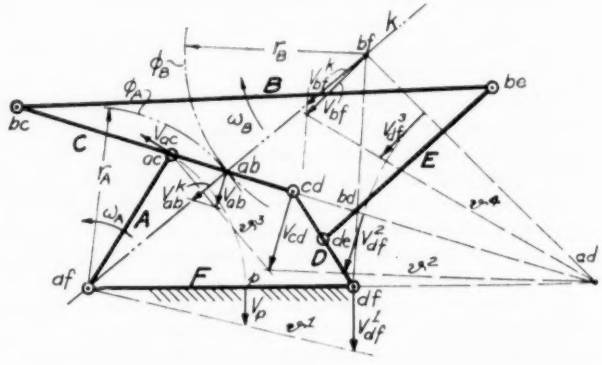

FIG. 3

the same scale that V_{ab} represents 20 in. per sec, V^k_{bf} represents 54.4 in. per sec $= \frac{dr_B}{dt}$. Also, by scale, $r_A = 2$ and $r_B = 6.06$. Substituting in Equation [13] of the original paper, we obtain

$$\alpha_B = \frac{1}{6.06}\left[0 - \left(\frac{10 \times 2}{6.06} \times 54.4\right) + (10 \times 2)\right] = -26.35$$

radians per sec per sec deceleration.

Note that when A is vertical, r_B becomes infinite and $\alpha_B = 0$, constituting one of the degenerate dimensional cases previously mentioned. Also, r_B may be calculated when bf falls off the paper, being a determinable part of the hypotenuse of the right triangle af, bf, bc, the base and angle of which (under the crank) are known, r_A being also known. V^1_{bf} may also be computed being in a simple right triangle. From this point on the graphical vector subtractions and additions may be brought into the area of the drawing board since they may be laid out independently of the mechanism skeleton.

In the complex mechanism which is of particular interest and shown in Fig. 3 of this closure, let link A be 2.13 in. long; $\omega_A = 2$ radians per sec counterclockwise; and $\alpha_A = -10$ radians per sec per sec deceleration. Required is the angular acceleration of link B. Note that link B has both of its connections through C, A and E, D twice removed from the reference frame F. By former methods this problem would be extremely troublesome.

Solution: Determine the rotopoles shown, including af, ab, and bf on pole line k. The other centers shown are of use in the solution, as will appear. $V_{ac} = \omega_A(af\text{——}ac) = 2 \times 2.13 = 4.26$ in. per sec. Let the velocity scale at full size be 0.50 in. = 4.26 in. per sec. Invert the mechanism, holding A and allowing F to move. Draw V_{ac} to the chosen scale and rotate it to p on F and, in view of the inversion, reverse it to produce V_p. By means of the theta line ϑ^1 determine V^1_{df}, noting that df is on link D which in the inversion rotates about ad. Rotate V^1_{df} into $(cd\text{——}ad)$, thus obtaining V^2_{df}. By means of the theta line ϑ^2 find V_{cd}. Now line $(ac\text{——}cd)$ determines the movement of ab considered to be on $(ac\text{——}cd)$. This line rotates on ac in the inversion. Therefore, by the theta line ϑ^3 find V_{ab}. A line drawn through the end of V_{ab} parallel to $(ac\text{——}cd)$ determines $V^k_{ab} = \frac{dr_A}{dt}$. Since V_{ac} to full scale is 0.61 in. long, $V^k_{ab} = \frac{4.26 \times 0.61}{0.50} = -5.18$ in. per sec $= \frac{dr_A}{dt}$. The negative sign arises from the fact that r_A is shortening.

As to $\frac{dr_B}{dt}$, or V^k_{bf}, it depends upon the motion of line $(bd\text{——}df)$ relative to the pole line k. This is because $(bd\text{——}df)$ extended determines bf. Since $(bd\text{——}df)$ contains line $(d\text{——}d)$ in link D which swings about point ad, swing V^1_{df} into the radius line $(ad\text{——}bf)$ obtaining V^3_{df} and by the theta line ϑ^4 find V_{bf}. A line drawn through the end of V_{bf} parallel to $(df\text{——}bf)$ determines $V^k_{bf} = 1.04$ in. (full scale). Now $V^k_{ab} - V^k_{bf}$ represents the rate at which r_B is decreasing $= 0.61 - 1.04 = -0.43$ in. Then $\frac{4.26 \times (-0.43)}{0.50} = -3.66$ in. per sec $= \frac{dr_B}{dt}$.

To full scale $r_A = 2.46$; $r_B = 2.46$. This equality is coincidental. Then substituting in Equation [13] of the original paper we obtain

$$\alpha_B = \frac{1}{2.46}\left\{\left[2 \times (-5.18)\right] - \left[\frac{2 \times 2.46}{2.46} \times (-3.66)\right] + \left[(-10) \times 2.46\right]\right\} = -9.56$$

radians per sec per sec decleration for link B.

This problem brings out the point that the rate at which r_B changes may depend upon the relative velocity of two rotopoles along the pole line k. However, the third pole on pole line k never moves, since it is always chosen on the frame. The examples given herein and in the original paper therefore exhaust all of the variations which will occur in respect to rotopole movements on the pole line.

Referring to the questions of notations which were raised, the author agrees that a lower-case p is a more appropriate index for the pole line; a lower-case u for pole velocity; and π for the circles of curvature of polodes (the author's instantaneous rolling circles). He is not convinced that the designation of a line segment as $P_{12}P_{23}$ is any simpler than, or as descriptive as $(a\text{——}a)$ or $(ab\text{——}af)$, for example. Superscripts were intended mostly to indicate sequences in the procedures. In any event, and fortunately, the controversial designations were used only in the proofs and examples, and do not appear in the working Equation [13]. Nevertheless, Mr. de Jonge's suggestions will be kept in mind on any future work on this subject. Some of the author's choices of designations grew out of his way of looking at the problem—"instantaneous rolling circles," for example.

In closing, the author wishes to thank Mr. de Jonge for his generous appraisal of the paper. It is sincerely hoped that his predictions as to the usefulness of the work to the profession will be fulfilled.

Book Reviews

Experimental Stress Analysis

EXPERIMENTAL STRESS ANALYSIS Proceedings of the Society for Experimental Stress Analysis, vol. 3, no. 1. Edited by C. Lipson and W. M. Murray. Published and distributed by Addison-Wesley Press, Inc., Cambridge, Mass., 1945. Cloth, 8½ × 11 in., xviii and 154, $5.

REVIEWED BY A. M. WAHL[1]

THE present volume, edited by C. Lipson and W. M. Murray, consists of a collection of twelve articles which treat a rather wide variety of problems having to do primarily with the determination of stress in structures and machine components and the evaluation of the effects of these stresses in terms of danger of failure. Many of the papers report very interesting observations of service failures and methods for reproducing these failures in the laboratory. However, it was the reviewer's impression that the value of several of these papers could be enhanced considerably for designers in general if more detailed theoretical stress analyses were given to supplement the experimental work. Perhaps the omission of such theoretical matter is justifiable, however, in a publication devoted primarily to experimental methods.

Coming now to individual articles, there are three papers devoted largely to applications and uses of wire resistance (SR-4) strain gages. The first of these by L. M. Ball on "Strain Gage Technique" contains much detailed technical information relat-

[1] Mechanics Department, Research Laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pa. Mem. A.S.M.E.

ing to the use of SR-4 gages, which should be of direct value to engineers using these gages in practical work. Such subjects as thermoelectric potentials, kinds of adhesives, music-wire leads for locations subject to vibration, strain-gage circuits, gage adaptations for measuring deflections, and the like, are treated in this paper. The second paper by K. F. Sibila treats the use of wire resistance gages in wind-tunnel models and describes the associated electrical equipment. The third paper on SR-4 gage applications is by Thurston and Cushman on precision determination of weight. The primary element in this equipment, used for determining loaded weights of airplanes, consists of a small cell (weight $2^1/_2$ lb) containing steel columns to which are cemented SR-4 gages. Load on the columns is measured by the change in resistance of the gages. Although the capacity of each cell is 50,000 lb, the authors state that visible deflection of the cell may be obtained by pressing on it with the finger; this gives an indication of the sensitivity of the device.

The use of models in stress analysis is treated in four papers. The first of these by S. F. Tingley discusses models for structural problems such as are encountered in airship design. This paper brings out the difficulty of simulating, in a model girder, the various stiffnesses of the prototype. A model girder of the so-called "fishworm" type, which is used for stiffness simulation, is discussed in considerable detail. Another paper by Pearce and Modrovsky treats the use of a plastic model (made from a slab of lucite) of a double row aircraft engine crankshaft. This paper gives an interesting analysis of stresses around an oil hole in a crankshaft based on elastic theory for an infinitely wide plate. The peak stress thus obtained is reduced in the ratio of 2.2 to 3 on the basis of strain measurements on several crankshafts. In the reviewer's mind, there is some question as to the accuracy of the stress distribution obtained theoretically for an infinitely wide plate when applied to a shaft with a transverse hole, and it would seem desirable to check this using short-gage-length extensometers on a large model. However, as these authors point out, too great accuracy in the stress analysis is futile in this case because of the large unknown factor of stress increase due to resonant vibration in engine crankshafts.

Another paper treating of model methods is that by T. J. Higgins on "Stress Analysis of Shafting as Exemplified by Saint Venant's Torsion Problem." Among other things, this author discusses discrepancies in the published torsional stress-concentration factors for shafts having fillets or grooves as obtained from various sources. It is suggested that there is need for further tests on actual shafts in order to resolve the differences in the published results.

In a paper on "Photoelasticity as a Designer's Tool," R. E. Orton treats the use of photoelastic models in the design of a tool for a steel strapping band. This paper also gives considerable detail relative to the technique of annealing and polishing bakelite models.

The application of brittle coatings to the study of impact stresses is discussed by Ellis and Stern. Practical problems involved in the use of brittle coatings for analysis of impact problems are considered. Interesting patterns showing strains in the breech of a shotgun on firing and in an aircraft landing-gear strut are also presented.

Certain problems connected with aircraft-engine design are discussed by F. R. McFarland. This author shows that bolt tightness is an important factor in reducing the variable stress range at critical locations in connecting rods due to a given load range. As shown by other investigators, it is also brought out that, because of variations in friction coefficient, bolt torque is not a good indication of bolt tightness. Another pertinent conclusion reached in connection with torsional fatigue failures of highly stressed splines is that the index error of the spline is an extremely important factor in the fatigue strength.

The inadequacy of static tests as a measure of strength of airplane structural components is clearly indicated in a paper by Jewett and Gordon. These investigators reach the conclusion that for structural parts subject to repeated loading in service (even for relatively few cycles) a repeated-load test is necessary to duplicate service types of failure while a static test may be misleading. It is of interest to note that in many components of the aircraft structure failure may occur within about 5000 to 15,000 cycles or less at loads under $^3/_4$ the ultimate static strength. Another article dealing with airplane components is that by G. E. Holback which treats of shear tests on various types of riveted joints for aluminum sheets. An interesting correlation of a large amount of test data on different types of riveted joints by means of nondimensional methods of plotting is given in this paper.

A rather comprehensive investigation of the effect of mechanically induced residual stresses (due to shot-peening, surface-rolling, or cold-bending) in an aluminum alloy is reported in an article by D. G. Richards. In this investigation, residual stresses were measured by determining the change in curvature of a simple rectangular beam, as successive surface layers were machined off. This author reports that for specimens rolled crosswise of the longitudinal axis there was a residual compressive stress at the surface, while for specimens rolled parallel to the longitudinal axis there was a residual tension at the surface with the specimen in equilibrium after rolling. It would be of interest to have an explanation of why these residual tensions are produced in some cases by surface rolling. Another point brought out by this investigation was that by simple cold-bending of a V-notch specimen the fatigue strength may be increased up to 100 per cent in some cases. The beneficial effects of shot-peening on stress corrosion resistance are also emphasized.

It is the reviewer's opinion that this collection of articles will warrant considerable study by engineers, designers, and stress analysts.

Torsional Vibration

EVALUATION OF EFFECTS OF TORSIONAL VIBRATION. S.A.E. War Engineering Board, October, 1945. (Compiled by the Torsional Vibration Committee of the S.A.E. War Engineering Board for the use of the U. S. Navy at the Request of Capt. L. F. Small, Bureau of Ships.) Cloth, 8 × 11 in., 577 pp., illustrated, $5.

PREPARED BY BERNARD UCKO[2]

CONFRONTED with a rather disturbing variety of approach and treatment of the torsional vibration problem, the U. S. Navy requested the S.A.E. War Engineering Board to sponsor committee activities with the object to gather, from experienced and authoritative sources, a comprehensive survey of the state of the art.

This volume is the final report of the Torsional Vibration Committee. Owing to its origin it is presented as a series of independent company contributions rather than in the sequence determined by the subject matter. The ensuing danger of discontinuity has been largely overcome by a concise yet comprehensive summary.

Deviating from its actual arrangement the book may be divided into four parts: (1) Measuring techniques; (2) calculation methods; (3) evaluation of nominal stresses, including stress-concentration and fatigue considerations; (4) recommendations and plans for further activities.

The first section gives a broad survey of practically all instruments. The General Motors phase-shift torsiograph, described

[2] Mechanical Engineer, International-Plainfield Motor Co., Plainfield, New Jersey.

by L. F. Hope, is based on the measurement of the phase difference between two signals. The absence of contact brushes and of seismic elements should avoid some of the difficulties usually encountered in electrical instruments. The General Motors mechanical torsiograph is a development of the well-known Summers instrument. It proves that satisfactory results can be obtained with a reasonably simple apparatus. The absence of a continuous record remains, however, a definite disadvantage if accurate evaluation is intended. J. D. Swannack and F. P. Porter present a thorough investigation of continuously recording mechanical instruments of the seismic type.

Chrysler (L. M. Ball, S. T. Foresman, E. E. Zimmerman, and H. R. Smith reporting) uses mechanical and electrical instruments, both employing the seismic principle. The mechanical polar torsiograph utilizes a light beam as the indicating medium. This permits phase determination and should facilitate limiting the record to its proper duration, which is rather troublesome on the mechanically indicating polar type. The electrical methods are based on the velocity pick-up pioneered by Sperry—M.I.T., but employ integrating amplifying circuits of original design. The use of a recording frequency analyzer appears to be an innovation in vibration recording. The description of the circuits emphasizes the pains taken to obtain stability of calibration.

Caterpillar, as reported by A. Goloff, relies on the conventional velocity pick-up method for simple installations while using an interesting application of strain gages on more complicated systems. Direct strain measurements permit, of course, stress determination without recourse to computed normal elastic lines. The results are obviously satisfactory, although the preparatory work of wiring and bonding the numerous strain gages must necessarily be a time-consuming task.

The General Motors walking-beam calibrator, discussed by A. W. Zmuda, is apparently the first mechanical device which permits independent changes of rotational as well as of vibrational frequencies during operation. The Caterpillar rocking-arm calibrator is actuated by a cam rather than by the usual eccentric.

The chapters on calculations were contributed by L. F. Hope, C. Criswell, F. P. Porter, L. M. Ball, S. T. Foresman, and A. Goloff. Hope discusses various methods, noting the increasing use of mechanical aids. C. Criswell describes the design problems of the G.M. "harmonic balancer." F. P. Porter illustrates his unique reduction method with a number of numerical examples which prove conclusively the accuracy of this approach. A second article by Porter is an exhaustive treatise on pendulum dampers, including even the less frequently met forms of this device.

L. M. Ball calls attention to the usefulness of electrical analogies. The simplified calculation method by the same author uses the conception of a torsional standing wave. There is no doubt that much time can be saved by this and also by analogy methods. The question arises, however, whether the physical significance of every step remains as evident as by the use of more conventional means. S. T. Foresman relates the evolution of damper designs within the Chrysler Corporation, illustrating the use of rubber in shear. A subsequent section is devoted to pendulum dampers. The conclusions concerning the proper fields for rubber and pendulum dampers are most interesting. The following report by Ball deals with the procedure followed in applying rubber dampers to automotive engines. A. Goloff concludes the survey of dampers with an interesting study on the design and the application of pendulum dampers. Not everybody, however, will agree with his conclusions. There is little doubt that the rather expensive pendulum damper is out of place wherever a simpler and cheaper device will suffice.

Papers by C. W. Gadd, J. O. Almen, A. L. Boegehold, L. M. Ball, Dr. C. Lipson and H. W. Fall form the section on the evaluation of nominal stresses. Gadd, Ball, and Fall outline the object and technique of stress analysis and of fatigue testing of crankshafts. Significant differences in their approach are apparent. There is obviously no agreement whether torsional fatigue tests should be made on full crankshafts, on a complete throw, or on a single journal specimen. These divergent opinions may be caused by the widely different engine types investigated. Full shaft or full throw specimens appear to be best suited as they are likely to include the influence of the manufacturing processes. A closer agreement exists in respect to bending-fatigue tests, where a single throw can approximate the actual loading conditions. Gadd's views that cast aluminum and magnesium specimens are not suitable for static tests can not be shared without reservations. The inherent lack of complete homogeneity in cast elements should not affect tests which are usually made on two or more specimens. The low modulus of the light metals, on the other hand, facilitates the strain measurements. Fall's precise and clear discourse on the significance of nominal stresses is a particularly pleasant example of technical reporting. The importance of residual stresses is discussed by Almen. Boegehold surveys crankshaft steels and their heat-treatment, no mention being made of cast materials. Dr. Lipson contributes a brief report on fatigue tests of aircraft-engine journals. The effect of progressive understressing is of special interest.

The book concludes with reports and recommendations. Detailed suggestions cover the specifications of torsiographs. Instrument manufacturers would do well to be guided by these laboratory-tested recommendations. Torsional-vibration data summary forms, suggested by Prof. Den Hartog, call attention to the desirability of arriving at generally accepted agreements on this subject.

It is hoped that the proposed co-operative test program will be continued, although the war emergency has passed. The suggested revision of torsional stress specifications will be of interest to engine builders as well as to the underwriting companies.

The proposed investigation of calculation methods, aimed at simplification, is likely to prove difficult. It is somewhat puzzling why the first step in this direction, the use of a common terminology, has not been taken here. Beyond this, standardization in these matters can necessarily not go far without conjuring the danger of regimentation.

Although clearly and readably written this report is, of course, by no means a textbook for beginners. To the engineer who is familiar with the subject, however, it is certain to prove of great value. The vast experimental and analytical experience, so generously proffered by the numerous contributors, makes the book a unique addition to the library of every engineer interested in vibration problems.

Statistical Thermodynamics

STATISTICAL THERMODYNAMICS. By Erwin Schrödinger. Second edition. The Macmillan Company, Cambridge University Press Department, New York, N. Y., 1946. Cloth, 5 × 7½ in., 88 pp., $1.50.

REVIEWED BY JOSEPH KAYE[3]

IT is uncommon to find a masterly exposition of the basic principles of statistical thermodynamics in a mere booklet of 88 pages. Schrödinger's little book is just that. Perhaps one reason for the unusual nature of the book is that its author is one of the founders of quantum mechanics.

The book is composed from a series of seminar lectures delivered at the School of Theoretical Physics, Dublin Institute for

[3] Assistant Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Jun. A.S.M.E.

Advanced Studies. The method of attack consists of a critical analysis of the assumptions usually made in solving the basic problem in statistical thermodynamics, namely, how to determine the distribution of a given amount of energy over N identical systems. In the first few chapters the method of the most probable distribution and Gibbs's method of the mean distribution are carefully analyzed and it is shown that both methods lead to the same result.

In the last two chapters the author discusses some of the interesting results of statistical analysis. The third law, the Gibbs paradox, the comparison of "classical" and quantum mechanics, the Fermi-Dirac and the Bose-Einstein statistics, and the problem of radiation are discussed with clarity and understanding.

This book is not recommended for engineers who are not trained in the field of statistical thermodynamics or who are not well versed in the mathematical methods used in the treatment. For those who are and, in particular, for teachers of thermodynamics it will be an invaluable aid.

Mathematical Theory of Elasticity

MATHEMATICAL THEORY OF ELASTICITY. By I. S. Sokolnikoff and R. D. Specht. Cloth, 6 × 9 in., vii and 373 pp. and 57 figures. McGraw-Hill Book Co., Inc., New York, N. Y., 1946. $4.50.

Reviewed by C. B. Biezeno[4]

IN the preface to his book, after having made some introductory remarks, the author states that his treatise, having to deal with objects of the real world, is not concerned with the world of abstraction. Its prime concern is to reduce to calculations the stresses and strains in an elastic body subjected to the action of a system of prescribed external forces. On the other hand, it may be stated that neither does the book deal with the innumerable elementary questions which are encountered in elementary engineering practice, the solution of which can be given by all those who have followed the normal courses of applied mechanics at any of the universities in this country. It has been written for the rapidly increasing number of research engineers who have to deal with the more intricate problems in the field of applied mechanics and who therefore must be acquainted with the underlying mathematical principles of their science. From this point of view it can only be expected, that the author lays great stress on the formal side of his subject, and it is not surprising that, in departure from the practice commonly followed in books on applied mathematics, the tensor calculus is introduced to convince the reader of the use of this discipline in some special fields (as, for example, the theory of shells) and of its compactness and clarity. It must be appreciated however, that the insistence on tensor notation is not carried too far, and no better proof of the sense of reality of the author can be given than by this statement, that whenever the economy of thought achieved by tensor symbolism is in doubt, it is dropped in favor of the customary scalar notation. The first three chapters are dedicated to the analysis of strain, the analysis of stress, and to the stress-strain relations (100 pages).

The fourth chapter (180 pages) representing the bulk of the book is devoted to the extensive mathematical treatment of homogeneous beams under tension, torsion, and flexure. In this chapter a characteristic feature of the book comes into full development and when a special problem requires the elucidation of some mathematical expedient, mathematical excursions are made. In this way the reader gets conveniently acquainted with the complex form of Fourier series, with some results of the complex variable theory (the theorem of Harnack, the formulas of Schwarz and Poisson), conform mapping, curvilinear co-ordinates, etc. The mechanical treatment of the beam can be said to be a most exhaustive one.

The fifth and last chapter of the book is concerned with the variational methods which find their principal exponent in the theorem of minimum potential energy. Here again the reader is incidentally made acquainted with mathematical discipline: the variational problem and Euler's equation. The principal mechanical subjects treated here are: the theorems of work and reciprocity, the Rayleigh-Ritz method, Galerkin's method, the error function, the estimation of error in the minimal integral, and the stress function for torsion, relaxation of boundary conditions.

Whereas Love's unsurpassed treatise on elasticity and some other books in the same field will still be used by a relatively small number of specialists, it may be expected that this book will be used by a greater number of scientific workers in the field of applied mechanics. The authority of the author, showing itself in his broad knowledge of the foreign literature and in his clear style, will be recognized by everyone who reads the book with due attention.

Hydraulics

A TREATISE ON APPLIED HYDRAULICS. By Herbert Addison. Third edition. John Wiley & Sons, Inc., New York, 1945. Cloth, 5¼ × 8¼ in., ix and 614 pp. $6.50. Illustrated.

REVIEWED BY A. T. GIFFORD[5]

THE change in title of this third edition from "textbook" to "treatise" is in keeping with the author's statement in his original preface that "The purpose of this book is to present a compact summary of the fundamental principles of hydraulics, and of the manner in which they are applied by the engineer." In the present volume the last part of the purpose definitely overshadows the first and thereby brings the book into the category of a reference work.

Part 1 is in the nature of a textbook, but the proofs are somewhat abbreviated and at times not too rigorous. The continuity of thought, however, is excellent and the field of hydraulic theory is well covered. The chapters on flow through closed conduits and dynamic pressure of liquids are extremely well written. There are many excellent graphs included in this portion of the book and several excellent tables. It is very interesting to note that all tabular values are given in both English and metric units.

Part 2, on practical applications of hydraulics, covers practical piping problems, control of water in open channels, hydraulic turbines, all types of pumps, hydraulic transmission of energy, and hydraulic measurements. The charts and tables in this section are very useful and should cover almost all situations met with in practice. Where necessary the author has introduced additional theory to cover the specific principles involved in the particular hydraulic machinery under discussion. He has made a special effort to include all methods of using and operating hydraulic machinery and also the best construction methods. The fact that he has used principally English machinery and methods in his descriptions and illustrations in no way detracts from the value of this portion of the book.

The almost 200 examples in the back of the book covering every chapter are very well chosen. Detailed solutions are given for approximately fifty per cent of them and the answers are given for the remainder. The large bibliography included in this book has been assembled from all parts of Europe and the United States and enhances the value of this book as a reference work.

Foreword

THE Transactions of The American Society of Mechanical Engineers include selected technical papers and reports delivered at meetings of the Society, its Professional Divisions, and its Sections, the *Journal of Applied Mechanics* (contributions of the Applied Mechanics Division), certain records of the Society of permanent value, and indexes to its publications.

In order to secure the advantages of timeliness and greater usefulness in issuing these Society Records, the material comprising them is divided into a number of parts, each one of which is mailed as a supplement to one of the regular monthly issues of the Transactions. For 1946, the first of these, the present issue, contains the personnel of the Council and committees for the year. Another, to be issued sometime later in the year, will contain memorial notices of deceased members. The indexes to miscellaneous publications, *Mechanical Engineering*, and to the Transactions themselves, must, necessarily, be issued in 1947, and will probably be mailed as a supplement to the January issue of that year.

In binding the 1946 Transactions, all of these parts of the Society Records will be assembled at the back of the volume as has been customary for some years. To aid in locating references in the bound volumes, the page numbers of the sections containing the *Journal of Applied Mechanics* and the Society Records are preceded by the letters A and RI, respectively.

D. ROBERT YARNALL

PRESIDENT OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS
1945-1946

D. Robert Yarnall

D. Robert Yarnall, co-founder and president of the Yarnall-Waring Company of Chestnut Hill, Philadelphia, Pa., and for more than a quarter of a century prominently and actively identified in an engineering capacity, was born on June 28, 1878, in Delaware County, Pa., a son of Edward S. and Sidney S. (Garrett) Yarnall, both of American Quaker ancestry for generations.

D. Robert Yarnall attended Westtown School and the University of Pennsylvania, from which he was graduated in 1901 with the degree of bachelor of science in mechanical engineering. He received the further degree of mechanical engineer in 1905.

Shortly after his collegiate career he went to work for the Coatesville Boiler Works and allied companies as an engineer and remained with them for five years. His next position was with Stokes & Smith Co., Philadelphia, in a similar capacity, with whom he also remained for five years. In 1912 be became vice-president and general manager of the Nelson Valve Company of Philadelphia and held this position until 1918. In 1908, with B. G. Waring, he organized the firm of Yarnall-Waring Company and has been continuously identified with the company to the present time, today holding the office of president of the company, to which duties he devotes most of his time and attention. The company manufactures power-plant specialties. He is also a director and president of the James G. Biddle Company of Philadelphia, who are manufacturers of electrical instruments.

He became a junior member of the A.S.M.E. in 1903, a member in 1911, and a Fellow in 1936. He was a manager of the Society from 1917 to 1920. As the representative of the A.S.M.E. he served as director and chairman of the Committee on Public Affairs of the American Engineering Council. He has been a director and vice-president of The Engineering Foundation; trustee of The Franklin Institute; president of the Engineers' Club of Philadelphia for the term of 1929-1930; vice-president and director of the American Friends Service Committee; member of Sigma Xi fraternity. For eleven years he was presiding clerk of the Philadelphia Yearly Meeting of the Society of Friends; and he is chairman of the board of directors of Pendle Hill School and of the Committee of Westtown School. He is also a professional engineer of the State of Pennsylvania, and a member of the Engineers' Club of New York and the Philadelphia Cricket Club.

On November 1, 1937, Mr. Yarnall was elected president of the United Engineering Trustees—joint agency for the four founder societies of civil, mining and metallurgical, mechanical, and electrical engineers.

Mr. Yarnall's work at design and construction in conjunction with his business for more than forty years has resulted in many patents on valves and steam specialties. These devices, manufactured by his company, are in use in practically every government controlled steam-operated ship, as well as in all high-pressure steam-generating plants in the United States. He is the author of technical papers which have been published in *Mechanical Engineering* and A.S.M.E. Transactions.

He was awarded the Hoover Medal in 1941, and in the following year was made Doctor of Engineering by Lehigh University.

Mr. Yarnall served as a member of the Commission having charge of feeding German children in 1920, being stationed there for about nine months, and during the latter part of his stay in Berlin served as chairman of that Commission. In 1924 he was again sent to Germany under the auspices of the American Friends Service Committee and the General Allen Committee, having charge of the liquidation of the relief program. In June, 1938, he and Mrs. Yarnall were sent by American Friends Service Committee to Austria to assist in organization of relief of refugees. Subsequently, as a representative of this Committee, he went to Berlin to protest to the German government against atrocities of 1938-1939. In 1941, he was a member of the Commission to England to make a survey of relief needs due to the war and to consult the British Government about the shipment of more food through the blockade for the aid of children and mothers of France. He was appointed a member of the City Planning Commission, Philadelphia, Pa., in 1942, and was reappointed in 1944 for a full term of five years.

The American Society of Mechanical Engineers

HEADQUARTERS: 29 West 39th St., New York 18, N.Y.
MID-WEST OFFICE: Room 1920, 205 West Wacker Drive, Chicago 6, Ill.

The members of the Council and of its standing and special committees given on the following pages are those in office on January 1, 1946, serving for the official year 1945-1946. The terms of office of members of other committees are not fixed by the official calendar.

OFFICERS AND COUNCIL

PRESIDENT

D. Robert Yarnall

PAST-PRESIDENTS

Terms expire December

William A. Hanley (1946)
James W. Parker (1947)
Harold V. Coes (1948)
Robert M. Gates (1949)
Alex D. Bailey (1950)

VICE-PRESIDENTS

Term expires 1946

Alton C. Chick—I *
Rudolph F. Gagg—II
Edward E. Williams—IV
Thomas S. McEwan—VI
Linn Helander—VIII

Term expires 1947

A. R. Stevenson, Jr.—III
Samuel R. Beitler—V
J. Calvin Brown—VII

* Roman numerals indicate Region.

DIRECTORS AT LARGE

Term expires 1946

Samuel H. Graf
David Larkin
John E. Lovely
James M. Rorert

Term expires 1947

Daniel S. Ellis
Arthur J. Kerr

Term expires 1949

Edgar J. Kates
J. Noble Landis

TREASURER

K. W. Japppe

SECRETARY

C. E. Davies

CHAIRMEN OF STANDING COMMITTEES

Representatives on Council without vote

Finance, W. H. Sawyer
Meetings and Program, R. A. North
Publications, L. N. Rowley, Jr.
Admissions, T. H. Wickenden
Professional Divisions, J. A. Goff
Sections, O. B. Lyman
Constitution and By-Laws (To be appointed)
Honors and Awards, L. W. Wallace
Relations With Colleges, R. P. Reece

T. Y. MULLEN
L. E. MYLTING
R. L. RANSOM
C. T. REILLY
D. D. SCHULZ
H. C. SCHWEIKART

ATLANTA

Organized: 1913
Territory: Radius of sixty miles from Atlanta, Ga.
Place of Meeting: Atlanta Athletic Club
Luncheon meeting every Monday at 12:30 p.m. at Atlanta Athletic Club
Number of Members: 119

EXECUTIVE COMMITTEE

J. A. DODD, *Chairman*
C. L. HUEY, *Vice-Chairman*
R. L. ALLEN, *Secretary-Treasurer*
A. C. KEISER, JR.
R. S. KING
EARLE MAULDIN
M. J. McWHORTER
J. W. PARKER, JR.
B. D. SMITH
T. E. SMITH
V. F. WATERS

BALTIMORE

Organized: 1916
Territory: Radius of thirty miles from Baltimore, Md.
Place of Meeting: Engineers Club of Baltimore
Number of Members: 310

EXECUTIVE COMMITTEE

J. H. POTTER, *Chairman*
H. W. WOODWARD, *Vice-Chairman*
L. E. CARTER, *Secretary-Treasurer*
R. C. DANNETTEL
J. D. ELDER
R. J. GREEN
E. H. HANHART
H. H. HOLLERITH
S. F. ROBERTSON

BIRMINGHAM

Organized: 1915
Territory: Radius of sixty miles from Birmingham, Ala.
Place of Meeting: Tutwiler Hotel
Number of Members: 103

EXECUTIVE COMMITTEE

D. H. GULDBERG, *Chairman*
J. B. EMORY, *Vice-Chairman*
C. M. ELLIS, *Secretary-Treasurer*
J. E. HANNUM
H. G. MOUAT

BOSTON

Organized: 1909
Territory: Radius of thirty miles from Boston, Mass.
Place of Meeting: Mass. Inst. of Technology

(*Continued*)

BOSTON
(Continued)

Local Organization: Engineering Societies of New England
Number of Members: 790

EXECUTIVE COMMITTEE

W. P. SAUNIER, *Chairman*
R. D. STAUFFER, *Vice-Chairman*
A. J. FERRETTI, *Secretary-Treasurer*
E. K. BANCROFT
ALTON KIRKPATRICK
C. W. MACGREGOR

BRIDGEPORT

Organized: 1917, as a Branch of Connecticut Section; reorganized as a Section, 1923
Territory: Fairfield County, Conn.
Place of Meeting: Stratfield Hotel
Local Organizations: The Bridgeport Tool Engineers Association; The Bridgeport Engineers Club
Number of Members: 203

EXECUTIVE COMMITTEE

W. E. HOGAN, *Chairman*
J. F. BANTHIN, *Vice-Chairman*
J. P. HEUMANN, *Treasurer*
W. H. SNIFFEN, *Secretary*
H. E. ADAMS
RUDOLF BECK
J. L. CORCORAN
F. G. D'ARCY
J. K. HAMIL
P. A. IBOLD
J. H. POWERS

BUFFALO

Organized: 1915
Territory: Radius of thirty miles from Buffalo, N.Y.
Place of Meeting: Markeen Hotel, 1391 Main St.
Local Organization: Engineering Society of Buffalo
Number of Members: 223

EXECUTIVE COMMITTEE

A. W. ECKSTROM, *Chairman*
C. GALE KIPLINGER, *Vice-Chairman*
N. S. SNYDER, *Secretary*
C. E. HARRINGTON, *Treasurer*
C. A. ROSS
J. L. YATES

CENTRAL ILLINOIS

Organized: 1937
Territory: All the territory in Central Illinois between the following counties on the northern boundary: Bureau, LaSalle, Knox, Stark, Putnam, Marshall, Livingston, Peoria; counties on the southern boundary: Pike, Scott, Morgan, Sangamon, Macon, Piatt, Douglas, and Edgar
Place of Meeting: Hotel Pere Marquette or Caterpillar Show Room
Number of Members: 116

EXECUTIVE COMMITTEE

R. S. STAINTON, *Chairman*
W. F. BIGGS, C. W. HAM, R. E. MCCLAIN } *Vice-Chairmen*
B. R. MILLER, *Secretary-Treasurer*

CENTRAL INDIANA

Organized: 1916
Territory: Radius of eighty miles from Indianapolis, within Indiana
Place of Meeting: Indianapolis Athletic Club
Local Organization: Indiana Engineering Society
Number of Members: 191

EXECUTIVE COMMITTEE

FERDINAND JEHLE, *Chairman*
H. L. SOLBERG, *Vice-Chairman*
G. H. GOBLE, *Secretary-Treasurer*
M. E. BECHTOLD
H. A. BOLZ
J. K. LOMAN
CARL WISCHMEYER

CENTRAL PENNSYLVANIA

Organized: 1921
Territory: Radius of approximately sixty miles from State College, Pa.
Place of Meeting: State College and Altoona, Pa.
Number of Members: 76

EXECUTIVE COMMITTEE

J. C. REED, *Chairman*
R. Y. SIGWORTH, *Vice-Chairman*
E. E. AMBROSIUS, *Acting Secretary-Treasurer*
J. S. DOOLITTLE
R. L. HULSIZER
L. B. JONES

CHICAGO

Organized: 1913
Territory: Radius of fifty miles from Chicago, Ill.
Headquarters: Mid-West A.S.M.E. Office, Room 1920, 205 West Wacker Drive, Chicago 6, Ill.
Place of Meeting: Civic Opera Bldg., 20 North Wacker Drive
Meetings: Tuesday, 7:30 p.m.
Local Organization: Western Society of Engineers
Number of Members: 1,073

EXECUTIVE COMMITTEE

J. C. MARSHALL, *Chairman*
LT. COL. H. M. BLACK, B. H. JENNINGS, A. H. JENS, L. M. JOHNSON, R. M. KRAUSE } *Vice-Chairmen*
H. L. NACHMAN, *Secretary-Treasurer*
C. C. AUSTIN
R. H. BACON
R. C. CLOUGH
F. D. COTTERMAN
C. O. DOHRENWEND
L. M. ELLISON
F. S. HARTENBERG
F. H. LANE
J. P. MAGOS
T. S. MCEWAN
J. R. MICHEL
W. H. OLDACRE
F. S. ORR
R. M. OSTERMANN
C. W. PARSONS
D. I. PAYNE
J. D. PIERCE

JUNIOR CHAIRMEN

R. C. CLOUGH
J. D. PIERCE

CINCINNATI

Organized: 1912
Territory: Radius of thirty miles from Cincinnati, Ohio
Place of Meeting: Herman Schneider Foundation (Engineering Society Building)
Local Organization: Engineers' Club of Cincinnati
Number of Members: 222

EXECUTIVE COMMITTEE

M. E. MARTELLOTTI, *Chairman*
R. J. SHORT, *Vice-Chairman*
H. B. WELGE, *Secretary*
A. T. BLACKBURN
W. S. BOYNTON
HANS ERNST
H. W. GUDMENS
H. L. HAWORTH
J. H. HEIMBROCK
H. S. MALANY
C. A. MITCHELL
E. W. VINNEDGE
J. M. WALTER
G. K. WANAMAKER
B. J. YEAGER

CLEVELAND

Organized: 1918
Territory: Counties of Lorain, Cuyahoga, Lake, Geauga, and Ashtabula in Ohio
Place of Meeting: Cleveland Engineering Society Club
Local Organization: Cleveland Engineering Society
Number of Members: 383

EXECUTIVE COMMITTEE

H. S. COLBY, *Chairman*
E. B. CRANKSHAW, *Vice-Chairman*
E. R. MCCARTHY, *Secretary-Treasurer*
J. W. AVERY
COLIN CARMICHAEL
R. C. SESSIONS
H. L. SPENCE
W. G. STEPHAN
F. H. VOSE

COLORADO

Organized: 1919
Territory: Entire State of Colorado
Place of Meeting: Albany Hotel, Denver, Colo.
Local Organization: Colorado Engineering Council (Colorado Society of Engineers)
Number of Members: 97

EXECUTIVE COMMITTEE

D. R. COLLINS, *Chairman*
J. F. RANSOM, *Vice-Chairman*
A. A. WOODWARD, *Secretary-Treasurer*
H. L. HARTENBURG
J. Y. PARCE
W. M. RICHTMANN
G. H. WOEBLING

COLUMBUS

Organized: 1920
Territory: Counties of Union, Delaware, Licking, Madison, Franklin, Fayette, Pickaway, and Ross in Ohio

Place of Meeting: Battelle Memorial Institute and The Ohio State University
Number of Members: 108

EXECUTIVE COMMITTEE

R. B. ENGDAHL, *Chairman*
A. P. JOHNSON, *Vice-Chairman*
W. H. BROWNE, *Secretary-Treasurer*
W. L. Davis
T. H. KERR
E. J. LINDAHL
L. R. TANSLEY
S. H. YOST

DAYTON

Organized: 1926
Territory: Counties of Drake, Miami, Champaign, Preble, Montgomery, Greene, and northern part of Butler and Warren in Ohio
Place of Meeting: Engineers' Club of Dayton
Local Organization: Engineers' Club of Dayton
Number of Members: 182

EXECUTIVE COMMITTEE

COLLINS WIGHT, *Chairman*
BURSON TREADWELL, *Vice-Chairman*
R. G. OLT, *Secretary*
A. W. KIMMEL, *Treasurer*
B. F. DOWNEY
M. J. FOLEY
F. B. NORTHRUP
A. L. PASCHALL
F. W. STEIN

DETROIT

Organized: 1916
Territory: Radius of thirty miles from Detroit, Mich.
Place of Meeting: Horace H. Rackham Educational Memorial, 100 Farnsworth Avenue, Detroit, Mich.
Local Organization: Engineering Society of Detroit
Number of Members: 565

EXECUTIVE COMMITTEE

A. C. PASINI, *Chairman*
R. K. WELDY, *Secretary-Treasurer*
J. W. BRENNAN
W. L. EDEL
R. V. ELEY
H. K. GANDELOT
F. T. HARRINGTON
J. W. MACKENZIE
R. C. PORTER
O. A. SODERBERG
R. H. STELLWAGEN
J. J. UICKER

JUNIOR GROUP

D. E. JAHNCKE, *Chairman*
H. D. CHICOINE
V. E. SCHAEFER
R. W. WAYMAN

EAST TENNESSEE

Organized: 1922
Territory: All counties in Tennessee east of the west boundary of Scott, Morgan, Cumberland, White, Warren, Coffee, Moore, Franklin; Belle County in Kentucky; and Rossville, Dade, Walker, Cattasa, Whitfield, Murray, Gordon, Chattooga in Georgia
Place of Meeting: Places varies
Local Organization: Chattanooga Engineers Club and Knoxville Technical Club
Luncheon Meeting every Monday noon at Chattanooga Engineers Club
Number of Members: 168

EXECUTIVE COMMITTEE

L. G. HALLER, *Chairman*
A. W. HARRIS, *Vice-Chairman*
J. MACK TUCKER, *Secretary-Treasurer*
J. L. FRANKUM
P. J. FREEMAN
C. B. KERNS
F. A. SALMON
J. L. TARWATER
F. H. THOMAS
J. R. THOMAS

ERIE

Organized: 1917
Territory: Radius of thirty miles from Erie, Pa.
Place of Meeting: Erie County Court House
Number of Members: 92

EXECUTIVE COMMITTEE

A. J. SHOWLER, *Chairman*
G. H. KAEMMERLING, *Vice-Chairman*
J. M. PASICK, *Secretary-Treasurer*
G. W. BACH
F. G. BRINIG
H. E. GOETZ
C. I. RAINESALO
M. S. REED
H. B. JOYCE, *Ex-Officio*

FLORIDA

Organized: 1925
Territory: State of Florida
Place of Meeting: Various cities in state
Local Organization: Florida Engineering Society, Gainesville, Fla.
Number of Members: 117

EXECUTIVE COMMITTEE

S. L. STEWART, II, *Chairman*
JOHN HUNTER, *1st Vice-Chairman*
J. T. LEGGETT, *2nd Vice-Chairman*
G. E. REMP, *Secretary-Treasurer*
P. C. CAPPS
ROBERT MAJOR
R. Y. POOL

FORT WAYNE

Organized: 1939
Territory: Counties of LaGrange, Steuben, Noble, DeKalb, Whitley, Allen, Wabash, Huntington, Wells, Adams, Miami, Blackford and Jay in Indiana; Counties of Williams, Defiance, Paulding, Van Wert and Mercer in Ohio
Local Organization: Fort Wayne Engineers' Society
Number of Members: 36

EXECUTIVE COMMITTEE

F. C. MASON, *Chairman*
I. A. PLANCK, *Vice-Chairman*
R. E. GALLATIN, *Secretary*
C. F. HARROD, *Treasurer*
E. S. BUCK
K. K. COOPER

GREEN MOUNTAIN

Organized: 1923
Territory: Entire State of Vermont and neighboring and closely related communities of Claremont and Hanover, N.H.
Place of Meeting: Springfield, Windsor, Vt., and Claremont, N.H.
Local Organization: Vermont Engineering Society
Number of Members: 58

EXECUTIVE COMMITTEE

C. H. ADAMS, *Chairman*
F. T. GEAR, *Vice-Chairman*
F. A. JOHNSON, *Secretary-Treasurer*
E. D. CLARK
H. L. DAASCH
D. T. HAMILTON
J. B. JOHNSON

GREENVILLE

Organized: As a Branch, 1923; as a Section, 1927
Territory: Radius of sixty miles from Greenville, S.C.
Place of Meeting: Meetings held at Greenville, Clemson College, S.C., Canton, Asheville, and Enka, N.C.
Number of Members: 62

EXECUTIVE COMMITTEE

A. KEITH POOSER, *Chairman*
E. M. WILLIAMS, *Vice-Chairman*
J. W. VAUGHAN, JR., *Secretary-Treasurer*
R. H. CHAPMAN
S. B. EARLE
P. B. KRIEK
G. R. MORGAN
R. S. PRUITT

HARTFORD

Organized: 1917, as Branch of Conn. Section; reorganized, 1923; New Britain Section merged with Hartford Section, July 1, 1940
Territory: Hartford County except that portion served by New Britain Section
Place of Meeting: Hartford Electric Light Company
Number of Members: 203

EXECUTIVE COMMITTEE

T. F. CASSIDY, JR., *Chairman*
E. R. LEWIS, JR. } *Vice-Chairmen*
J. C. WALTERS }
A. E. ANDERSON
J. S. APPLEYARD
HERBERT BURDICK
SIDNEY CORNELL
WILLIAM FERGUSON
E. P. HERRICK
F. O. HOAGLAND
R. D. KELLER
L. B. LE BEL
W. S. PAINE
K. E. PEILER
H. F. RAMM
H. P. SMITH
L. C. SMITH
C. C. STEVENS
S. J. TELLER
ALBERT VUILLEUMIER
MISS HOPE M. WOHNUS

INLAND EMPIRE

Organized: 1921
Territory: East of Columbia River in State of Washington, and Counties of Okanogan and Benton, and part of Northern Idaho
Place of Meeting: Davenport Hotel, Spokane
Luncheons: Wednesdays at 12:00 noon, Davenport Hotel, Spokane
Local Organization: Associated Engineers of Spokane
Number of Members: 39

Executive Committee

I. A. Shirk, *Chairman*
D. R. Gray, *Vice-Chairman*
N. W. Humphrey, *Secretary-Treasurer*
F. W. Candee
H. F. Gauss
L. J. Pospisil

ITHACA

Organized: 1936
Territory: Radius of thirty miles from Ithaca plus following cities: Binghamton, Corning, Endicott, Geneva, Painted Post
Place of Meeting: Alternately in different cities of Section territory, as announced
Number of Members: 100

Executive Committee

F. S. Erdman, *Chairman*
C. W. Vail, *Vice-Chairman*
H. C. Perkins, *Secretary-Treasurer*
W. G. Baird
S. W. Fairman
J. C. Kennedy
M. P. Whitney

KANSAS CITY

Organized: 1921
Territory: Radius of sixty miles from Kansas City, Mo.
Place of Meeting: University Club
Local Organization: Engineers' Club of Kansas City
Number of Members: 170

Executive Committee

R. P. Hahn, *Chairman*
Chester Cotter, *Vice-Chairman*
C. C. Holt, *Secretary*
Weldon Mooney, *Treasurer*
H. B. Atherton
B. B. Brainard
E. S. Gray
H. E. Manuel
L. T. Mart
N. L. Miller

LOUISVILLE

Organized: 1922
Territory: Radius of thirty miles from Louisville, Ky. (includes Lexington, Ky.)
Place of Meeting: University of Louisville, Louisville, Ky.
Local Organization: Engineers and Architects Club
Number of Members: 75

Executive Committee

O. C. Krause, *Chairman*
E. J. Dreyer, *Vice-Chairman*
J. E. Glass, Secretary
W. V. Hambleton, *Treasurer*
J. H. Davis
A. G. Rosenbaum
F. P. Shannon, *Ex-Officio*

MEMPHIS

Organized: 1923
Territory: Radius of sixty miles from Memphis, Tenn., and eastern half of Arkansas including all the territory east of a line drawn north and south through the western boundary of the City of Little Rock
Number of Members: 33

Executive Committee

C. K. Sharp, *Chairman*
G. R. Schneider, *Vice-Chairman*
J. H. Tole, *Secretary-Treasurer*
E. H. Elam
R. M. King
W. H. Roberts
J. J. Thomason

METROPOLITAN

Organized: 1910
Territory: Metropolitan District, New York and New Jersey
Place of Meeting: Engineering Societies Building, 29 West 39th Street, New York, N.Y., and Newark, N.J.
Number of Members: 3,983

Executive Committee

R. W. Flynn, *Chairman*
W. L. Betts, *Secretary*
H. R. Kessler, *Treasurer*
A. D. Blake
F. P. Brand
E. V. David
E. D. Grimison
J. H. Sengstaken
Herman Weisberg
Adolf Ehbrecht, *Ex-Officio*

Junior Group

J. M. Sexton, *Chairman*
E. S. Rowell, *Vice-Chairman*
J. W. Simonson, *Secretary*
J. P. Pollak, *Treasurer*

MID-CONTINENT

Organized: 1919
Territory: Entire State of Oklahoma; territory in Arkansas not included in Memphis Section; part of Louisiana; and territory in Texas north of the southern boundaries of the counties of Gaines, Dawson, Bordon, Scurry, Fisher, Jones, and Shackelford
Place of Meeting: Usually Mayo Hotel, Tulsa, Okla.
Luncheon Meetings with Engineers Club of Tulsa, Mondays at 12:00 noon
Local Organization: Engineers Club of Tulsa
Number of Members: 191

Executive Committee

O. L. Lewis, *Chairman*
J. T. Carmichael, F. J. Daasch, L. Wood Jackson, Gwynne Raymond, V. J. Walker } *Vice-Chairmen*
W. F. Stewart, *Secretary*
C. A. Stevens, *Treasurer*
D. O. Barrett
R. A. Colgin
D. E. Fields
D. E. Foster
C. O. Glasgow
J. D. Jones
F. D. Ratcliffe
W. S. Sherman
H. G. Thuesen

MILWAUKEE

Organized: 1904
Territory: Radius of fifty miles from Milwaukee, Wis.
Place of Meeting: Wisconsin Club
Local Organization: Engineers' Society of Milwaukee
Luncheon Meetings once each month, 3rd Wednesday at Wisconsin Club
Number of Members: 286

Executive Committee

T. A. Wetzel, *Chairman*
H. L. Heywood, *Secretary*
M. E. Ruess, *Treasurer*
S. J. Gates
E. G. Huber
Sebastian Judd
E. H. Laabs
G. V. Minniberger
J. T. Rettaliata

MINNESOTA

Organized: Minneapolis, 1913; St. Paul, 1913; the two Sections merged, 1934
Territory: Entire State of Minnesota
Place of Meeting: Minnesota Union, Univ. of Minnesota
Local Organization: Minneapolis Engineers' Club, Minnesota Federation of Architectural and Engineering Societies
Number of Members: 132

Executive Committee

E. S. Howard, *Chairman*
F. M. Thuney, *Vice-Chairman*
A. O. Lee, *Secretary-Treasurer*
W. H. Erskine
D. M. Forfar
L. C. Sprague
L. S. Whitson
M. S. Wunderlich

NEBRASKA

Organized: 1922
Territory: State of Nebraska, and Council Bluffs, Iowa
Place of Meeting: Lincoln and Omaha
Local Organization: Engineers' Clubs of Lincoln and Omaha
Luncheon Meeting every Wednesday noon at the Omaha Engineers' Club—4th Monday Evening at Lincoln
Number of Members: 57

EXECUTIVE COMMITTEE

J. W. KURTZ, *Chairman*
J. K. LUDWICKSON, *Vice-Chairman*
CHAS. A. N. ARMSTRONG, *Secretary-Treasurer*
N. H. BARNARD
A. A. LUEBS
O. R. PRATT

NEW HAVEN

Organized: 1912; reorganized, 1923
Territory: Portions of New Haven and Middlesex Counties, Conn.
Place of Meeting: Mason Laboratory, Yale University
Number of Members: 101

EXECUTIVE COMMITTEE

A. S. REDWAY, *Chairman*
A. D. WILCOX, *Secretary-Treasurer*
E. E. CASPELL
H. D. FISHER
I. T. HOOK
C. A. HORST
B. R. ONUF

NEW LONDON

Organized: 1930, as the Norwich Section; name changed, 1943
Territory: Counties of Tolland, Windham, and New London in Connecticut, and Westerly District in Rhode Island
Place of Meeting: New London Junior College, Pequot Ave., New London, Conn.
Number of Members: 43

EXECUTIVE COMMITTEE

K. P. HANSON, *Chairman*
L. A. LACHMAN, *Secretary-Treasurer*
W. E. BEANEY
J. S. LEONARD
FRANK PERUTZ
E. R. STEPHAN

NEW ORLEANS

Organized: 1916
Territory: All of Louisiana except the northern part allotted to Mid-Continent Section
Place of Meeting: Room 422, St. Charles Hotel
Local Organization: Louisiana Engineering Society
Number of Members: 162

EXECUTIVE COMMITTEE

A. M. HILL, *Chairman*
E. A. MCLELLAN, *Vice-Chairman*
M. C. ABRAHM, *Secretary-Treasurer*
F. B. BLACKSTONE
E. L. DENNIS
F. R. MENDOW
R. L. NALL
R. M. SEAGO

NORTH TEXAS

Organized: 1922
Territory: All of Texas north of an approximately straight line through Del Rio, Fredericksburg, Georgetown, Cameron, Nacogdoches, and Center, including the cities mentioned, and south of north boundaries of the counties of Parmer, Castro, Swisher, Briscoe, Hall, and Childress. Also the City of Texarkana, Ark.
Place of Meeting: Dallas Power & Light Co. Bldg. Auditorium
Local Organization: Technical Club of Dallas
Number of Members: 158

EXECUTIVE COMMITTEE

E. J. WACKER, *Chairman*
O. A. ST. CLAIR, C. H. SHUMAKER } *Vice-Chairmen*
H. R. HUGHES, JR., *Secretary-Treasurer*
J. H. KEYES
G. E. KIDD
H. R. PEARSON
D. C. PFEIFFER

ONTARIO

Organized: 1917
Territory: Province of Ontario, Canada
Place of Meeting: Hart House, University of Toronto
Number of Members: 241

EXECUTIVE COMMITTEE

R. C. WIREN, *Chairman*
W. R. TRUSLER, *Secretary-Treasurer*
C. E. BEYNON
L. J. CLAYTON
J. W. GALLOWAY
J. S. HALL
S. J. LIDDINGTON
JAMES MCKENZIE
A. I. SCOTT
W. D. SHELDON
FREDERICK TRUMAN
H. H. ANGUS, S. G. CLARKE } *Ex-Officio*

JUNIOR GROUP

D. G. HUBER, *Chairman*
WILLIAM BRUCE, *Secretary-Treasurer*
G. J. JARRELL
D. J. PARRISH
E. J. W. SHEARE

OREGON

Organized: 1919
Territory: State of Oregon and that territory in Washington within a radius of thirty miles from Portland, Ore.
Place of Meeting: Usually Public Service Bldg., Portland, Ore.
Local Organization: Oregon Society of Engineers
Number of Members: 76

EXECUTIVE COMMITTEE

A. J. CHAPUT, *Chairman*
B. J. DICK, *Vice-Chairman*
J. C. OTHUS, *Secretary*
G. E. JOOST, *Treasurer*
M. M. CLAYTON
L. T. HAYS
K. W. KETCHUM

PENINSULA

Organized: 1923
Territory: West of the east boundaries of the following counties: Emmet, Charlevoix, Antrim, Kalkaska, Missaukee, Clare, Isabell, Gratiot, Clinton, Eaton, Calhoun, and Branch, Mich.
Place of Meeting: Grand Rapids, Mich.
Luncheon Meeting last Thursday noon each month
Local Organization: Engineers' Club of Grand Rapids
Number of Members: 78

EXECUTIVE COMMITTEE

J. M. GORRIE, *Chairman*
D. C. MCSORLEY, *1st Vice-Chairman*
K. E. CROWSER, *2nd Vice-Chairman*
C. J. KUENZEL, *Secretary-Treasurer*
C. P. BUCK
J. R. DEHAMMER
G. E. GEBBEN
C. G. LOHMANN
C. A. HAMILTON, *Ex-Officio*

PHILADELPHIA

Organized: 1912
Territory: Counties of Bucks, Montgomery, Chester, Philadelphia, Delaware, Pa., and the State of Delaware
Place of Meeting: Philadelphia Engineers' Club, 1317 Spruce Street, Philadelphia, Pa.
Local Organization: Philadelphia Engineers' Club
Luncheon Meeting every Thursday noon at 12:30 p.m. at Philadelphia Engineers' Club
Number of Members: 1,244

EXECUTIVE COMMITTEE

J. J. MCCARTHY, *Chairman*
S. T. MACKENZIE, *Vice-Chairman*
M. C. RANDALL, *Secretary-Treasurer*
C. B. CAMPBELL
J. P. CLARK
B. F. KEENE
W. J. KINDERMAN
STANLEY MOYER
G. M. MUSCHAMP
H. E. SCHOCH, JR.
G. B. THOM
A. W. THORSON
B. W. WEBB

JUNIOR GROUP

H. E. SCHOCH, JR., *Chairman*
E. N. ROBERTSON, *Vice-Chairman*
FRED HIRSCH, *Secretary-Treasurer*

PIEDMONT—NORTH CAROLINA

Organized: As a Branch, 1923; as a Section, 1927; name changed from Charlotte Section to Piedmont—North Carolina, July 1, 1940
Territory: Radius of seventy-five miles from Charlotte, N.C.
Luncheon Meeting every other Monday at 1:00 p.m. at Efirds Department Store Dining Room
Local Organization: Charlotte Engineers Club
Number of Members: 51

EXECUTIVE COMMITTEE

T. O. SILLS, *Chairman*
F. R. JACKSON, *Vice-Chairman*
N. H. BROWN, *Secretary-Treasurer*
E. H. BRANDT, JR.
J. H. DOUTHIT
J. T. POTTER
C. E. STINE
T. W. WILSON

PITTSBURGH

Organized: 1920
Territory: Counties bounded by and including Beaver, Butler, Venango, Forest, Jefferson, Indiana, Somerset, Fayette, Greene, and Washington, Pa.
Place of Meeting: Engineers' Society of Western Pennsylvania, William Penn Hotel
Local Organization: Engineers' Society of Western Pennsylvania
Number of Members: 525

Executive Committee

H. F. Hebley, *Chairman*
Tomlinson Fort, *Vice-Chairman*
T. O. Schrader, Jr., *Secretary*
K. F. Treschow, *Treasurer*
G. E. Dignan
J. N. Evans
J. F. Mattern
W. T. Reid
G. W. Smith

PLAINFIELD

Organized: 1921
Territory: Plainfield and territory included between Elizabeth, Bound Brook, Metuchen, and Watchung, N.J.
Place of Meeting: Elizabeth Carteret Hotel, Elizabeth, and Plainfield Masonic Temple, Plainfield
Local Organization: Plainfield, Engineers Club, Singer Engineering Society
Number of Members: 223

Executive Committee

J. D. Potter, *Chairman*
R. H. Chankalian, P. C. Osterman } *Vice-Chairmen*
G. N. Hodge, *Secretary*
P. N. Fimbel, *Treasurer*
W. L. Boswell
A. J. De Matteo
M. J. Grubelich
H. F. Skarbek

PROVIDENCE

Organized: 1920
Territory: Radius of thirty miles from Providence, R.I.
Place of Meeting: Providence Engineering Society Building, 195 Angell St., Providence, R.I.
Local Organization: Providence Engineering Society
Number of Members: 190

Executive Committee

E. W. Harrington, *Chairman*
F. C. Tanner, *Vice-Chairman*
Charles Haggerty, *Secretary-Treasurer*
J. B. Coleman
W. M. Davies, Jr.
E. M. Gordon
B. P. Graves
E. A. Johnson
A. H. MacGillivray
G. W. Kelsey, *Ex-Officio*

RALEIGH

Organized: As a Branch, 1923; as a Section, 1927
Territory: Radius of sixty miles from Raleigh, N.C.
Place of Meeting: North Carolina State College, Raleigh, N.C.; Duke University, Durham, N.C.
Local Organizations: North Carolina Society of Engineers, Raleigh Engineers Club
Number of Members: 40

Executive Committee

E. S. Theiss, *Chairman*
E. O. Gibbs, *Vice-Chairman*
W. A. Hinton, *Secretary-Treasurer*
G. W. Baity
F. J. Reed
R. B. Rice
F. B. Turner
H. I. West

ROCHESTER

Organized: 1919
Territory: Radius of thirty miles from Rochester, N.Y.
Place of Meeting: Rochester Engineering Society Rooms, Sagamore Hotel
Local Organization: Rochester Engineering Society, Sagamore Hotel
Luncheon Meeting every Tuesday at 12:15 p.m. at Sagamore Hotel
Number of Members: 148

Executive Committee

W. A. Schell, *Chairman*
A. E. Schell, *Secretary-Treasurer*
M. L. Baxter
E. R. Birkicht
A. S. Hamilton
C. E. Krause
J. T. Lindsey
H. L. Mason
C. B. McCathron
C. C. Ross

ROCK RIVER VALLEY

Organized: 1926
Territory: Thirty miles east and west of Madison, Wis., and extending southward through Rockford, Ill.
Place of Meeting: Madison, Wis., Beloit, Wis., and Rockford, Ill.
Local Organization: Rock River Valley Engineering Council
Number of Members: 82

Executive Committee

E. L. Dahlund, *Chairman*
L. A. Wilson, *Vice-Chairman*
R. S. Smith, *Secretary-Treasurer*
W. C. Fischer
B. R. Granberg
R. R. Smith
J. D. Swannack

ST. JOSEPH VALLEY

Organized: 1929
Territory: Counties of La Porte, Starke, Pulaski, St. Joseph, Marshall, Fulton, Elkhart, and Kosciusko in Indiana, and Cass and Berrien Counties in Michigan
Place of Meeting: South Bend, Ind.
Number of Members: 70

Executive Committee

C. Robert Egry, *Chairman*
G. R. McNeil, *Vice-Chairman*
R. C. Fitch, *Secretary-Treasurer*
O. K. Fay
P. T. Sprague
L. E. Waddington
C. C. Wilcox
O. E. Zahn

ST. LOUIS

Organized: 1909
Territory: Radius of thirty miles from St. Louis, Mo.
Place of Meeting: Place varies
Local Organization: Engineers' Club of St. Louis
Number of Members: 235

Executive Committee

P. H. Buxton, *Chairman*
J. C. Parmely, *Vice-Chairman*
G. R. Hughins, *Secretary-Treasurer*
R. M. Boyles
Herbert Kuenzel
R. P. Schlatter
R. C. Thumser

SAN FRANCISCO

Organized: 1910
Territory: All territory north of the northern boundaries of the counties of San Luis Obispo, Kern, and San Bernardino
Place of Meeting: Engineers' Club, 206 Sansome St.
Luncheon Meetings, Tuesdays, California Hotel, Oakland; Thursdays, Engineers' Club, San Francisco
Local Organization: San Francisco Engineers' Club
Number of Members: 792

Executive Committee

H. E. Prescott, *Chairman*
M. P. O'Brien, *Vice-Chairman*
F. W. Beichley, *Secretary-Treasurer*
Major W. A. Doble
W. S. Everett
E. G. Gothberg
V. A. Rumble
Alf Hansen, *Ex-Officio*

SAVANNAH

Organized: 1923
Territory: Radius of 125 miles from Savannah in Georgia
Place of Meeting: Savannah Hotel
Local Organization: Engineers' Council of Savannah Chamber of Commerce
Number of Members: 28

Executive Committee

D. E. Kehoe, *Chairman*
T. H. Gardner, *Vice-Chairman*
B. J. Sams, *Secretary-Treasurer*
W. H. Artley
A. M. Ormond
L. C. Roesell

SCHENECTADY

Organized: As a Branch, 1919; as a Section, 1927
Territory: Radius of thirty miles from Schenectady, N.Y.
Place of Meeting: Rice Hall
Number of Members: 255

EXECUTIVE COMMITTEE

A. O. WHITE, *Chairman*
J. B. NOLAN, *1st Vice-Chairman*
I. A. TERRY, *2nd Vice-Chairman*
N. P. BAILEY, *3rd Vice-Chairman*
F. R. FOWLER, *Secretary*
CHARLES CONCORDIA, *Treasurer*
J. S. APPERSON, III
C. M. GARDINER
C. J. WALKER

SOUTHERN CALIFORNIA

Organized: 1915 as Los Angeles Section; reorganized, 1941
Territory: South of southern boundaries of following counties: Monterey, Kings, Tulares, and Inyo, Calif.
Place of Meeting: Barker Bros. Store
Local Organization: Technical Societies of Los Angeles
Luncheon Meetings Thursdays at 12:00 noon at Engineers' Club
Number of Members: 734

EXECUTIVE COMMITTEE

R. G. ROSHONG, *Chairman*
J. S. EARHART, *Vice-Chairman*
V. A. PETERSON, *Secretary-Treasurer*
E. O. BERGMAN
J. W. DAILEY
L. V. HORNE
R. F. O'MARA
V. L. PEICKII
A. R. WEIGEL

JUNIOR GROUP

C. M. SANDLAND, *Chairman*
J. I. BREWSTER, *Secretary*
D. A. R. JONES, *Member at Large*

SOUTH TEXAS

Organized: 1919
Territory: South Texas and the northern part of the State not included in the North Texas Section territory
Place of Meeting: No fixed meeting place, but all meetings held in Houston
Number of Members: 197

EXECUTIVE COMMITTEE

C. J. ECKHARDT, JR., *Chairman*
J. G. H. THOMPSON, *Vice-Chairman*
J. B. T. DOWNS, *Secretary-Treasurer*
D. D. ALTON
M. L. BEGEMAN
P. E. DARLING
V. M. FAIRES
B. W. FARQUHAR
H. G. HIEBELER
COMDR. M. I. KEARNS
R. H. KNIPPING
G. W. LOWTHER
H. F. MOLLER
A. B. STEEN, JR.

SUSQUEHANNA

Organized: 1927
Territory: Counties of Cumberland, Dauphine, Lebanon, Adams, York, and Lancaster
Place of Meeting: Engineering Society of York, and at Lancaster twice a year
Local Organization: Engineering Society of York and Engineers' Society of Pennsylvania, Harrisburg, Pa.
Number of Members: 99

EXECUTIVE COMMITTEE

E. L. ROGERS, *Chairman*
C. H. NEIMAN, JR., *Vice-Chairman*
J. A. GALAZZI, *Secretary-Treasurer*
E. W. GALLENKAMP
G. DUGAN JOHNSON
L. S. MORSE, SR.
E. M. POWELL
E. O. REESE, III
G. I. SMITH

SYRACUSE

Organized: 1920
Territory: Radius of thirty miles from Syracuse, N.Y.
Place of Meeting: Ball Room of the Onondaga Hotel
Local Organization: The Technology Club of Syracuse
Number of Members: 105

EXECUTIVE COMMITTEE

G. I. VINCENT, *Chairman*
J. A. KING, *Vice-Chairman*
L. EDWARD POTTER, *Secretary-Treasurer*
H. T. AVERY
H. W. JEFFCOCK
W. E. JOHNSON
M. B. MOYER
D. V. SHETLAND
H. P. SONTAG
M. F. WILLIAMS

TOLEDO

Organized: 1920
Territory: Radius of thirty miles from Toledo, Ohio
Place of Meeting: University Club, Toledo, Ohio
Local Organization: Affiliated Technical Societies of Toledo
Number of Members: 66

EXECUTIVE COMMITTEE

PAUL GRAVELLE, *Chairman*
W. A. NELDEN, *Vice-Chairman*
*R. H. HUNTINGTON, *Secretary-Treasurer*
H. A. BENNETT
JOHN GILLETT
F. E. GRAVES
J. C. GREINER
WILLIAM MCCANDLESS
F. J. MEYER
L. S. PLATOU
O. C. SCHULTZ
ARTHUR VOTSBERGER

TRI-CITIES

Organized: 1920
Territory: Radius of thirty miles from Moline, Ill.
Place of Meeting: Rock Island, Ill., Moline, Ill., and Davenport, Iowa
Luncheon Meeting every Wednesday, Davenport Hotel, 12:00 noon
Number of Members: 86

EXECUTIVE COMMITTEE

C. A. CARLSON, *Chairman*
C. C. ANDERSON, *Vice-Chairman*
R. A. CROSS, *Secretary-Treasurer*
H. O. CROFT
J. M. HARTMAN
K. R. HODGES

* Resigned Oct. 13, 1945.

UTAH

Organized: 1923
Territory: State of Utah
Place of Meeting: University Club, Salt Lake City
Local Organization: Utah Society of Professional Engineers
Number of Members: 39

EXECUTIVE COMMITTEE

M. B. HOGAN, *Chairman*
D. A. ELKINS, *Vice-Chairman*
R. E. KUNKEL, *Secretary-Treasurer*
W. J. COPE
H. L. ZETTERMAN

VIRGINIA

Organized: 1919
Territory: State of Virginia
Place of Meeting: Richmond, Norfolk, Blacksburg, Charlottesville, Roanoke, University, Petersburg
Local Organization: Central Virginia Engineers Club of Hampton Roads
Number of Members: 231

EXECUTIVE COMMITTEE

ARTHUR ROBERTS, JR., *Chairman*
H. R. HOPKINS, F. Q. SAUNDERS } *Vice-Chairmen*
J. B. JONES, *Secretary*
W. J. BARBER, *Treasurer*
A. L. BELL
D. W. BENNETT
D. H. GRENOBLE
A. B. HETTRICK
M. L. IRELAND, JR.
A. F. MACCONOCHIE
F. Q. SAUNDERS

WASHINGTON, D.C.

Organized: 1919
Territory: District of Columbia
Place of Meeting: Auditorium, Potomac Electric Power Co., 10th & E Sts., Washington, D.C.
Number of Members: 530

EXECUTIVE COMMITTEE

RUDOLPH MICHEL, *Chairman*
B. C. CRUICKSHANKS, *Vice-Chairman*
C. E. BERBERICH, *Secretary-Treasurer*
L. R. BURDICK
R. S. DILL
MORTON GERLA
F. J. HANRAHAN
H. P. HARWOOD
F. EVERETT REED, JR.
M. A. MASON, *Ex-Officio*

WATERBURY

Organized: 1917, as a Branch; reorganized as a Section, 1923
Territory: Litchfield County and a portion of New Haven County
Place of Meeting: Elton Hotel
Number of Members: 75

EXECUTIVE COMMITTEE

J. H. RAUB, *Chairman*
T. M. RIANHARD, SR., *Vice-Chairman*
E. W. SODERBERG, *Secretary-Treasurer*
H. C. ASHLEY

(*Continued*)

WATERBURY
(Continued)

A. W. Miner
P. E. Peterson
R. W. Simpson
R. S. Storrs
C. M. Warner

WESTERN MASSACHUSETTS

Organized: 1922
Territory: Includes counties of Berkshire, Franklin, Hampden, and Hampshire
Place of Meeting: Highland Hotel, Springfield, Mass.
Local Organization: Engineering Society of Western Massachusetts
Number of Members: 94

Executive Committee

J. R. Connelly, *Chairman*
Sidney Low, *Vice-Chairman*
D. A. Bartlett, *Secretary-Treasurer*
Leo Kresser
W. S. Mabb

WESTERN WASHINGTON

Organized: 1919
Territory: State of Washington west of Columbia River with exception of territory included in 30-mile radius of Portland, Ore.
Place of Meeting: Engineers' Club, Seattle, Wash.
Local Organization: Seattle Engineers' Club
Luncheon Meetings daily at noon at Engineers' Club, Seattle
Number of Members: 224

Executive Committee

F. B. Lee, *Chairman*
O. F. Lamson, *Vice-Chairman*
R. W. Crain, *Secretary-Treasurer*
R. L. Dyer
R. L. Rockwell
F. R. Young

WEST VIRGINIA

Organized: 1925
Territory: State of West Virginia, South of Parallel 39
Place of Meeting: Charleston, W.Va.
Number of Members: 71

Executive Committee

J. L. Barker, Jr., *Chairman*
C. B. Cochran, *Vice-Chairman*
Donald Thompson, *Secretary-Treasurer*
J. C. Bond, *Assistant Secretary*
W. B. Bible, Jr.
M. C. Brooke
O. C. Lang
G. D. MacMillan
L. B. McQuaide
R. D. Webb

WORCESTER

Organized: 1915
Territory: Radius of thirty miles from Worcester, Mass.
Place of Meeting: Sanford Riley Hall, Worcester Poly. Inst.
Local Organization: Worcester Engineering Society
Number of Members: 131

Executive Committee

E. H. Smith, *Chairman*
F. E. Bailey, *Vice-Chairman*
C. C. Tucker, *Secretary-Treasurer*
F. W. Mierke
H. F. Ritterbusch
R. L. Rougemont
R. H. Tolman
R. H. Wood

YOUNGSTOWN

Organized: 1928
Territory: Counties of Trumbull, Mahoning, and Columbiana in Ohio, and Mercer and Lawrence in Pennsylvania
Place of Meeting: Republic Rubber Co. Club Rooms, Albert St., Youngstown, Ohio
Number of Members: 48

Executive Committee

H. W. Smith, *Chairman*
F. J. Bowers, *Secretary-Treasurer*
C. H. Legler
W. J. Longacher
H. E. Melin

STUDENT BRANCHES

ARTICLE B6A, PAR. 20: The Standing Committee on Relations With Colleges shall, under the direction of the Council, have supervision of the Student Branches of the Society and of such work of the Society as aims to further the education of engineers through the colleges and schools of accepted standing.

STANDING COMMITTEE, RELATIONS WITH COLLEGES

R. P. REECE, *Chairman*
H. J. BROWN
HERBERT KUENZEL
H. R. PEARSON
G. L. SULLIVAN

E. STANLEY AULT
N. P. BAILEY
D. S. CLARK
W. J. COPE
R. H. PORTER
Advisory Members

Communicate with Student Branch through Honorary Chairman

RESEARCH COMMITTEES

ARTICLE B6A, PAR. 24: The Standing Committee on Research shall, under the direction of the Council, have supervision of the research activities of the Society.

The first Standing Committee on Research was organized in 1909.

STANDING COMMITTEE

J. F. DOWNIE SMITH, *Chairman* (1946)
HERMAN WEISBERG (1947)
G. A. HAWKINS (1948)
E. L. ROBINSON (1949)
To be appointed (1950)

LUBRICATION

Appointed October, 1915, to investigate the fundamental problems of lubrication, to formulate results of investigations previously made, and to keep in touch with contemporary research in this field

(Reorganized May, 1936)

B. L. NEWKIRK, *Chairman*
S. J. NEEDS, *Secretary*
A. L. BEALL
W. E. CAMPBELL
H. A. EVERETT
P. G. EXLINE
J. C. GENIESSE
M. D. HERSEY
C. M. LARSON
F. C. LINN
S. A. McKEE
E. S. PEARCE
W. A. ZISMAN

FLUID METERS

Appointed 1916 to develop the theory of fluid meters of all kinds and to report on the best methods for their installation and use

(Reorganized July, 1926)

R. J. S. PIGOTT, *Chairman*
J. R. CARLTON, *Secretary*
H. S. BEAN
S. R. BEITLER
R. K. BLANCHARD
B. O. BUCKLAND
LOUIS GESS
E. W. JACOBSON
A. J. KERR
T. H. KERR
I. O. MINER
M. P. O'BRIEN
W. S. PARDOE
L. K. SPINK
R. E. SPRENKLE
T. R. WEYMOUTH
M. J. ZUCROW

STRENGTH OF GEAR TEETH

Appointed in December, 1921, to investigate factors affecting the strength and life of gear teeth

R. E. FLANDERS, *Chairman*
C. H. LOGUE, *Secretary*
EARLE BUCKINGHAM
A. M. GREENE, JR.
C. W. HAM
F. E. McMULLEN
E. W. MILLER
ERNEST WILDHABER

METAL CUTTING DATA AND BIBLIOGRAPHY

Appointed in September, 1923, to study the problems of metal cutting, including tool materials, tool design, speeds and feeds

(Reorganized December, 1943)

M. E. MARTELLOTTI, *Chairman*
O. W. BOSTON
W. C. DE GRAFF
F. M. FISHER
W. W. GILBERT
T. F. GITHENS
W. L. KENNICOTT
F. W. LUCHT
F. J. OLIVER

CUTTING FLUIDS

Appointed in September, 1923, to study the problems of metal cutting, including lubrication and cooling

(Reorganized December, 1943)

O. W. BOSTON, *Chairman*
J. T. BEARD
JOSEPH GESCHELIN
F. W. LUCHT
M. E. MARTELLOTTI
W. H. OLDACRE
DON WANGELIN
G. P. WITTEMAN

MECHANICAL SPRINGS

Appointed May, 1924, to determine the status of the mechanical-spring art, to promote and conduct necessary and adequate research, and to develop the art to the point of standardization

J. R. TOWNSEND, *Chairman*
C. T. EDGERTON, *Secretary*
R. D. BRIZZOLARA, *Alternate*
R. W. COOK
W. T. DONKIN
RUPEN EKSERGIAN
G. E. HANSEN
A. C. KELLER
BENJAMIN LIEBOWITZ
DAVID LOFTS
D. J. McADAM, JR.
L. C. PESKIN
R. E. PETERSON
J. W. ROCKEFELLER, JR.
B. W. ST. CLAIR
M. F. SAYRE
T. R. WEBER
KEITH WILLIAMS
J. K. WOOD
F. P. ZIMMERLI

ELEVATORS

Appointed June, 1924, to study the function and operation of elevator safeties and buffers and their associated mechanisms and to develop methods of test for the approval of elevator safety devices

(Reorganized August, 1940)

D. J. PURINTON, *Chairman*
J. A. DICKINSON, *Secretary*
S. W. JONES, *Ex-Officio*
E. M. BOUTON
K. A. COLAHAN
G. P. KEOGH
J. J. MATSON
M. B. McLAUTHLIN
W. S. PAINE
C. A. PETERS

EFFECT OF TEMPERATURE ON THE PROPERTIES OF METALS

Appointed December, 1924, as a Joint Research Committee of the A.S.T.M. and the A.S.M.E. to encourage the investigation and accumulation of data on the properties of metals used in the mechanic arts at extremely high and low temperatures

N. L. MOCHEL, *Chairman*
H. J. KERR, *Vice-Chairman*
J. W. BOLTON, *Secretary*
W. H. ARMACOST
A. B. BAGSAR
A. D. BAILEY
F. E. BASH
C. L. CLARK
E. S. DIXON
F. B. FOLEY
J. R. FREEMAN, JR.
H. J. FRENCH
H. W. GILLETT
A. J. HERZIG
G. F. JENKS
J. J. KANTER
C. E. MACQUIGG
V. T. MALCOLM
R. F. MILLER
HENRY NORTH
E. L. ROBINSON
J. H. ROMANN

Representative of Bureau of Ships, U.S. Navy Department

BOILER FEEDWATER STUDIES

Appointed March, 1925, as a Joint Research Committee of the American Boiler Manufacturers Association, American Railway Engineering Association, American Water Works Association, Edison Electric Institute, the American Society for Testing Materials, and the A.S.M.E. to study methods of analysis and treatment of boiler feedwater for stationary and railroad practice

EXECUTIVE COMMITTEE (Total personnel, 41)

C. H. FELLOWS, *Chairman*
R. C. BARDWELL, *Vice-Chairman*
J. B. ROMER, *Secretary*
A. G. CHRISTIE *
R. E. COUGHLAN
B. W. DE GEER
MAX HECHT
H. E. JORDAN

(*Continued*)

* Official A.S.M.E. representative serving on this committee.

BOILER FEEDWATER STUDIES
(Continued)

P. B. Place
S. T. Powell
F. N. Speller
M. F. Stack
G. E. Tate
E. H. Tenney
A. E. White *

CONDENSER TUBES

Appointed May, 1925, to investigate and report on the causes of failure of tubes used in steam condensers and similar heat interchange apparatus

A. E. White, *Chairman*
D. C. Weeks, *Vice-Chairman*
P. A. Bancell
H. Y. Bassett
R. A. Bowman
E. S. Bunn
D. K. Crampton
C. A. Crawford
R. E. Dillon
C. O. Evans
J. R. Freeman, Jr.
V. M. Frost
C. F. Harwood
G. C. Holder
W. C. Holmes
J. C. Phillips
W. B. Price
J. S. Rodgers
Director, Bureau of Ships, U.S. Navy Department

WORM GEARS

Appointed May, 1927, to investigate certain problems in connection with the action of worm gear drives and to recommend improvements in their design, manufacture, and use

Earle Buckingham, *Chairman*
G. H. Acker
L. R. Buckendale
A. A. Ross
B. F. Waterman
Representative of Bureau of Ships, U.S. Navy Department

STRENGTH OF VESSELS UNDER EXTERNAL PRESSURE

Appointed June, 1929, to develop reliable design data on the strength of cylindrical and spherical surfaces under external pressure, particularly with reference to jacketed vessels

F. V. Hartman, *Chairman*
M. B. Higgins
E. C. Korten
H. E. Saunders
E. E. Shanor
R. G. Sturm
D. B. Wesstrom
D. F. Windenburg
Dana Young

WIRE ROPE

Appointed April, 1930, to investigate existing rope so that it may be better understood and more effectively used

W. H. Fulweiler, *Chairman*
H. LeR. Brink
A. H. McDougall
B. V. E. Nordberg
W. S. Paine
W. J. Ryan
George Simpson
L. E. Young

CRITICAL PRESSURE STEAM BOILERS

Appointed June, 1931, to study the characteristics of high-pressure forced-circulation steam-generating units

H. L. Solberg, *Chairman*
W. H. Armacost
A. D. Bailey
C. L. Clark
F. S. Clark
C. H. Fellows
H. J. Kerr
E. C. Petrie
E. L. Robinson
W. H. Rowand
P. W. Thompson

PLASTIC FLOW OF METALS

Appointed October, 1938, to study plasticity in the particular field of rolling of steel

A. L. Nadai, *Chairman*
C. W. MacGregor, *Secretary*
E. C. Bain
C. L. Eksergian
LeVan Griffis
J. H. Hitchcock
W. P. Roop
M. D. Stone
W. Trinks

FURNACE PERFORMANCE FACTORS

Appointed in October, 1941, to collect and rationalize data on the performance of commercially important furnaces as an aid to design and operation

A. R. Mumford, *Chairman*
John Blizard
O. F. Campbell
W. A. Carter
B. J. Cross
T. B. Drew
F. G. Ely
A. C. Fieldner
J. H. Harlow
H. C. Hottel
E. L. Lindseth
W. H. McAdams
J. R. Michel
G. R. Milne
A. J. Nerad
E. B. Powell
A. A. Raymond
W. T. Reid
W. C. Schroeder, *Alternate*
L. B. Schueler, *Alternate*
R. A. Sherman
Philip Sporn
A. W. Thorson
Herman Weisberg
W. J. Wohlenberg

FORGING OF STEEL SHELLS

Appointed in October, 1941, to study methods of shell manufacture under modern conditions

M. D. Stone, *Chairman*
W. Trinks, *Projects Director*
John Dierbeck
M. S. Evans
D. W. Fletcher
W. M. Frame
W. N. Howley
A. F. Macconochie
W. P. Muir
A. L. Nadai
A. R. Nettenstrom
George Sachs
A. E. Van Cleve
U.S. Army, Ordnance Department
U.S. Navy, Bureau of Ordnance

DEMOLITION BOMB BODIES

Appointed in October, 1943, to study methods of demolition bomb body manufacture under modern conditions

M. D. Stone, *Chairman*
W. O. Clinedinst, *Secretary*
W. Trinks, *Projects Director*
G. M. Croft
F. C. Fantz
W. M. Frame
R. Furrer
J. M. Hopkins
H. B. Liggett
A. L. Nadai
George Sachs
U.S. Army, Ordnance Department
U.S. Navy, Bureau of Ordnance

INTERNAL-COMBUSTION ENGINES

Appointed in September, 1944, to prosecute, correlate, analyze, and report on research relating to efficiency, reliability, maintenance, and operating conditions of internal-combustion engines

Lee Schneitter, *Chairman*
W. L. H. Doyle
M. A. Elliott
C. W. Good
W. F. Joachim

FINISHING AND MACHINING OF H.E. STEEL SHELLS

Appointed in February, 1945, to study and critically compare the various methods of machining and finishing steel shells

D. W. Fletcher, *Chairman*
R. W. Biggs, *Secretary*
W. Trinks, *Projects Director*
O. W. Boston
W. C. De Graff
M. S. Evans
D. M. Galloway
C. G. Grazioso
W. N. Howley
M. L. Katke
M. D. Stone
U.S. Army, Ordnance Department

PROPERTIES OF GASES AND GAS MIXTURES

Appointed in June, 1945, to assemble and co-ordinate present available data on the properties of gases and gas mixtures

J. A. Goff, *Chairman*
H. W. Emmons
Serge Gratch
Gerhard Herzberg
H. L. Johnston
R. V. Kleinschmidt
E. L. Robinson
F. D. Rossini
R. B. Smith

AUTOMATIC REGULATION THEORY

Appointed in November, 1945, to supply basic data for correlating the apparent conflicts between the various approaches to the theory of automatic process control

C. E. Mason, *Chairman*
G. S. Brown
D. P. Campbell
C. O. Fairchild
Herbert Harris, Jr.
Nicholas Minorsky
George Philbrick
A. F. Sperry

J. H. HORIGAN
G. W. METZ, *Alternate*
L. F. NENNINGER

No. 4 on SPINDLE NOSES AND COLLETS FOR MACHINE TOOLS

A.S.M.E. Members (Total personnel, 5)

J. E. LOVELY, *Chairman*
H. W. FAHRLANDER
E. D. GANGWERE
F. O. HOAGLAND

No. 5 on MILLING CUTTERS

A.S.M.E. Members (Total personnel, 19)

J. B. ARMITAGE
A. N. GODDARD
E. E. GRIFFITHS
J. H. HORIGAN
G. W. METZ, *Alternate*
E. K. MORGAN
ERIK OBERG
E. DON VANCIL

No. 6 on DESIGNATIONS AND WORKING RANGES OF MACHINE TOOLS

A.S.M.E. Members (Total personnel, 19)

JOHN HAYDOCK, *Chairman*
T. H. DOAN
H. W. FAHRLANDER
H. W. FAUS
B. P. GRAVES
J. J. MCBRIDE
L. F. NENNINGER
E. R. SMITH

No. 7 on Twist Drill Sizes

A.S.M.E. Members (Total personnel, 6)

W. C. Mueller, *Chairman*
E. E. Griffiths
J. H. Horigan
G. W. Metz, *Alternate*

No. 8 on Jig Bushings

A.S.M.E. Members (Total personnel, 8)

E. E. Griffiths — G. W. Metz, *Alternate*
J. H. Horigan

No. 9 on Punch Press Tools

A.S.M.E. Members (Total personnel, 13)

D. H. Chason — H. E. Harris
E. W. Ernest — G. W. Metz, *Alternate*
E. E. Griffiths — D. M. Palmer

No. 10 on Forming Tools and Holders

A.S.M.E. Members (Total personnel, 10)

W. C. Mueller, *Chairman*
W. E. Blank
E. E. Griffiths
G. W. Metz, *Alternate*
L. D. Spence

No. 11 on Chucks and Chuck Jaws

A.S.M.E. Member (Total personnel, 9)

J. E. Lovely, *Chairman*

No. 12 on Cut and Ground Thread Taps

A.S.M.E. Member (Total personnel, 7)

J. E. Ennis

No. 13 on Splines and Splined Shafts

A.S.M.E. Members (Total personnel, 20)

J. B. Armitage — F. O. Hoagland
H. W. Fahrlander — J. E. Lovely
R. E. W. Harrison

No. 17 on Nomenclature for Small Tools and Machine Tool Elements

A.S.M.E. Members (Total personnel, 12)

O. W. Boston, *Chairman and Secretary*
F. S. Blackall, Jr.
F. H. Colvin
H. E. Harris
F. O. Hoagland

No. 19 on Single-Point Cutting Tools

A.S.M.E. Members (Total personnel, 2)

F. H. Colvin, *Chairman*
O. W. Boston, *Secretary*

No. 20 on Reamers

A.S.M.E. Members (Total personnel, 15)

F. H. Colvin — J. H. Horigan
T. F. Githens — O. E. Koehler
E. E. Griffiths — G. W. Metz, *Alternate*

No. 21 on Tool-Life Tests for Single-Point Tools

A.S.M.E. Members (Total personnel, 9)

O. W. Boston, *Chairman*
E. E. Griffiths
M. F. Judkins
F. W. Lucht
G. W. Metz, *Alternate*
H. L. Moir

No. 23 on Machine Pins

A.S.M.E. Members (Total personnel, 14)

G. W. Metz, *Secretary* — J. J. McBride
E. E. Griffiths — R. H. Smith

GEARS (B6)

** Joint sponsorship with the American Gear Manufacturers Association. Sectional Committee organized June, 1921*

A.S.M.E. Members (Total personnel, 23)

U. S. Eberhardt, *Chairman*
Earle Buckingham, *Vice-Chairman* †
G. H. Acker
A. H. Candee †
S. L. Crawshaw
L. H. Fry
C. B. Hamilton, Jr.
D. T. Hamilton
O. A. Leutwiler †

SUBCOMMITTEE CHAIRMEN

No. 3 on Nomenclature, D. T. Hamilton
No. 9 on Inspection, Granger Davenport

PIPE FLANGES AND FITTINGS (B16)

** Joint sponsorship with the Heating, Piping and Air Conditioning Contractors National Association, and the Manufacturers Standardization Society of the Valve and Fittings Industry. Sectional Committee organized November, 1921*

A.S.M.E. Members (Total personnel, 51)

C. P. Bliss, *Chairman* †

POWER TEST CODES COMMITTEES

ARTICLE B6A, PAR. 27: The Standing Committee on Power Test Codes shall, under the direction of the Council, have supervision of all the activities of the Society in connection with the A.S.M.E. Power Test Codes, including the interpretation of such codes.

The first Standing Committee on Power Test Codes was organized in December, 1918, to revise and extend the Power Test Codes which had been formulated by various technical committees appointed to develop particular codes. This work began in 1884.

STANDING COMMITTEE

A. G. CHRISTIE, *Chairman* (1946)

BOILER CODE COMMITTEES

ARTICLE B6A, PAR. 26: The Special Committee on Boiler Code shall, under the direction of the Council, have supervision of all the activities of the Society in connection with the A.S.M.E. Codes for Pressure Vessels, including the interpretations of these codes.

The first Special Committee on Boiler Code was organized in September, 1911.

MAIN COMMITTEE

H. B. OATLEY, *Chairman*
H. E. ALDRICH, *Vice-Chairman*
D. S. JACOBUS, *Honorary Chairman*
C. A. ADAMS
T. B. ALLARDICE
H. C. BOARDMAN
P. R. CASSIDY
R. E. CECIL
A. J. ELY
V. M. FROST
W. P. GERHART
W. D. HALSEY
W. F. HESS

THE WOMAN'S AUXILIARY TO THE A.S.M.E.

The Woman's Auxiliary to the A.S.M.E. was organized on May 10, 1923, and its Constitution and By-Laws was approved by the Council of the A.S.M.E. on October 27, 1924. The objects of the Auxiliary are to render service to all that pertains to the interest of the profession of mechanical engineering; to co-operate with any committees of the A.S.M.E.; to assist the sons and daughters of the members of the Society or worthy students of mechanical engineering in obtaining scholarships; and to promote any other objects consistent with the aims or objects of the A.S.M.E.

NATIONAL OFFICERS

President, MRS. J. NOBLE LANDIS
First Vice-President, MRS. JUSTIN J. MCCARTHY
Second Vice-President, MRS. EARL B. SMITH
Third Vice-President, MRS. D. K. WRIGHT
Fourth Vice-President, MRS. P. M. KING
Fifth Vice-President, MRS. F. M. FARMER
Recording Secretary, MRS. RANDALL B. PURDY
Corresponding Secretary, MRS. L. W. BENNETT
Treasurer, MRS. CHARLES E. GUS

STANDING COMMITTEE CHAIRMEN

Courtesy, MRS. CROSBY FIELD
Student Loan, MRS. F. M. GIBSON
Membership, MRS. G. E. HAGEMANN
Publicity, MRS. C. H. KENT
Sections, MRS. G. W. FARNY
Custodian, MRS. WALDO M. MCKEE

COUNCIL REPRESENTATIVES

Chairman, MRS. F. W. MILLER

AWARDS

The following paragraphs deal with the medals, awards, scholarships, and loan funds which come within the jurisdiction of the A.S.M.E. Other awards available to Student Members are listed in *Mechanical Engineering*, February, 1938, page 183. The Society also participates with other engineering societies in a number of joint awards. Further details concerning all the awards may be obtained from the headquarters of the Society.

Honorary Membership, to which persons of acknowledged professional eminence are elected by unanimous vote of the Council under the provisions of the By-Laws and Rules. A list of honorary members is given on page RI-43.

Life Membership, which may be conferred by the Council for distinguished service to the Society; or secured by a member by payment for an annuity in accordance with the provisions of the By-Laws.

A.S.M.E. Medal, established by the Society in 1920 to be presented, together with an engraved certificate, for distinguished service in engineering and science. May be awarded for general service in science having possible application in engineering.

Holley Medal, instituted and endowed in 1924 by George I. Rockwood, Past Vice-President of the Society, to be bestowed, together with an engraved certificate, for some great and unique act of genius of engineering nature that has accomplished a great and timely public benefit.

Worcester Reed Warner Medal, established in 1930, provision for which was made in the will of Worcester Reed Warner, Honorary Member of the Society, is a gold medal to be bestowed, together with an engraved certificate, for an outstanding contribution to permanent engineering literature.

Melville Prize Medal for Original Work, established in 1914 by the bequest of Rear-Admiral George W. Melville, Honorary Member and Past-President of the Society, to be presented, together with an engraved certificate, for an original paper or thesis of exceptional merit, presented to the Society by a member for discussion and publication during the calendar year previous to the year of award, to encourage excellence in papers. Only papers of single authorship are eligible. The medal may be presented annually.

Spirit of St. Louis Medal, established by an endowment fund created in 1929 by citizens of St. Louis, Mo., to be awarded for meritorious service in the advancement of aeronautics. This medal will be awarded at the discretion of the Council of the Society at approximately three-year periods upon the recommendation of its Board of Honors and Awards.

Spirit of St. Louis Junior Award, established in 1938 by an endowment fund created by the General Committee for the 1935 Aeronautic Meeting in St. Louis; a cash award of $50 and certificate made every three years, for the best paper on an aeronautic subject presented at any A.S.M.E. meeting during the three-year period either personally by the author (a Junior Member of the Society under thirty years of age) or by a Junior Member designated by him, and submitted to the Board of Honors and Awards within a reasonable period (to be determined by the Committee) after its initial presentation.

Pi Tau Sigma Medal Award, established in 1938, endowed by Pi Tau Sigma, the national honorary mechanical engineering fraternity, to be presented annually, together with an engraved certificate, to a young mechanical engineer for outstanding achievement in his profession within the ten years after graduation from a regular four-year mechanical engineering course of a recognized American college or university. Any mechanical engineering graduate, not more than thirty-five years of age, whose achievement has been all or in part in any field including industrial, educational, political, research, civic, etc., is eligible.

Junior Award, annual cash award of $50, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with an engraved certificate, for the best paper or thesis submitted during the calendar year previous to the year of award by a Junior Member not more than thirty years of age. Papers of joint authorship are eligible.

Charles T. Main Award, annual cash award of $150, established in 1919 from a fund created by Charles T. Main, Past-President of the Society, to be awarded, together with an engraved certificate, to a Student Member of the Society, for the best paper within the general subject of the influence of the profession upon public life. The exact subject is assigned by the Board of Honors and Awards, subject to the approval of the Council, and is announced each year through the Honorary Chairmen of the Student Branches.

Student Awards, two annual cash awards of $25 each, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with engraved certificates, for the best papers or theses submitted by Student Members. The awards for 1932 and subsequent years have been given, one for undergraduate and the other for postgraduate work.

SCHOLARSHIPS AND LOAN FUNDS

Max Toltz: Loan Fund of $15,000 established by Major Max Toltz, former member of the Council of the Society, the income to be used for assistance to Student Members.

John R. Freeman: Fund of $25,000 established in 1926 by John R. Freeman, Past-President of the Society, the income to be used for travel scholarships and research.

Woman's Auxiliary: Educational Loan Fund offered by the Woman's Auxiliary to the Society to assist sons and daughters of members or worthy students of mechanical engineering. Calvin W. Rice Memorial Scholarship Fund for students in mechanical engineering from South America.

RECIPIENTS OF AWARDS

The names of the recipients of the different awards to date are given in the following lists, together with the dates of presentation, and the services or papers for which the awards were made. There were no awards for the years not listed.

A.S.M.E. Medal

1921 Hjalmar Gotfried Carlson, in recognition of the services rendered the Government because of his invention and part in the production of 20,000,000 Mark III drawn steel booster casings used principally as a component of 75-mm high explosive shells, but also used extensively in gas shells and bombs

1922 Frederick Arthur Halsey, for his paper describing the premium system of wage payments presented before the Society at the Providence Meeting in 1891, as the adoption of the methods there proposed has had a profound effect toward harmonizing the relations of worker and employer

1923 John Ripley Freeman, for his eminent service in engineering and manufacturing by his meritorious work in fire prevention and the preservation of property

1926 R. A. Millikan, in recognition of his contributions to science and engineering

1927 Wilfred Lewis, for his contributions to the design and construction of gear teeth

1928 Julian Kennedy, for his services and contributions to the iron and steel industry

1929 William LeRoy Emmet, for his contributions in the development of the steam turbine, electric propulsion of ships, and other power-generating apparatus

1931 Albert Kingsbury, for his research and development work in the field of lubrication

1933 Ambrose Swasey, for his contributions to the advancement of the engineering profession and for his part in the development of the turret lathe and the astronomical telescope

1934 Willis H. Carrier, in recognition of his research and development work in air-conditioning

1935 Charles T. Main, for distinguished achievements in the textile and other industries, in engineering education, and for eminent service to the engineering profession

1936 Edward Bausch, for meritorious mechanical developments in the field of optics

1937 Edward P. Bullard, for outstanding leadership in the development of station-type machine tools

1938 Stephen J. Pigott, for outstanding leadership in marine propulsion and construction

1939 James E. Gleason, for service to the cause of safer and better transportation

1940 Charles F. Kettering, for outstanding inventions and research

1941 THEODOR VON KÁRMÁN, for his brilliance as a teacher, his researches in elasticity and many fields of physics and mechanics, and his distinguished leadership in the fields of aerodynamics and aircraft design
1942 E. G. BAILEY, for achievement and leadership in steam and combustion engineering
1943 LEWIS K. SILLCOX, pre-eminent learned technologist—lover of wisdom—inspirer of men
1944 EDWARD G. BUDD, for the development of stainless-steel railway passenger cars
1945 WILLIAM F. DURAND, world renowned authority in hydrodynamic and aerodynamic science and its practical application; great teacher with an inspiring character and a unique capacity for lucidity and simplicity in imparting highly technical material; trusted adviser to Government in the solution of many intricate scientific problems in peace and during two world wars

HOLLEY MEDAL

1924 HJALMAR GOTFRIED CARLSON, for his inventions and processes which made possible the timely production of drawn steel booster casings for artillery ammunition, thereby aiding victory in World War I (diploma in recognition of achievements presented in 1921)
1927 ELMER AMBROSE SPERRY, for achievements and inventions that have advanced the naval arts, including the gyroscope that has freed navigation from the dangers of the fluctuating magnetic compass
1929 BARON CHUZABURO SHIBA, for his contributions to knowledge through fundamental research, including the field of aerodynamics, by the development of ultra-rapid kinematographic methods
1934 IRVING LANGMUIR, for his contributions to science and engineering, including the development of gas-filled incandescent lamps, thoriated filament for thermionic emission, atomic hydrogen welding, phase control operation of the thyratron tube, and fundamental research in oil films
1936 HENRY FORD, for revolutionary influence through invention and practice on transportation and on mass production methods in manufacturing
1937 FREDERICK G. COTTRELL, for pre-eminent public service—the invention of electric precipitation—advancement of the science of gas liquefaction—gifts for engineering research
1938 FRANCIS HODGKINSON, for meritorious services in the development of the steam turbine
1939 CARL E. JOHANSSON, in recognition of his pioneer work in the development of basic measuring gages
1940 EDWIN HOWARD ARMSTRONG, for his leadership in the field of radio communication
1941 JOHN C. GARAND, for the invention and development of the semi-automatic rifle, which has been adopted by the U.S. Army as the U.S. Rifle, Caliber .30, M1, an outstanding contribution to our national defense
1942 ERNEST O. LAWRENCE, for originating the cyclotron, a unique invention for producing high-speed electrified particles, and for adapting it to research in physics, chemistry, medicine, and the properties of engineering materials
1943 VANNEVAR BUSH, for machines used in easing applied mathematics from computational barriers
1944 CARL L. NORDEN, for the invention and development of the Norden bombsight and other valuable devices which should hasten the peace
1945 SANFORD A. MOSS, for his many contributions over a long period of years to the development of centrifugal compressors, particularly as related to the highly successful application of turbosuperchargers to internal-combustion engines in the field of aeronautics

WORCESTER REED WARNER MEDAL

1933 DEXTER S. KIMBALL, for his contributions to efficiency in management as exemplified by his recently revised "Principles of Industrial Organization" and by his many articles, engineering society papers, and public addresses
1934 RALPH E. FLANDERS, for his contributions to a better understanding of the relationship of the engineer to economic problems and social trends as exemplified by the many papers which he has presented
1935 STEPHEN TIMOSHENKO, for his contributions to the theory of the design of elastic structures and the treatment of dynamics of moving machinery
1936 CHARLES M. ALLEN, for his early and continued hydraulic laboratory work and for the permanent value of the papers on his development of methods of testing large hydraulic turbine installations
1937 CLARENCE F. HIRSHFELD, for his research and contributions to the theory and practice of heat-power engineering as exemplified by books and papers
1938 LAWFORD H. FRY, for contributions relating to improved locomotive boiler design and utilization of better materials in railway equipment
1939 RUPEN EKSERGIAN, for influential papers of permanent value in A.S.M.E. Transactions
1940 WILLIAM BENJAMIN GREGORY, for distinguished work in hydraulic engineering, which has been the basis for many engineering papers
1941 RICHARD VYNNE SOUTHWELL, for his many distinguished services to engineering and science through papers and publications in many fields, including aeronautics, theory of structures, elasticity, and hydrodynamics
1942 FRED H. COLVIN, for his contributions to both technical advancement and improvement in management in the metal-working industries, as influenced by more than fifty years of articles and books—particularly American Machinists' Handbook
1943 IGOR I. SIKORSKY, for contributions inspiring creative engineering, especially in aeronautics
1944 EARLE BUCKINGHAM, for original contributions to engineering literature
1945 JOSEPH M. JURAN, for his outstanding contributions to the problem of quality control in mass production and his splendid records of such work as are contained in his books "Bureaucracy, A Challenge to Better Management" and "Management of Inspection and Quality Control"

MELVILLE PRIZE MEDAL FOR ORIGINAL WORK

1927 LEON P. ALFORD, "Laws of Manufacturing Management"
1929 JOSEPH W. ROE, "Principles of Jig and Fixture Practice"
1930 HERMAN DIEDERICHS and WILLIAM D. POMEROY, "The Occurrence and Elimination of Surge or Oscillating Pressure in Discharge Lines From Reciprocating Pumps"
1931 ARTHUR E. GRUNERT, "Comparative Performance of a Pulverized-Coal-Fired Boiler Using Bin System and Unit System of Firing"
1932 ALEXEY J. STEPANOFF, "Leakage Loss and Axial Thrust in Centrifugal Pumps"
1933 WILLIAM E. CALDWELL, "Characteristics of Large Hell Gate Direct-Fire Boiler Units"
1935 OSCAR R. WIKANDER, "Draft-Gear Action in Long Trains"
1936 H. A. STEVENS HOWARTH, "The Loading and Friction of Thrust and Journal Bearings With Perfect Lubrication"
1937 ALFRED J. BÜCHI, "Supercharging of Internal-Combustion Engines With Blowers Driven by Exhaust-Gas Turbines"
1938 ALPHONSE I. LIPETZ, "Air Resistance of Railrod Equipment"
1939 LESTER M. GOLDSMITH, "High-Pressure High-Temperature Turbine-Electric Steamship *J. W. Van Dyke*"
1940 CARL A. W. BRANDT, "The Locomotive Boiler"
1941 ROGER V. TERRY, "Development of the Automatic Adjustable-Blade-Type Propeller Turbine"
1942 J. KENNETH SALISBURY, "The Steam-Turbine Regenerative Cycle—An Analytical Approach"
1944 ERNEST L. ROBINSON, "Bursting Tests of Steam-Turbine Disk Wheels"
1945 WILLIAM J. KING, "The Unwritten Laws of Engineering"

SPIRIT OF SAINT LOUIS MEDAL

1929 DANIEL GUGGENHEIM, founder of the Guggenheim Fund for the Promotion of Aeronautics
1932 PAUL LITCHFIELD, for his work in encouraging and sponsoring airship design and construction in this country
1935 WILL ROGERS, for his splendid, constructive, and unselfish work in the achievement of aviation, and the building up of public confidence in aviation through his articles in the press, over the radio, and from the speaker's platform
1938 JAMES H. DOOLITTLE, for meritorious service in the advancement of aeronautics
1941 JOHN E. YOUNGER, for notable contributions to the science of airplane design, particularly in the conception, analysis, and supervision of the development of the fundamental design principles, requirements, and criteria which first assured the success of the pressure-cabin type of high-altitude airplane

1944 George W. Lewis, for leadership in direction and encouragement of aeronautical research, having an extensive influence on aeronautical engineering during the past quarter century

Spirit of Saint Louis Junior Award

1941 Wilbur W. Reaser, "Calculation of the Heat Loss From an Airplane Cabin"
1944 Martin Goland, "The Influence of the Shape and Rigidity of an Elastic Inclusion on the Transverse Flexure of Thin Plates"

Pi Tau Sigma Medal

1938 Wilfrid E. Johnson, for his development work in the field of refrigeration
1939 John I. Yellott, Jr., in recognition of significant achievements in steam-flow research and engineering education; also contributions on "Supersaturated Steam" and "Condensation of Flowing Steam in Diverging Nozzles"
1940 George A. Hawkins, for significant achievements in high-pressure steam research and engineering education
1941 R. Hosmer Norris, for outstanding achievement in mechanical engineering, particularly in the heat-transfer field
1942 John T. Rettaliata, for outstanding achievement in mechanical engineering

Junior Award

1915 Ernest O. Hickstein, "Flow of Air Through Thin Plate Orifices"
1916 L. M. McMillan, "The Heat Insulating Properties of Commercial Steam-Pipe Coverings"
1919 E. D. Whalen, "Properties of Airplane Fabrics"
1921 S. Logan Kerr, "Moody Ejector Turbine"
1922 R. H. Heilman, "Heat Losses From Bare and Covered Wrought-Iron Pipe at Temperatures up to 800 Degrees Fahrenheit"
F. L. Kallam, "Preliminary Report on the Investigation of the Thermal Conductivity of Liquids"
1923 S. S. Sanford and Sabin Crocker, "The Elasticity of Pipe Bends"
1924 R. H. Heilman, "Heat Losses Through Insulating Material"
1925 Gilbert S. Schaller, "An Investigation of Seattle as a Location for a Synthetic Foundry Industry"
1927 William M. Frame, "Stresses Occurring in the Walls of an Elliptical Tank Subjected to Low Internal Pressure"
1928 M. D. Aisenstein, "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump"
1929 Arthur M. Wahl, "Stresses in Heavy, Closely Coiled Helical Springs"
1930 Ed Sinclair Smith, "Quantity-Rate Fluid Meters"
1931 M. K. Drewry, "Radiant-Superheater Developments"
1932 Edmond M. Wagner, "Frictional Resistance of a Cylinder Rotating in a Viscous Fluid Within a Coaxial Cylinder"
1933 Townsend Tinker, "Surface Condenser Design and Operating Characteristics"
1934 John I. Yellott, Jr., "Supersaturated Steam"
1935 Stanley J. Mikina, "Effect of Skewing and Pole Spacing on Magnetic Noise in Electrical Machinery"
1936 Harwood F. Mullikan, Jr., "Evaluation of Effective Radiant Heating Surface and Application of the Stefan-Boltzman Law to Heat Absorption in Boiler Furnaces"
1937 Leslie J. Hooper, "American Hydraulic-Laboratory Practice"
1938 Arthur C. Stern, "Separation and Emission of Cinders and Fly Ash"
1940 Robert E. Newton, "A Photoelastic Study of Stresses in Rotary Disks"
1941 John T. Rettaliata, "The Combustion Gas Turbine"
1942 Winston M. Dudley, "Analysis of Longitudinal Motions in Trains of Several Cars"
1943 Troels Warming, "Power Pulsation Between Synchronous Generators"
1945 Bruce E. Del Mar, "Presentation of Centrifugal-Compressor Performance in Terms of Nondimensional Relationships"

Charles T. Main Award

1925 Clement R. Brown, Catholic University of America. Subject: "The Influence of the Locomotive on the Unity of the United States"
1926 W. C. Saylor, Johns Hopkins University. Subject: "The Effect of the Cotton Gin Upon the History of the United States During Its First Seventy Years"
1927 No Award. Subject: "Scientific Management and Its Effect Upon the Industries"
1928 Robert M. Meyer, Newark College of Engineering. Subject: "Scientific Management and Its Effect Upon Manufacturing"
1929 No Award. Subject: "The Influence of Engineering on Farm Production"
1930 Jules Podnossoff, Polytechnic Institute of Brooklyn. Subject: "The Value of the Safety Movement in the Industries"
1931 Robert E. Klise, University of Michigan. Subject: "Interchangeability—Its Development and Significance in Industry"
1932 Marshall Anderson, University of Michigan. Subject: "Apprenticeship and Vocational Training"
1933 George D. Wilkinson, Jr., Newark College of Engineering. Subject: "Progress in the Prevention of Smoke and Atmospheric Pollution"
1934 Philip P. Self, Colorado State College. Subject: "Air Conditioning—Its Practicability and Relation to Public Welfare"
1935 G. Lowell Williams, Lafayette College. Subject: "Coordinated Transportation—An Economic Comparison of Railroad, Bus, Truck, Water, and Air Transportation for Long and Short Haul"
1936 No Award. Subject: "Developments in the Generation and Distribution of Power and Their Effect Upon the Consumer"
1937 Allan P. Stern, Case School of Applied Science. Subject: "The Influence of the Introduction of Labor Saving Machinery Upon Employment in the United States"
1938 Edward W. Connolly, University of Detroit. Subject: "Economic Limitations in Engineering Design, With Concrete Examples"
1939 James R. Bright, Lehigh University. Subject: "The Economics of Investment in New Manufacturing Equipment—With Concrete Cases"
1940 Frank De Pould, Case School of Applied Science. Subject: "What Has Been the Effect of Technological Advance on Employment?"
1941 John J. Balun, University of Detroit. Subject: "The Need and Possibilities of Participation by Engineers in Public Affairs"
1942 Bernard J. Isabella, Case School of Applied Science. Subject: "The Engineer and Preparation for the Coming Peace"
1943 Mitchell C. Kazen, University of Detroit. Subject: "Government as Affected by Engineering"
1944 Fred M. Piaskowski, University of Detroit, "A Case Study of Labor-Management Co-operation"
1945 Jack Drandell, Southern Methodist University, "Engineering in the New South"

Student Award

1916 Boynton M. Green, Stanford University, "Bearing Lubrication"
Howard E. Stevens, Rensselaer Polytechnic Institute, "An Investigation of the Dynamic Pressure on Submerged Flat Plates"
M. Adam, Louisiana State University, "The Adaptability of the Internal-Combustion Engine to Sugar Factories and Estates"
1917 H. R. Hammond and C. W. Holmberg, The Pennsylvania State College, "Study of Surface Resistance With Glass as the Transmission Medium"
1919 C. F. Leh and F. G. Hampton, Stanford University, "An Experimental Investigation of Steel Belting"
W. E. Helmick, Stanford University, "An Experimental Investigation of Steel Belting"
1920 Howard G. Allen, Cornell University, "Wire Stitching Through Paper"
1921 Karl H. White, University of Kansas, "Forces in Rotary Motors"
Richard H. Morris and Albert J. R. Houston, University of California, "A Report Upon an Investigation of the Herschel Type of Improved Weir"
1923 Charles F. Olmstead, University of Minnesota, "Oil Burning for Domestic Heating"
H. E. Doolittle, University of California, "The Integrating Gate: A. Device for Gaging in Open Channels"

1924 George Stuart Clark, Stanford University, "Two Methods Used for the Determination of the Gasoline Content of Absorption Oils in Absorption Plants"
L. J. Franklin and Charles H. Smith, Stanford University, "The Effect of Inaccuracy of Spacing on the Strength of Gear Teeth"

1925 Harry Pease Cox, Jr., Rensselaer Polytechnic Institute, "A Study of the Effect of End Shape on the Towing Resistance of a Barge Model"
W. S. Montgomery, Jr., and E. Ray Enders, Jr., The Pennsylvania State College, "Some Attempts to Measure the Drawing Properties of Metals"

1926 R. E. Peterson, University of Illinois, "An Investigation of Stress Concentration by Means of Plaster of Paris Specimens"
Cecil G. Heard, University of Toronto, "Pressure Distribution Over U.S.A. 27 Aerofoil With Square Wing Tips—Model Tests"

1927 Alfred H. Marshall, Princeton University, "Evaporative Cooling"
Roger Irwin Eby, University of Washington, "Measurement of the Angular Displacement of Flywheels"

1928 Clarence C. Franck, Johns Hopkins University, "Condition Curves and Reheat Factors for Steam Turbines"

1929 Frank Vernon Bistrom, University of Washington, "An Investigation of a Rotary Pump"
William Wallace White, University of Washington, "An Investigation of a Rotary Pump"

1930 Gerard Eden Claussen, Polytechnic Institute of Brooklyn, "High-Temperature Oxidation of Steel"
Harold L. Adams and Richard L. Stith, University of Washington, "A Wind Tunnel for Undergraduate Laboratory Experiments"

1931 Jules Podnossoff, Polytechnic Institute of Brooklyn, "Pressure and Energy Distribution in Multi-Stage Steam Turbines Operating Under Varying Conditions"

1932 H. E. Foster, Jr., University of Tennessee, "Factors Affecting Spray Pond Design" (Undergraduate Award)
William A. Mason, Stanford University, "An Experimental Investigation of the Flame Propagation in Internal-Combustion Engines" (Postgraduate Award)

1933 Hugo V. Cordiano, Polytechnic Institute of Brooklyn, "Thermal Analysis of Lithium-Magnesium System of Alloys" (Undergraduate Award)
James A. Ostrand, Jr., Princeton University, "Sudden Enlargement in the Open Channel" (Postgraduate Award)

1934 H. Reynolds Hudson, Georgia School of Technology, "Dynamic Balance and Functional Utility Applied to Automotive Design" (Undergraduate Award)

1935 Charles P. Bacha, Rutgers University, "The Behavior of Metals Subjected to Combined Stress" (Postgraduate Award)
Robert W. Beal, Oregon State College, "Do Lubricating Oils Wear Out?" (Undergraduate Award)

1936 Leon B. Stinson, Oklahoma Agricultural and Mechanical College, "Polymerized Motor Fuels; Their Economic Significance" (Undergraduate Award)
DeWitt D. Barlow, Jr., Princeton University, "The Critical Speeds of Lateral Vibrations of Shafts With Gyroscopic Effects" (Postgraduate Award)

1937 Gino J. Marinelli, Rensselaer Polytechnic Institute, "Investigation of the Towing Resistance of a Model Submarine Hull" (Undergraduate Award)

1938 Marshall C. Long, Princeton University, "An Investigation Into the Angular Characteristics of an Adjustable Blade Current Meter" (Postgraduate Award)
Donald C. McSorley, Michigan State College, "Humidity Insulation" (Undergraduate Award)

1939 David T. James, Michigan State College, "Bells—Concerning Their Tones" (Undergraduate Award)

1940 George W. Shepherd, Jr., Princeton University, "An Automatic Mechanical Control for Synchronizing Prime Movers" (Postgraduate Award)
Edward D. Rowan, Oregon State College, "Powder Metallurgy" (Undergraduate Award)

1941 G. Walker Gilmer, III, University of Florida, "Center of Pressure Characteristics of a Marconi Yacht Sail" (Undergraduate Award)

1942 Arthur W. McClure, Princeton University, "A Specific Speed Analysis of Turbosuperchargers for Aircraft" (Postgraduate Award)
J. Packard Laird, Princeton University, "An Analysis of Motorcycle Behavior" (Undergraduate Award)

1943 William L. Hutton, Princeton University, "The Aerodynamic Development of the Star Sail" (Undergraduate Award)

1944 Nelson B. Hammond, University of Pennsylvania, "An Investigation of Silver Solder Penetration in Brass Joints" (Undergraduate Award)

1945 John W. Erickson, Illinois Institute of Technology, "Increasing the Efficiency of Gas Turbine Cycles" (Undergraduate Award)

Freeman Travel Scholarship

1927	Herbert N. Eaton	1933	H. J. Casey
1928	Blake R. Van Leer	1934	H. J. Casey
1929	Robert T. Knapp	1935	Victor L. Streeter
1931	Reginald Whitaker	1936	Victor L. Streeter
1932	G. Ross Lord		

HONORARY MEMBERS

HONORARY MEMBERS IN PERPETUITY

Alexander Lyman Holley, Founder of the Society. Died 1882.

John Edson Sweet, Founder of the Society. Died 1916.

Henry Rossiter Worthington, Founder of the Society. Died 1880.

DECEASED HONORARY MEMBERS

	ELECTED	DIED
Leon Pratt Alford	1941	1942
Horatio Allen	1880	1889
Lorenzo Allievi	1937	1941
Sir William Arrol	1905	1913
Sir John Audley Frederick Aspinall	1911	1937
William Wallace Atterbury	1925	1935
Sir Benjamin Baker	1886	1907
Edmund Bruce Ball	1939	1944
Johann Bauschinger	1884	1893
Sir Henry Bessemer	1891	1898
Sir Frederick Joseph Bramwell	1884	1903
John Alfred Brashear	1908	1920
Gustave Canet	1900	1908
Andrew Carnegie	1907	1919
Daniel Kinnear Clark	1882	1896
Rudolph Julius Emmanuel Clausius	1882	1888
Hutchinson I. Cone	1936	1941
Sir John Coode	1889	1892
Mortimer Elwyn Cooley	1928	1944
Peter Cooper	1882	1883
Charles de Fréminville	1919	1936
Carl Gustaf Patrick de Laval	1912	1913
Rudolph Diesel	1912	1913
Alex Dow	1936	1942
James Dredge	1886	1906
Victor Dwelshauvers-Dery	1886	1913
Thomas Alva Edison	1904	1931
Alexandre Gustave Eiffel	1889	1923
Marshal Ferdinand Foch	1921	1929
Sir Charles Douglas Fox	1900	1921
John Ripley Freeman	1932	1932
John Fritz	1900	1913
Major General George Washington Goethals	1917	1928
Franz Grashof	1884	1893
Rear Admiral Robert Stanislau Griffin	1920	1933
Otto Hallauer	1882	1883
Charles Haynes Haswell	1905	1907
Nathanael Greene Herreshoff	1921	1938
Friedrich Gustav Herrmann	1884	1907
Gustav Adolph Hirn	1882	1890
Joseph Hirsch	1889	1901
Ira N. Hollis	1928	1930
Robert Woolston Hunt	1920	1923
Benjamin Franklin Isherwood	1894	1915
Albert Kingsbury	1940	1943
Henri Léauté	1891	1916
Erasmus Darwin Leavitt	1915	1916
Henri Le Chatelier	1927	1936
Charles Thomas Main	1939	1943
Anatole Mallet	1912	1919
Charles H. Manning	1913	1919
Rear Admiral George Wallace Melville	1910	1912
George A. Orrok	1936	1944
The Honorable Sir Charles Algernon Parsons	1920	1931

Masawo Kamo	1929
Dexter Simpson Kimball	1939
Vice-Admiral Emory S. Land	1944
Lieutenant General Andrew G. L. McNaughton	1943
Sir (Standen) Leonard Pearce	1944
Grande Ufficiale Ing. Pio Perrone	1920
Andrey Abraham Potter	1945
Harry R. Ricardo	1942
Vice-Admiral Samuel Murray Robinson	1941
Sir William Arthur Stanier	1945
Major General William H. Tschappat	1938
Right Honorable Lord Weir	1920
Major General Charles Macon Wesson	1941
Wong Wen-hao	1945
Orville Wright	1918
Roy V. Wright	1943

PAST-PRESIDENTS

Dates in parentheses denote year of death.

Alexander Lyman Holley, *Chairman of the Preliminary Meeting for Organization of The American Society of Mechanical Engineers* (1882)

1880–1882	Robert Henry Thurston (1903)
1883	Erasmus Darwin Leavitt (1916)
1884	John Edson Sweet (1916)
1885	Josephus Flavius Holloway (1896)
1886	Coleman Sellers (1907)
1887	George H. Babcock (1893)
1888	Horace See (1909)
1889	Henry Robinson Towne (1924)
1890	Oberlin Smith (1926)
1891	Robert Woolston Hunt (1923)
1892	Charles Harding Loring (1907)
1893–1894	Eckley Brinton Coxe (1895)
1895	Edward F. C. Davis (1895)
1895	Charles Ethan Billings (1920)
1896	John Fritz (1913)
1897	Worcester Reed Warner (1929)
1898	Charles Wallace Hunt (1911)
1899	George Wallace Melville (1912)
1900	Charles Hill Morgan (1911)
1901	Samuel T. Wellman (1919)
1902	Edwin Reynolds (1909)
1903	James Mapes Dodge (1915)
1904	Ambrose Swasey (1937)
1905	John Ripley Freeman (1932)
1906	Frederick Winslow Taylor (1915)
1907	Frederick Remsen Hutton (1918)
1908	Minard Lafever Holman (1925)
1909	Jesse Merrick Smith (1927)
1910	George Westinghouse (1914)
1911	Edward Daniel Meier (1914)
1912	Alexander Crombie Humphreys (1927)
1913	William Freeman Myrick Goss (1928)
1914	James Hartness (1934)
1915	John Alfred Brashear (1920)
1916	David Schenck Jacobus
1917	Ira Nelson Hollis (1930)
1918	Charles Thomas Main (1943)
1919	Mortimer Elwyn Cooley (1944)
1920	Fred J. Miller (1939)
1921	Edwin S. Carman
1922	Dexter Simpson Kimball
1923	John Lyle Harrington (1942)
1924	Frederick Rollins Low (1936)
1925	William Frederick Durand
1926	William Lamont Abbott
1927	Charles M. Schwab (1939)
1928	Alex Dow (1942)
1929	Elmer Ambrose Sperry (1930)
1930	Charles Piez (1933)
1931	Roy V. Wright
1932	Conrad N. Lauer (1943)
1933	A. A. Potter
1934	Paul Doty (1938)
1935	Ralph E. Flanders
1936	William L. Batt
1937	James H. Herron
1938	Harvey N. Davis
1939	Alexander G. Christie
1940	Warren H. McBryde
1941	William A. Hanley
1942	James W. Parker
1943	Harold V. Coes
1944	Robert M. Gates
1945	Alex D. Bailey

TREASURERS

Apr. 1880—Dec. 1881	Lycurgus B. Moore *
Dec. 1881—Nov. 1884	Charles W. Copeland (1895)
1884—1925	William H. Wiley (1925)
1925—1935	Erik Oberg
1935—1944	William D. Ennis
1944—date	K. W. Jappe

SECRETARIES

Organization Meeting, 1880	Samuel S. Webber, Jr. (1921)
Acting Secretary, Apr.-Nov. 1880	Lycurgus B. Moore *
Nov. 1880—Mar. 1883	Thos. Whiteside Rae (1895)
1883—1906	Frederick R. Hutton (1918)
1906—1934	Calvin W. Rice (1934)
1934—date	Clarence E. Davies

* Deceased. Year not known.

Index to Society Records, Part 1

The page numbers in this section are preceded by the letters "RI," which are omitted in the following index.

Abbreviations and Symbols, Graphical, Comm.. 31
Abbreviations and Symbols, Letter, Comm.... 31
Abrasive Wheels, Rep. on Safety Comm..... 37
Acoustical Measurements, Rep. on Comm.... 32
Administrative Organization Comm..... 12
Admissions Comm. 6
Advertising Manager, A.S.M.E..... 5
Aeronautic Div. *See* Aviation Div.
Aeronautics, Rep. on Standardization Comm... 32
Agriculture Comm. 13
Air Conditioning Comm..... 13
Alfred Noble Prize, A.S.M.E. Rep..... 9
Allowances and Tolerances, Gages, Comm.... 28
American Association for the Advancement of Science, A.S.M.E. Reps..... 9
American Documentation Institute, A.S.M.E. Rep. 9
American Standards Association, A.S.M.E. Reps. 9
American Year Book Corporation, A.S.M.E. Rep. 9
Applied Mechanics Div. Comms..... 10
ASA Mechanical Standards Comm., Reps. on.. 32
ASA Safety Code Correlating Comm., Reps. on. 37
ASA Standards Council, Reps. on..... 33
A.S.M.E. Medal
  Recipients 40
  Statement about 40
Assistant Secretaries, A.S.M.E..... 5
Automatic Regulation Theory Comm..... 27
Aviation Div. Comms..... 10
Awards, A.S.M.E.
  Recipients 40
  Statements about 40
Awards Comm. *See* Honors and Awards
Ball and Roller Bearings Comm..... 28
Biography Comm. 7
Biomechanics Comm. 10
Board of Honors and Awards..... 6

ADVISORY MEMBERS OF THE COMMITTEE ON PUBLICATIONS:

N. C. EBAUGH, GAINESVILLE, FLA. HUNTER R. HUGHES, JR., DALLAS, TEXAS

Published monthly by The American Society of Mechanical Engineers. Publication office at 20th and Northampton Streets, Easton, Pa. The editorial department is located at the headquarters of the Society, 29 West Thirty-Ninth Street, New York 18, N. Y. Cable address, "Dynamic," New York. Price $1.50 a copy, $12.00 a year; to members and affiliates, $1.00 a copy, $7.50 a year. Changes of address must be received at Society headquarters two weeks before they are to be effective on the mailing list. Please send old as well as new address. . . . By-Law: The Society shall not be responsible for statements or opinions advanced in papers or . . . printed in its publications (B13, Par. 4). . . . Entered as second-class matter March 2, 1928, at the Post Office at Easton, Pa., under the Act of August 24, 1912. . . .

Copyrighted, 1947, by The American Society of Mechanical Engineers. Reprints from this publication may be made on condition that full credit be given the Transactions of the A.S.M.E. and the author, and that date of publication be stated.

Depositories for A.S.M.E. Transactions in the United States, Including Territories and Dependencies

BOUND copies of the complete Transactions of The American Society of Mechanical Engineers will be found in the libraries in the United States and other countries which are listed on the following pages.

Indexes to A.S.M.E. Papers and Publications

THIS and the following pages will serve as a guide to the current publications of the A.S.M.E.

Regular Society Publications, 1946

Mechanical Engineering, monthly (see index on page RI-55)
A.S.M.E. Transactions, monthly including the *Journal of Applied Mechanics* (see index on page RI-68)
A.S.M.E. Mechanical Catalog and Directory, 1947 edition.

Publications Issued in 1946

Metal Cutting Data (monthly publication)
Sources of Information on Instruments
1944 Oil-Engine Power Cost Report

American Standards

Drawings and Drafting-Room Practice
Inspection and Tolerance of Gears
Involute Splines
Tool Life Tests

Boiler Construction Code

1946 Addenda to:
- Locomotive Boiler Code
- Low-Pressure Heating Boiler Code
- Miniature Boiler Code
- Power Boiler Code
- Unfired Pressure Vessel Code
- Specifications for Materials
- Welding Qualifications

Power Test Codes

Stationary Steam Generating Units

How to Find Papers Presented at 1946 A.S.M.E. Meetings

THE technical programs of the meetings of the Society and of its Professional Divisions have been published in *Mechanical Engineering* and may be located by consulting the index on pages RI-55-RI-67. A majority of these papers were published, or will be published, in *Mechanical Engineering* or the Transactions (including the *Journal of Applied Mechanics*) and may be located by reference to the indexes of these publications.

Publications Developed by the Technical Committees

THE Society's technical committees, the first of which was organized many years ago and all of which have been continuously at work on codes, standards, research, and other special reports, have developed a series of publications of permanent value to the membership. The following list is presented here for record and for ready reference. This list covers the entire group of publications of these committees completed and published.

To assist members in securing copies of these publications the sale price is also given. A discount of 20 per cent is allowed to A.S.M.E. members on all publications except where otherwise noted.

A.S.M.E. AMERICAN STANDARDS

Bolt, Nut, and Rivet Proportions

Large Rivets (B18.4—1937), $0.80
Plow Bolts (B18f—1928), $0.45
Round Unslotted-Head Bolts (B18.5—1939), $0.60
Slotted-Head Proportions; Machine Screws, Cap Screws, and Wood Screws (B18c—1930), $0.55
Small Rivets (B18a—1927 with 1942 Addendum), $0.40
Tinners', Coopers', and Belt Rivets (B18g—1928, with 1942 Addendum), $0.45
Track Bolts and Nuts (B18d—1930), $0.50
Wrench-Head Bolts and Nuts and Wrench Openings (B18.2—1941), $0.80

Piping and Pipe Fittings

Air Gaps and Backflow Preventers in Plumbing Systems (A40.4—1942 and A40.6—1943), $0.55
Brass Fittings for Flared Copper Tubes (A40.2—1936), $0.45
Cast-Iron Pipe Flanges and Flanged Fittings for 25 Lb Maximum Saturated Steam Pressure (B16b2—1931), $0.50
Cast-Iron Pipe Flanges and Flanged Fittings Class 125 (B16a—1939), $0.60
Cast-Iron Pipe Flanges and Flanged Fittings Class 250 (B16b—1944), $0.55.
Cast-Iron Pipe Flanges and Flanged Fittings for 800 Lb Maximum Hydraulic Pressure (B16b1—1931), $0.45.
Cast-Iron Soil Pipe and Fittings (A40.1–1935), $0.80
Cast-Iron Long Turn Sprinkler Fittings for 150 and 250 Lb Maximum Saturated Steam Pressure (B16g—1929) and Addendum (B16g1—1937), $0.60
Cast-Iron Screwed Fittings for 125 and 250 Lb Maximum Saturated Steam Pressure (B16d—1941), $0.50
Cast-Iron Screwed Drainage Fittings (B16.12—1942), $0.55
Code for Pressure Piping (B31.1—1942), $2.50
Face-to-Face Dimensions of Ferrous Flanged and Welding End Valves (B16.10—1939), $0.65
Ferrous Plugs, Bushings, Lock Nuts, and Caps (B16.14—1943), $0.50
Malleable-Iron Screwed Fittings for 150 Lb Maximum Saturated Steam Pressure (B16c—1939), $0.60
Pipe Threads (B2.1—1945), $1.50
Scheme for the Identification of Piping Systems (A13—1928), $0.60
Steel Pipe Flanges and Flanged Fittings for 150 to 2500 Lb Maximum Steam Service Pressure (B16e—1939), $1.50
Soldered-Joint Fittings (A40.3—1941), $0.55
Steel Butt-Welding Fittings (B16.9—1940), $0.50
Threaded Cast-Iron Pipe for Drainage, Vent, and Waste Services (A40.5—1943), $0.30
Wrought-Iron and Wrought-Steel Pipe (B36.10—1939), $0.60

Letter and Graphical Symbols and Charts

Abbreviations for Scientific and Engineering Terms (Z10.1—1941), $0.45
Drawings and Drafting-Room Practice (Z14.1—1946), $1.50
Engineering and Scientific Charts for Lantern Slides (Z15.1—1932), $0.60
Engineering and Scientific Graphs for Publications (Z15.3—1943), $0.90
Graphical Symbols for Use on Drawings in Mechanical Engineering (Z32.2—1941), $0.60
Letter Symbols for Gear Engineering (B6.5—1943), $0.30
Letter Symbols for Hydraulics (Z10.2—1942), $0.45
Letter Symbols for Mechanics of Solid Bodies (Z10.3—1942), $0.30
Letter Symbols for Heat and Thermodynamics (Z10c—1943), $0.65
Time Series Charts (Z15.2—1938), $1.50

AMERICAN STANDARDS—MISCELLANY

Fire-Hose Coupling Screw Threads (B26—1925), $0.30
Hose Coupling Screw Threads (B33.1—1935), $0.30
Indicating Pressure and Vacuum Gages (B40—1939), $0.50
Preferred Thickness for Uncoated Thin Flat Metals (B32.1—1941), $0.30
Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases (C44—1931, Reaffirmed in 1946), $0.45
Gear Tolerances and Inspection (B6—1946), $0.80
Preferred Standards for Large 3600-Rpm 3-Phase 60-Cycle Condensing Steam Turbine-Generators (published 1945), $0.30
Shaft Couplings (B49—1932), $0.45
Spring Lock Washers (B27.1—1944), $0.35
Spur Gear Tooth Form (B6.1—1932) $0.55

SMALL TOOLS AND MACHINE TOOL ELEMENTS

Machine Tapers (B5.10—1943), $0.75
Milling Cutters (B5c—1930), $0.90
Reamers (B5.14—1941), $0.90
Taps—Cut and Ground Threads (B5.4—1939), $1.50
Terminology and Definitions for Single-Point Cutting Tools (B5.13—1939), $0.50
Adjustable Adapters (B5.11—1937), $0.60
Chucks and Chuck Jaws (B5.8—1936), $0.55
Circular and Dovetailed Forming Tool Blanks and Holding Elements (B5.7—1943), $0.60
Shafting and Stock Keys (B17.1—1943), $0.55
Markings for Grinding Wheels (B5.17—1943), $0.30
Involute Splines, Side Bearings (B5.15—1946), $0.80
Jig Bushings (B5.6—1941), $0.45
Spindle Noses and Arbors (B5.18—1943), $0.30
Rotating Air Cylinders and Adapters (B5.5—1932), $0.45
Tool Shanks and Tool Posts (B5.2—1943), $0.45
Tool Life Tests (B5—1946), $0.55
T-Slots, Their Bolts, Nuts, Tongues, and Cutters (B5a—1941), $0.45
Twist Drills (B5.12—1940), $0.65
Code for Design of Transmission Shafting (B17c—1927), $0.90
Screw Threads for Bolts, Nuts, Machine Screws, and Threaded Parts (B1.1—1935), $0.75
Screw Threads for High-Strength Bolting (B1.4—1945), $0.30
Screw Thread Gages and Gaging (B1.2—1941), $0.75
Acme and Other Translating Threads (B1.3—1941), $0.55
Tolerances, Allowances, and Gages for Metal Fits (B4a—1925), $0.60
Woodruff Keys, Keyslots, and Cutters (B17f—1930), $0.45

BOILER CONSTRUCTION CODE

1946 Editions:
- Boilers of Locomotives, $1.00
- Low-Pressure Heating Boiler Code, $1.00
- Miniature Boiler Code, $0.75
- Power Boiler Code, $2.75
- Specifications for Materials, $3.50
- Suggested Rules for Power Boilers, $1.25
- Unfired Pressure Vessel Code, $2.00
- Welding Qualifications, $0.90

Boiler Code Interpretation Service, $5.00 annually
API-ASME Code for Unfired Pressure Vessels
1943 Edition, with 1944 Supplement, $2.00

POWER TEST CODES AND AUXILIARY SECTIONS

TEST CODES FOR

Atmospheric Water-Cooling Equipment (1930), $0.55
Coal Pulverizers (1944), $0.85
Displacement Compressors, Vacuum Pumps, and Blowers (1939), $0.90
Dust Separating Apparatus (1941), $0.90
Evaporating Apparatus (1941), $0.60
Feedwater Heaters (1927), $0.45
Fans (1945), $1.00
Gaseous Fuels (1944), $0.90
Gas Producers (1928), $0.65
Hydraulic Prime Movers (1938 with 1942 Addenda), $0.75
Reciprocating Steam-Driven Displacement Pumps (1927), $0.80
Reciprocating Steam Engines (1935), $0.80
Refrigerating Systems (1927), $0.65
Steam Condensing Apparatus (1938), $0.80
Steam Locomotives (1941), $0.65
Stationary Steam Generating Units (1946), $0.75

INSTRUMENTS AND APPARATUS

General Instructions (1945), $0.55
Definitions and Values (1945), $0.80
Part 1—General Considerations (1935), $0.45
Part 2—Pressure Measurement
- Chapter 1, Barometers; Chapter 6, Tables, Multipliers, and Standards (1941), $0.75
- Chapter 2, Static and Total Pressure, Static Holes and Tubes, and Impact Tubes, $0.75
- Chapter 3, Static Pressure Hole, Static Tube, or Impact Tube (1945), $0.75
- Chapter 4, Bourdon, Bellows, Diaphragm, and Deadweight Gages (1938), $0.75
- Chapter 5, Liquid Column Gages (1942), $0.75

Part 3—Temperature Measurement
- Chapter 1, General; Chapter 5, Pyrometric Cones; Chapter 6, Liquid-in-Glass Thermometers; and Chapter 7, Bourdon-Tube Thermometers (1931), $0.75
- Chapter 2, Radiation Pyrometers (1936), $0.65
- Chapter 3, Thermocouple Thermometers or Pyrometers (1940), $0.75
- Chapter 4, Resistance Thermometers (1945), $0.80
- Chapter 8, Optical Pyrometers (1940), $0.45

Part 4—Head Measuring Apparatus (1933), $0.45
Part 5—Chapter 4, Flow Measurement by Means of Standardized Nozzles and Orifice Plates (1940), $2.75
Part 6—Electrical Measurements (1934), $1.25
Part 8—Measurement of Indicated Horsepower (1941), $0.75
Part 9—Heat of Combustion (1943), $0.50
Part 11—Determination of Quality of Steam (1940), $0.55
Part 12—Measurement of Time (1942), $0.50
Part 13—Speed Measurements (1939), $0.55
Part 14—Linear Measurements (1936), $0.65
Part 15—Measurement of Surface Areas (1944), $0.75
Part 16—Density Determinations (1931), $0.40
Part 17—Determination of the Viscosity of Liquids (1931), $0.75
Part 18—Humidity Determinations (1932), $0.60
Part 20—Smoke-Density Determinations (1945), $0.75
Part 21—Leakage Measurements (1942), $0.75

RESEARCH

Fluid Meters:
- Part 1—Theory and Application (1937), $3.25
- Part 3—Selection and Installation (1933), $1.75

Report of the A.G.A.-A.S.M.E. Committee on Orifice Coefficients. (1935), $2.75
Tests on Electrical Equipment for Drilling Rotary Drilled Oil Wells (1932), $0.85
Tests on Steam Equipment for Drilling Rotary Drilled Oil Wells (1933), $0.85
Bibliography on Aircraft Plywood (1944), $1.00
Bibliography on Marketing Research (1935), $1.00
Bibliography on the Cutting of Metals (published 1945), $6.50
Riveted Joints—A Critical Review of the Literature Covering Their Development, with Bibliography and Abstracts of the Most Important Articles (Published 1945), $4.50
Sources of Information on Instruments (published 1945), $0.75

SAFETY CODES

Safety Code for Cranes, Derricks, and Hoists (B30.2—1943), $1.80
Safety Code for Elevators (A17.1—1937 with 1942 Supplement), $1.50
Elevator Inspectors' Manual (A17.2—1945), $1.50
Safety Code for Jacks (B30.1—1943), $0.40
Safety Code for Mechanical Power-Transmission Apparatus (B15—1927, Reaffirmed in 1935 without change), $0.45
Compressed-Air Machinery and Equipment (B19—1938), $0.40
Description and Schematic Layouts of Various Types of Undercar Safeties and Governors (published 1945), $0.40
Handling and Socketing of Wire Rope (published 1945), $0.25

Biographies

BIOGRAPHIES issued under the sponsorship of the A.S.M.E. Biography Committee are as follows:
Autobiography of an Engineer, by W. LeR. Emmet (1940), $3.50

Autobiography of John Fritz (1940), $3.25
Biography of Fred J. Miller (1941), $1.25
Life of Henry Laurence Gantt, by L. P. Alford (1934), $5.00

Books and Pamphlets on Special Subjects

Automatic Control Terms (1946) (no discount allowed), $0.25
Automotive-Diesel Engine Cost and Performance Data (1943), $0.25
Corrosion-Resistant Metals (1936), $1.25
Creative Engineering (1944), $0.75
Creative Thinking (1946) (no discount allowed), $0.25
Unwritten Laws of Engineering (1944) (no discount allowed), $0.25
Design Data on Strength of Materials, Book 1 (1944), $1.50
Design Data on Mechanics (1944), $1.50
Engineering's Part in the Development of Civilization (1939), $1.50
Flow of Water in Pipes and Pipe Fittings (1941), $8.00
Furnace-Performance Factors (1944), $1.00
General Discussion on Lubrication (1938) (no discount allowed), $6.50
Graphitization of Steel Piping (1943–1944 and 1945), $2.50
Hydraulic Structures (1937), $18.00
I.S.A. Tolerance System (1942), $2.50
Manual on Cutting of Metals (1939), $5.00
Manual of Consulting Practice (1939), $0.40
Oil Engine Power Cost Report (1944), $1.25
Reflections on the Motive Power of Heat (1943), $2.75
Theoretical Steam Rate Tables (1937), $1.25

Regular Society Periodicals

*Mechanical Engineering**—Annual subscription rate in United States $6.00; to Canada $6.75; elsewhere, $7.50
A.S.M.E. Transactions,* including *Journal of Applied Mechanics*, Annual subscription rate in United States, $12.00, elsewhere, $12.75
1946 A.S.M.E. Mechanical Catalog and Directory, $3.00 (sent gratis to members upon request)
Metal Cutting Data: Annual subscription rate in the United States $15.00; to Canada $15.75; elsewhere $16.50.

*Subscription price included in A.S.M.E. membership dues.
